GENERAL PROGRAM

PRESENTATION

Dear participants

On behalf of the International Union of Soil Science (IUSS), the Brazilian Soil Science Society (SBCS) and the Latin American Soil Science Society (SLCS), it is our pleasure to present the two volumes of the 21st World Congress of Soil Science Proceedings. This volume covers the abstracts presented in poster sessions. We want to acknowledge the authors of the papers, peer reviewers, committee members, and the production staff whose volunteer work put shape to the 21st WCSS Proceedings.

During the meeting, eight (8) conferences from highly renowned scientists and authorities were held, with subjects related to the event theme - Soil Science: beyond food and fuel. There were also 73 conferences in 16 Interdivisional Symposia, and 5 Technical & Innovation Symposia.

The themes of these lectures were defined over the last three years, with the participation of the scientific divisions of IUSS and SBCS, and were structured during InterCongress 2016 and in others meetings of the Organizing Committee and Scientific Committee. The 21st WCSS also had oral presentations of 648 papers submitted in 75 divisional symposia and 15 IUSS working group symposia, plus 3 poster sessions with 1,608 submissions in total.

The Proceedings of the 21st WCSS with the abstracts of the 2,256 papers, presented orally or as poster are also available to download from the 21st WCSS homepage. The conference / lecture summaries that were provided by the speakers are included as well.

Again, thank you all for the participation and support.

Prof. **Leandro Souza da Silva**
Editor, Scientific Committee Chair

PREFACE

Fellow Soil Scientists,

I congratulate you all for celebrating the 21st WCSS being held in Rio, Brazil from 12-17th August 2018. The theme "Beyond Food and Fuel" is highly pertinent. Multifarious demands of humanity provisioned by soil include: (i) moderating the environment, (ii) strengthening biogeochemical and biogeophysical cycles, (iii) sourcing of raw materials, (iv) creating an archive of human and planetary history, and (v) generating cultural and aesthetical values. Above all, the world peace and security depend on healthy soil capable of provisioning numerous ecosystem services. Indeed, a healthy soil is an essential prerequisites to attaining peace at: (i) local, regional and global scale on the one hand, and (ii) at personal, family, community, national and international level on the other. The goal is to lead a life in perfect harmony with mother nature – the soil.

Personal or individual transformation to create a healthy soil is the pathway to peace, by being at peace with ourselves. Soil degradation and desertification, anthropogenic climate change and the related extreme events, pedological/agronomic droughts and the attendant extreme events, low agronomic yields and perpetual hunger, and marginal living and desperateness are also serious threats to global peace and stability, and require policy interventions at local, regional and global scale. If soils are not restored, crops will fail even if rains do not; hunger will perpetuate even with emphasis on biotechnology and genetically modified crops; civil strife and political instability will plague the developing world even with sermons on human rights and democratic ideals; and humanity will suffer even with great scientific strides.

Political stability and global peace are threatened because of soil degradation, food insecurity, and desperateness. Therefore, restoring degraded soils and desertified lands are essential to global peace and security. Soil is the gift of nature for achieving eternal peace and prosperity.

I wish you all a personally pleasant and professionally rewarding experience at the 21st WCSS in Rio.

Prof. **Rattan Lal**
President, International Union of Soil Sciences

(9328 - 3146) Effect of wetting and drying cycles in genesis of cohesive soil horizons from north-east Brazil

Juliana Matos Vieira[1]; Ricardo Espíndola Romero[1]; Miguel Cooper[2]; Jaedson Cláudio Anunciato Mota[1]

Universidade Federal do Ceará[1]; Escola Superior de Agricultura Luiz de Queiroz[2]

The Coastal Tablelands have cohesive soils, which interfere directly in the growth of plants, due to high soil resistance to penetration and the reduction of the availability of water and air in the soil. Faced with a heterogeneity of the Coastal Soils, research has not yet been able to attribute the dominant factor about the genesis of horizons with a cohesive character. Thus, the aim of this study was to evaluate the influence of wetting and drying cycles on the cohesion of soils with a cohesive character in North-east Brazil. In the present study, samples of cohesive soils (deformed samples) of four soil profiles of the Coastal Tablelands, located in the states of Bahia, Pernambuco and Ceará. To evaluate the influence of the wetting and drying cycles on the soil densification, three different treatments were applied, corresponding to different amounts of wetting and drying cycles (6, 9, 12 cycles). After these cycles, the samples were submitted to micromorphological analysis and image analysis of the pores of the soils. Soil resistance to penetration was also determined in the three treatments. The increase of the wetting and drying cycles promoted a greater soil densification, this reveals that the soil has returned to cohesion, presenting a low porosity and high soil resistance to penetration. The increase in the wetting and drying cycles led to a reorganization of the soil particles, where they were observed argilluviation in some of the studied soils, suggesting that the accumulation of iluvial clay may be one of the causes related to the genesis of soils with cohesive character.

(7170 - 2771) hydraulic-energy indices and functions associated with micromorphological analysis to evaluate soil structure under integrate crop-livestock system

Aline M. Huf dos Reis[1]; Robson A. Armindo[1]; Luiz F. Pires[2]; Miguel Cooper[3]

Universidade Federal do Paraná[1]; Universidade Estadual de Ponta Grossa[2]; Universidade de São Paulo/ESALQ[3]

Characterizing the soil structure in macro and micro scale is very difficult. Soil structure is resulted of the arrangement of its particles and aggregates, forming its porous system. The porous medium influences plant germination, root accommodation, gas exchange, and mainly retention and redistribution of water and solutes. In this work, some soil physics quality (SPQ) indices and hydraulic functions and micromorphological analysis were carried out to evaluate the structure of a Haplohumox under integrate crop-livestock system (ICLS). Two soil depths were analyzed (0.0-0.10 m and 0.10-0.20 m) in four systems: conventional tillage (CT), minimum tillage (MT), no-tillage (NT), and chiseled no-tillage (CNT), taking into account the annual ryegrass cropped during the winter for different uses: cover crop (C), grazing (G), and silage (S). The SPQ indices and hydraulic-energy functions were applied from information obtained with soil water retention curves (SWRCs). The soil absolute aeration energy (A_a) index was used because it is related with the gravitational potential energy to perform soil water drainage from saturation (θ_s) to field capacity (θ_{fc}). Other six SPQ indices based on pore volume distribution (PVD) function were applied. Micromorphological analyses were also carried out from blocks impregnated with resin. The collected soil samples were impregnated with a polyester resin mixed with fluorescent pigments. The images (2D) were processed and analyzed using the Noesis-Visilog 5.4 software. The areal porosity (AP) was determined according to their shape and size, using three major shape groups: rounded (R), elongated (E), and complex (C); and accordingly to their function based on equivalent diameter: storage pores (<50 µm), transmission pores (50-500 µm) and fissures (>500 µm). Based on these techniques association, soil structure damages caused by management systems was identified. In the upper assessed layer (0.0-0.10 m), MT with S presented the highest A_a (19.6 hPa m^3m^{-3}), which was bigger than other samples. AP showed contribution in transmission pores (58%) exhibiting that the greatest contribution was given by pores of R shape, suggesting less connection among them. CT with C had the highest A_a (23.1 hPa m^3m^{-3}) in the lower layer (0.10-0.20 m) showing the largest pore diameter of 7.8 µm with higher retention pores abundance. A_a results indicated large work-energy to drain water needing probably long time to reach θ_{fc}.

(9936 - 2731) Micromorphological comparison of impacted and non-impacted soils un the Sonora river basin: case of Buenavista del cobre mine

Maria Yazmin Rivera-Uria[1]; Jaime Díaz-Ortega[2]; Sergey Sedov[2]; Francisco Romero[2]; Elizabeth Solleiro-Rebolledo[2]

Posgrado en Ciencias de la Tierra, UNAM[1]; Instituto de Geología, UNAM[2]

The Buenavista del Cobre is the most important mine in Mexico, where mainly cupper is exploited. This mine is located north of Mexico in the state of Sonora. In autum of 2014 the mine had an accident where 40000 m^3 of acid leached (containing high concentrations of Fe, Al, As, Cu, Mn, Cd, Cr, Pb, Zn) was poured into the Tinajas stream and Bacanuchi river. We presented a profile (with impact of the spill and compare with other profile without impact evidence. All the samples were characterized geochemical and chemically in laboratory. Additionally, undisturbed samples were taken in field for the morphometric and micromorphological analysis, it was used an Olympus BX 51 microscope, software Image Pro Plus 7.0 and high resolution scanner Epson Perfection 700. The site belongs to Bacanuchi river, in this place we identified two profiles BR1-A (impacted) and BR1-B (non impacted), the distance between them are 1.5 m. The main characteristic in BR1-B was low pH basic and low electrical conductivity, the colour was light brown, the observations micromorphologicals were commons the carbonates infillings the pores, another minerals presents were plagioclase, quartz. The profile BR1-A had high concentrations in Fe, Al, As, Cu Pb and Zn, pH acid, high electrical conductivity and the color was reddish yellow, in the micromorphology the carbonates was not founded but was very strongly the precipitation of Fe rounded the minerals as plagioclase and quartz. So a morphometric study was done identifying organic matter, pore space, precipitation with Fe and minerals. The results showed that the concentrations of Fe in BR1-A increases and decreases pore space comparing with BR1-B. These changes are associated with precipitations of the spill, besides the carbonates dissolved assumed that changed the pH and gypsum and copiapite were identified. With the micromorphological and geochemical studies determined the changes between impacted and non-impacted soils. They soil impacted were modified the porosity, it was identified new minerals, the color change and high concentrations of potentially toxic elements. Results that will help identify recent and historical contamination of the area

Keywords: morphometric, acid leached, potentially toxic elements

(1851 - 3194) Micromorphological study of thionic technosols formed of mine tailings: case of ecological restoration of Peña Colorada, Colima Mexico.

Jaime Diaz-Ortega[1]; Francisco Romero[2]; Sergey Sedov[2]; Gerardo Martínez-Jardines[3]

Posgrado en Ciencias de la Tierra, UNAM[1]; Instituto de Geología, UNAM[2]; Instituto de Geología. UNAM[3]

The mining site of Peña Colorada is located NE of the state of Colima, Mexico. It is an ortho-magmatic field where magnetite predominates (> 85%). This site is located in the Mamey Formation in the sub-province of the Sierra Madre del Sur. At the Peña Colorada mine only iron is extracted, the tailings produced by these extractions are deposited in the Arrayanal dam. The region has a sub-humid and semi-warm climate with rain in summer and an average annual rainfall of 1600 mm, the average temperature of 26.3 ° C. The objective of this work is to recognize the development of thionic horizons and micromorphological changes in soils formed from the mine tailings with a development time of 10 years after reforestation. Three profiles were described that are located in a toposequence on a slope of the dam of tailings. These soils have A-Bti-C horizons with a depth greater than 70 cm. It was noted abundant superficial fine roots; the structure was in subangualres blocks. On the other hand, the horizon A had a dark brown color, the Bti horizon was yellowish brown and the C horizon was gray. The horizons identified as thionic (Bti) have an acidic pH of 4, are located at an average depth of 60 cm with thicknesses of 30 cm, in the micromorphology it was observed in small fragments of rocks and sand-sized particles which present coatings of Fe and gypsum minerals. In the A horizons, a development of granular structure with abundant plant tissues and evidence of coprolithic product of biological activity was observed. During the time that the dam materials have been exposed (10 years) it has allowed the formation of soils classified as Hypertonic Technosols, incorporating the landscape and allowing the restoration of vegetation that has developed organic horizons and a granular structure.
Keywords: ecological restoration, mine, technosol

(9467 - 1293) Micromorphology of soils erosion processes in applied urban expansion area of the coastline north of Maceió-AL

Samuel Vitor Oliveira dos Santos[1]; Antonio Soares da Silva[1]; Gabriel Spinola Garcia Tavora[1]; Vanessa Ingrid Carvalho Saraiva[1]; Roberto Marques Corrêa Junior[1]; Julia Valença Santiago[1]

Universidade do Estado do Rio de Janeiro[1]

The erosion processes tend to happen naturally in the earth's surface, but are enhanced with the interference of man in the landscape. Urban expansion stimulates degradation of green areas in the city, with the removal of the vegetation cover, the soils are exposed and become vulnerable to impacts caused by torrential rains. As a result, accelerating the breakdown of soil and the consequent sediment transport. The present work aims to understand the erosion processes that occur in three urban areas on the coast north of Maceió-AL, characterizing the soils of this region and identifying the main constraints of erosion. For the study of erosion soil samplings were made in neighborhoods of Jacarecica (Area 1), São Jorge (Area 2) and Guaxuma (Area 3). Physical and chemical analyses were carried out in the laboratory, who followed the methodology developed by Embrapa (1997), and the micromorphology of soils based on the study of Castro (2008). This analysis had as objective to characterize and describe the soils of the region so that this way it was possible to identify if they have features that accelerate erosion. The samples collected in the three studied areas indicate that these soils are vulnerable to erosion, mainly by, a high content of sandy texture, which does not favor a good stability. The micromorphology enabled show organizations of constituents of the matrix fund. From there, it was observed that in the area 1 is there any impediment to the movement of the water, while in Area 2 the favoritism of the vertical circulation. It is also worth mentioning that the area 2 presented more modifications and there's an erosive process faster, these soils presented: high content of sand and little clay, by micromorphology you can view the participation of skeletal grains of smaller diameter in the B horizon, there is a predominance of grains with bigger diameter on the horizon to this characterization allows to deduce that the circulation of water is easier in the superficial horizon, because were not observed structures that come cause impediments to the vertical circulation of water. Besides the withdrawal of much of the vegetation to the construction of a road, further exacerbating the problem. It is now strengthening the preservation of green areas still exist and studies that take into account the characteristics of soils for that to happen a better appropriation and use of these areas.

(2117 - 1198) Micromorphology of the superficial horizons of the Yellow Red Acrisol subject to cattle grazing

Antonio Soares da Silva[1]; Roman Seliger[2]; Gabriel Campos Pereira da Costa[1]; Dietmar Sattler[2]; Jürgen Heinrich[2]

University of State of Rio de Janeiro[1]; University of Leipzig[2]

Soil degradation is one of the main environmental problems in Brazil. The effect of cattle trampling on soils can result in the induction of laminar erosion processes, leading to the total removal of A horizon. This research was developed in an extensive dairy farm, where severe erosive signs are observed with stretches of bare soils. The study area was divided into four sectors: terrace 1, terrace 2, terrace 3 and terrace 4, from the foothill to the top of the slope. Undisturbed samples were collected at depths of 0 cm and 25 cm, in areas with bare soil (cattle trails) and grass cover. The samples were impregnated with epoxy type resin and after hardening, cut and polished to a thickness of 30µm for description under a petrographic type microscope. In terrace 4, there is a higher biological activity due to being in a top position and less affected by the cattle trampling. In the thin sections this sector, there was almost no alteration in the porosity organization when compared to the areas with and without grass cover. In terrace 3, there are differences in the organization of soil constituents between samples collected in the cattle trails and in the areas with grass cover. In the trail sample, the soil presents compact appearance and low porosity. The color of the superficial sample is yellow-red, like the color of the B horizon. In the sample under grass cover, the color is brown, due to a higher content of organic matter. In terrace 2, the soils presented higher levels of degradation in the study area. As well as in the terrace 3, there is a predominance of reddish colors in the surface and planar pores, which may originate from the expansion and contraction of clays. At terrace 1 accumulates the debris removed uphill and the samples collected under vegetation show connected and abundant pores and root traces. The thin sections of the bare soil samples show more pores than the upslope bare soil samples and small aggregates moderately developed. The main differences between bare soil and grass-covered samples are related to color which is similar to the color of the B horizon in the areas without vegetation. Furthermore, the quantity and type of the pores varies between samples, where samples under vegetation show channels and chambers and bare soil samples have planes. These characteristics indicate that the A horizon was removed at the bare soil cattle trails and the remaining textural B horizon now forms the (new) surface.
Keywords: micromorphology; soil erosion; land use

(3068 - 2998) Soil micromorphometric analysis as indicator of the subsurface erosive process genesis

Renata Cristina Bovi[1]; Nayana Alves Pereira[1]; Matheus Ortega Gomes[2]; Miguel Cooper[3]

Luiz de Queiroz School of Agriculture, University of São Paulo[1]; Federal University of São Carlos[2]; googLuiz de Queiroz School of Agriculture, University of São Paulo[3]

Erosive process on the soil surface has been well studied and comprehended by several researchers, however, little is known about subsurface erosive processes (piping). Subsurface erosive processes have a greater occurrence than is generally assumed, being found in all climates, natural and agricultural lands and in unconsolidated sediments and rocks. Piping is a type of subsurface erosion caused by water flowing in subsurface and the origin of this process is difficult to determine. Many factors have been considered as causing this process and their interaction is complex and difficult to be studied separately. The study area is located in Piracicaba, State of São Paulo, Brazil, which has several erosive features, ranging from laminar erosion to gullies and pipings. Six pits were opened and described in the study area, in which the soil was classified as Hapludults (Argissolo Amarelo distrófico típico). To detect differences in soil porosity that could favor the stagnation of water at the top of the Bt horizon and consequently trigger the activation of the subsurface erosive process, micromorphometric analyzes of the soil horizons were performed to understand the type and sizes of the pores that constitute such horizons. Undisturbed samples, representative of the soil horizons, were collected on the E and Bt horizon and subsequently impregnated with polyester resin, styrene monomer, a catalyst and a fluorescent pigment. After hardened, the blocks were polished and from these blocks were acquired images using a 10X magnification camera. The pore areas were classified as large, medium and small, while pore sizes were classified as rounded, elongated and complex. The results showed that there is a porosity gradient between these soil horizons: there is a decrease in the total pore area of the horizon E to Bt and this decrease is reflected in the large pore complex pores. This contrast is also reflected in the soil texture (sandy to medium texture) and structure (simple grains to sub-angular blocks, medium to large and moderate). We concluded that this change in the gradient was responsible for the reduction of the hydraulic conductivity between the horizons E and Bt, causing the accumulation of water at the top of the Bt horizon, which is stagnant in a seasonal manner, facilitating lateral flow instead of vertical. This flow, when reaching erosive velocity, due to the relief, can give origin to the subsurface erosive process.

C1.1.2 - Structural indicators of soil quality using X-ray computed tomography

(7268 - 2516) Assessing the consequences of improved plant water use efficiency on soil structure using X-Ray computed tomography

Tinashe Mawodza[1]; Manoj Menon[1]; Stuart Casson[1]

Sheffield University[1]

Agricultural production across the world currently accounts for more than 70% of global freshwater withdrawals. The increased agricultural intensification required to feed an ever-expanding global population is set to put serious strain on the worlds' already limited freshwater resources. Development of plants with improved drought tolerance and water use efficiency to maximise on the erratic global freshwater supply has largely been suggested as a possible strategy to bring about significantly increased crop production per unit of water available. The effectiveness of the utility of such plants however may come at a cost to soil health, which would ultimately lead to reduced sustainability of crop production. We used high resolution 3-dimensional X-Ray micro-tomography as well as other classical soil structural assessment methods to assess the potential effects of the cultivation of plants with genetically altered water use efficiency (and or drought resistant) on various soil structural properties. We analysed the changes in soil structural properties as brought about by water use efficient mutants of the model plant, Thale Cress (*Arabidopsis Thalyana)* as well as wheat *(Triticum aestivum*). 3D maps of plant root proliferation into the soil and their subsequent effect on the soil was examined allowing for a close-up quantitative assessment of the intricate interactions occurring within the rhizosphere. We did not find any significant differences in the effect of plants with genetically induced water use efficiency as compared to wild type plants. Our results demonstrate that genetic modification of plants may possibly be used to improve water productivity without compromising on important soil structural properties.

(5245 - 2689) Assessing the impact of soil-seed contact on water relations for efficient seed germination using X-ray Computed Tomography

Sebastian Blunk[1]; Martine I de Heer[2]; Craig J Sturrock[3]; Sacha J Mooney[3]

Division of Agriculture and Environmental Science, School of Biosciences – University of Nottingham, Sutton Bonington, Loughborough. LE12 6HW, UK (sebastian.blunk@nottingham.ac.uk)[1]; Syngenta Crop Protection, Bracknell, RG42 6EY, UK[2]; Division of Agriculture and Environmental Science, School of Biosciences – University of Nottingham, Sutton Bonington, Loughborough. LE12 6HW, UK[3]

With an increasing global population and demand for agricultural food production, there is a need to improve crop yield and efficiency. Seedbed preparation is a crucial first step prior to sowing, especially for field crops planted using precision drilling techniques. The seed is placed into the seedbed layer and the topsoil rolled slightly to improve the contact area to the surrounding soil matrix. The common theory of seed germination is based on water absorption from the surrounding soil matrix (imbibition) to initiate the germination process. In this study, we develop a method to non-destructively quantify seed-soil contact using X-ray Computed Tomography and apply it to compare a variety of common seed enhancement technologies that influence the seed morphology (e.g. seed pelleting, seed coating and seed priming) under laboratory conditions (sieved sandy loam soil <2 mm). Results show that naked star-shaped sugar beet seeds had a lower contact to the soil matrix compared to the spherical pelleted seeds. The compatibility of the method for field structured soil was verified by sampling field cores within 24 hours after sowing by a tractor-mounted seed drill. Furthermore, we introduce the concept of the *iceberg effect* describing the relationship between the contact area of soil aggregates with the seed and the larger soil mass of the aggregates surrounding the seed. A larger iceberg effect could therefore be an indicator of a greater accessibility to water sources in the immediate vicinity to the seed. With this study, we introduce a method of quantifying the interaction potential of precision-sown seed with its surrounding soil matrix and gave an indicator for its water accessibility. This study contributes towards the selection of appropriate seedbed management techniques as well as seed enhancement technologies to improve water uptake and ultimately crop yield.

(7444 - 2719) Mitigation of soil compaction by the use of cover crops in compacted Oxisol

Altamir Mateus Bertollo[1]; Renato Levien[1]; Moacir Tuzzin de Moraes[2]; Henrique Debiasi[3]; Lucas Zulpo[1]
Federal University of Rio Grande do Sul[1]; University of São Paulo[2]; Embrapa Soybean[3]

The Soybean (Glycine max) is the most produced crop in Brazil, which stands out as the second largest grain exporter in the world. The cultivation of this cereal is, mostly, in a no-tillage system in the straw, where there is only soil mobilization in the sowing line. The non-mobilization of the soil associated with low crop rotation bring to soil compaction caused by the accumulation of agricultural machine traffic. Land use and management systems are tools for prevention and, where it occurs, remediation of soil compaction. For this, the presence of cover crops in the rotation system is important. The objective of the present work was to quantify the use of plants of economic interest in autumn-winter period in the mitigation of soil compaction. For this, a study with a split plot desing was developed at the Embrapa Soybean experimental farm, in Londrina, Paraná state, Brazil, in a Oxisol with levels compaction. The treatments cover plants: black oat (Avena strigosa), brachiaria (Urochloa ruziziensis), corn (Zea mais) and wheat (Triticum aestivum) were allocated to the plots and subplots treatments land use: chiseling, no-tillage, no-tillage with four additional agricultural tractor traffic, and no-tillage with eight additional harvesters traffic. After two years of treatment, soil samples were collected in the layers of 0.00-0.10, 0.10-0.20, 0.20-0.30- 0.30-0.40 and 9.40-0.50 m, being determined the physical parameters of the soil, morphological parameters of the soybean root system and soil tomographic analysis. No effects of the use of cover crops on conventional soil physical properties (porosity, soil bulk density and mechanical resistence to penetration) were diagnosed. Through computed tomography it was possible to diagnose soil pore space alterations for brachiaria and corn treatments up to depth of 0.20 m. The compaction levels changed the physical properties of the soil to a depth of 0.30 m. Harvested traffic increased soil bulk density, mechanical resistence to penetration and microporosity. The chiseling of the soil presents residual effects in the subsurface layer of the soil, with decrease in bulk density and mechanical resistance to penetration and increase in macroporosity and total porosity. Soybeans grown in a continuous no-tillage area show higher grain yield. Chiseling of the soil and the machine traffic decreased production.

(3938 - 1499) Quantifying Soil Structure Dynamics in Agroforestry Riparian Buffers using X-ray Computed Tomography

Anastassia Lagounova[1]; Richard Heck[1]; Naresh V. Thevathasan[1]
University of Guelph[1]

As a component of a project entitled “Riparian buffer plantings: An agroforestry land-use for greenhouse gas mitigation including multiple benefits to Canadian agriculture”, the goal of the study is to characterize the temporal variability of soil structure in common riparian agroforestry ecosystems. This study takes place within the Grand River Watershed of Ontario. Intact soil cores are taken over a period of a year (post-winter, end-of-spring, end-of-summer and pre-winter) from various riparian systems, considering soil texture (loam vs. sand soils), forest age (mature vs. restored forests) and forest type (deciduous vs. coniferous forests). High-resolution 3D imagery of the soil cores are obtained by X-ray Computed Tomography (CT). Computerized analysis of the digital imagery is used to derive both morphometric (size, shape etc) and spatial distribution (3D semivariance indices) parameters of soil phases (resolvable voids, solids and matrix). Specific attention is also given to the spatial radiodensity of the soil matrix. Results to be presented will emphasize reference soils within a natural stand of deciduous forest, typical of the region under study.

(3434 - 3096) Quantifying the Effect of Crop Rotation on Topsoil Structure Dynamics using X-ray Computed Tomography

Richard J Heck[1]; Mila Maric[1]; Lars J Munkholm[2]; Bill Deen[1]
University of Guelph[1]; Aarhus University[2]

Within temperate agriculture systems, soil structure maybe subject to both management-related (tillage, root growth) and natural (faunal activity, wetting/drying, freezing/thawing) processes. Understanding the nature and magnitude of annual changes in topsoil structure is ultimately important for establishing sustainable management practices. This study was undertaken on long-term (>30 years) management plots, maintained at the University of Guelph’s Elora Research Station, in Ontario, Canada. Five rotations, all on zero-tillage, were included: corn-corn-soybean-soybean, corn-corn-soybean-wheat, corn-corn-soybean-wheat (under-seeded to red clover), corn-corn-alfalfa-alfalfa and continuous alfalfa (as reference). Intact cores of topsoil were collected early-September (pre-harvest), early-December (pre-winter) and late-April (post-winter), from first-year and second-year corn crops in each of the rotations. High-resolution (40 micron voxel size) 3D radiodensity imagery was obtained by x-ray computed tomography. The greyscale imagery was segmented into resolvable voids and solids, as well as matrix phases. Morphometric analysis of the intra-aggregate voids considered their size, shape and orientation. Image masking permitted quantification of the spatial variabilty of matrix radiodensity, using orthogonal semivariance analysis. Indices of anisotropy and short-range variability were derived from the semivariograms. Attention will be given to comparing the relative influence of growing season and winter processes on structural parameters and their variability.

(2028 - 1071) Renting the same room: Do roots repeatedly reoccupy the same spaces?

Ivanah Oliver[1]; Dr Richard Flavel[1]; Dr Brian Wilson[2]; Dr Oliver Knox[1]
University of New England[1]; University of New England; Office of Environment and Heritage NSW[2]
With X-ray computed tomography (xCT), we are now better equipped to understand the impact soil structure has on the spatial distribution of root systems. The distribution of root systems throughout a soil profile is influenced by many physio-chemical properties of the soil, including the pore space characteristics and presence of root channels from previous plant growth. Currently there is limited understanding about how many and how often roots will occupy the same pore spaces season after season. This in turn has implications for the spatial distribution of resource depletion (e.g. phosphorus) and accumulation of plant products (e.g. root exudates) and physical legacy. This research investigated how much of the root system of an actively growing plant utilised the existing pore spaces from a previous root system. The experiment involved growing Rhodes grass (*Chloris gayana*) in pots, with two differing soil structures, for a period of 8

weeks. X-ray computed tomography was then used to image a small section of the pot to determine the spatial distribution of the roots and pore spaces. After 12 weeks of decomposition, the pots were rescanned before a second season of plant growth and a final scan. The final images of the pore spaces and root systems at each phase were then overlayed and compared to determine the proportion of roots that reoccupied previous root channels. The results of this research will be presented and discussed. Improved understanding of the amount of reutilised pore spaces by successive crops will have broader implications for nutrient and water acquisition, help explain microbial and exudate hotspots and soil physical properties.

Keywords: Root distribution, X-ray computed tomography, Soil pore spaces, Rhodes grass

(6729 - 3218) Surface caracterization of an entisol using microtomography

Cassia Bezerra Machado[1]; Antonio Celso Dantas Antonino[1]; Richard Heck[2]; Larissa Fernandes Costa[1]; José Romualdo de Sousa Lima[3]
UFPE[1]; U of G[2]; UFRPE[3]

The soil structure can be defined as the arrangement of soil particles and their pore space, it is important for the maintenance of porosity, aeration, plant growth and microorganisms. The study of soil microstructure is advancing with the use of computerized microtomography (µTC). This work aims to study the microstructure in an Entisol's surface using the µTC. The samples were collected at the Várzea do Barro Farm, in São João-PE. The images were obtained using the Nikon XT H 225 ST, resulting in high-resolution images with 50 micron voxels size. A morphometric analyse were done using Image-J. The images were segmented in three phases: voids, rocks fragment and matrix, where were applied thresholding values using a Pure Voxel Extration (PVE) for each phase. Then the pores were classified in inter-agregate and intra-agregate using the Image J's plug-in Particle Analyzer. The soil's samples had 41,57% of medium porosity, with 41,51% for inter-agregate voids and 0,11% for the intra-agregate voids. The Entisols it's a highly sandy soil, so it's expected for the higher percentage of the inter-agregates. There was a high percentage (73%) for the complex pores, indicating pores with high connectivity.

(4186 - 857) Using X-ray Computed Tomography to assess how plant roots can remediate compacted soils via reorganisation of the rhizosphere

Jasmine Burr-Hersey[1]; Sacha Mooney[1]; Glyn Bengough[2]; Karl Ritz[1]
University of Nottingham[1]; The James Hutton Institute[2]

Soil compaction is a form of degradation that affects agricultural land on a global scale. Primarily caused by the passage of heavy farm machinery, the effects on soils can be persistent and difficult to alleviate effectively. Currently, deep-tillage practices are used as a short-term solution to lessen soil compaction in agricultural contexts, however this intensifies the risk of permanent subsoil compaction. Plant species that are able to grow in heavily compacted soil may increase the number and size of pores helping to positively alter a degraded soils structure. Hence plants may offer a simple field-scale means to improve a compacted soil via localised structural remediation in the rhizosphere. We analysed the root growth patterns of three non-cultivated plant species often found occurring naturally on compacted soils, suggesting they have an intrinsic ability to grow effectively under such circumstances. Ribwort plantain (*Plantago lanceolata*), dandelion (*Taraxacum officinale*) and spear thistle (*Cirsium vulgare)* plants were grown for 28 days in a sandy-loam soil compacted to 1.8 g cm^{-3} with a penetration resistance of 2.55 MPa. X-ray Computed Tomography was used to observe root architecture *in situ* and visualise changes in rhizosphere porosity with distance from the root surface at a resolution of 35 µm, at 14 and 28 days after sowing. Porosity of the soil was analysed within four incremental zones up to 420 µm from the root surface. In all species the porosity of the rhizosphere was greatest closest to the root and decreased with distance from the root surface. There were significant differences in rhizosphere porosity between the three species, with the spear thistle plants exhibiting the greatest pore space creation across all rhizosphere zones. This study indicates that roots can have a localised effect in increasing the formation of pore space in the rhizosphere, counteracting any initial compression due to root penetration. The resulting structural alteration of the soil indicates the potential for a natural way to create and improve soil structure in heavily degraded soils.

(4550 - 1867) Visualization of soil microstructure under conventional tillage and fallow using micro-focus x-ray computed tomography.

Isaiah IC Wakindiki[1]; Mashapa E Malobane[2]; Adornis D Nciizah[3]; Fhatuwani N Mudau[4]
University of Venda/University of South Africa[1]; University of South Africa/Agricultural Research Council[2]; Agricultural Research Council[3]; University of South Africa[4]

Tillage affects a soil's structure. In general, soil structure regenerates under fallow but degrades under conventional tillage. However, the effect of fallow and tillage on soil microstructure and morphology is not conclusive. Aggregates ~ 10 mm diameter of an Haplic Cambisol were collected from the top 0.1m in adjacent fields at the University of Fort Hare experimental farm (latitude 32°46'S and longitude 26°50'E). One field was under a five-year-old fallow management (FM) and the other under conventional tillage (CT). Soil aggregates were fixed on a rotary stage that rotated from 0° to 360° and sample absorption radiographs taken at the same step interval. 1000 slices were reconstructed for each sample. CT Pro 3D software® was used to reconstruct the 1000 slices into 3D images. Analysis of 3D soil aggregates was done using VGstudio MAX 3.0®. To avoid the edge effects, a region of interest of 52 ± 0.1 mm^3 volume was selected at the middle of the 3D soil aggregates. The pores were classified into seven classes: <50, 50-100, 100-200, 200-300, 300-400, 400-500 and > 500 µm. Sphericity (S) was used to classify pores into three pore shape classes: regular pores ($S \geq 0.5$), irregular pores ($0.2 < S < 0.5$) and elongated pores ($S \leq 0.2$). The soil pore distribution, pore shape, pore proportion and visualizations were similar in both treatments. Therefore, both FM and CT had a similar effect to the soil's microstructure and morphology at the time of sampling. The fractions of elongated pores, which are crucial for soil water and gas transport were ≤ 0.1% in both treatments. The low fraction of elongated pores suggest that there is high chance of soil degradation especially by erosion under both treatments. It was concluded that a five-year difference in soil use and management may not affect its microstructure and morphology but other soil properties such as the organic matter.

(9855 - 1040) X-ray computed microtomography against retention curve for assessing porosity in Latossolos (Ferralsols) with contrasting vegetation cover

Marcelo Wermelinger Aguiar Lemes[1]; Gustavo Mattos Vasques[2];

Alessandra Silveira Machado[3]; Hugo Machado Rodrigues[4]; Ricardo Tadeu Lopes[3]; Reiner Olíbano Rosas[5]
UNESA / UFF[1]; EMBRAPA SOLOS[2]; COPPE / UFRJ[3]; UFRRJ[4]; UFF[5]

Soil porosity is conventionally measured by the retention curve method and is affected by a number of factors, but mainly by the relative distribution of particles with different sizes, shapes and arrangement. X-ray computed microtomography (microCT) appears as a novel non-destructive and rapid method to characterize the particle arrangement and calculate soil porosity. This work aims to compare the retention curve and microCT methods to assess the total, macro and microporosity of the soil. The work was developed in Silva Jardim, RJ, southeastern Brazil, using Latossolo (Ferralsol) soil samples taken at about 10-cm depth. For both methods, four samples were taken from grass-covered soil, and four samples from bare soil, using either 50-mm-high x 32-mm-wide acrylic cylinders (microCT) or 50-mm-high x 26.5-mm-wide steel cylinders (retention curve). For the determination of the porosity values using the retention curve method, the Richards pressure chamber was used applying the following tensions: 0.01, 0.033, 0.06, 0.1, 0.33, 1.5, 15 bar. For the microCT assays the samples were digitized in a high energy system - Skyscan / Bruker, model 1173. Using the retention curve method, the following average porosity values were obtained in covered and bare soil, respectively: 52% and 45% total porosity, 12% and 5% macroporosity, and 40% microporosity for both cases. Using microCT, porosity values were: 27% and 22% total porosity, 11% and 10% macroporosity, and 16% and 12% microporosity in covered and bare soil, respectively. The study confirmed that grass-covered Ferralsols have higher porosity due to the presence of roots. More importantly, the total porosity measured by the retention curve was considerably higher than that measured by microCT. This may be due to the fact that Ferralsols store most of the water in micropores, whose detection using microCT is limited by the minimum detection limit of the method of 30 µm. Thus, some adaptation of the method is required for monitoring Ferralsols, which are the main agricultural soils of the Brazilian Cerrado (savanna).

Tension Infiltrometer and Simple Ring Infiltrometer are useful in situ techniques which are commonly used to determine soil hydrodynamic properties. Comparing the effects of these techniques on the soil structure in a pore scale is fundamental to identify the ideal in situ method for infiltration and water storage study. This study is being conducted in areas of Caatinga vegetation in the Agreste and Sertão of Pernambuco, Brazil. Infiltration tests were carried out with the two techniques mentioned on the soil surface layer, where undisturbed soil samples were collected of the area in direct contact with the tests. For the pore scale analysis, high-resolution tomographic images (50 micron voxel size) have been obtained with scanner Nikon XT H 225 ST. The grayscale images are segmented in three phases: voids, rocks fragment and matrix. A morphometric analysis of intra-aggregate voids was done in order to quantify their size and shape. Moreover, spatial variability of matrix radiodensity are been studied to obtain more details about voids smaller than the resolution adopted. This study compare soil structural differences caused by these two infiltration techniques.

(3095 - 271) X-ray microtomography analysis of lime application effects on soil porous system

Talita R. Ferreira[1]; Luiz F. Pires[1]; Dorthe Wildenschild[2]; Richard J. Heck[3]; Antonio C. D. Antonino[4]
State University of Ponta Grossa[1]; Oregon State University[2]; University of Guelph[3]; Federal University of Pernambuco[4]

Soil liming has demonstrated to be efficient to make acidic soils suitable to agriculture but little research has been done to evaluate its effect on soil structure in the microscale. X-ray microtomography (µCT) is a useful technique to obtain valuable information about the micromorphological characteristics of soil and, thus, can provide important insight into how liming affects such a porous system. In this study, µCT was used to evaluate changes on micromorphological physical properties (porosity, number of pores, pore length, elongation, shape, connectivity and tortuosity) of a soil cultivated under no-tillage (NTS) caused by the application of lime on the surface. A degraded pasture area representing soil conditions before the NTS implementation was also analyzed. Samples from two soil layers (0-10 cm, A, and 10-20 cm, B) were analyzed with a voxel size of 60 µm. Image visualization, processing and analysis were performed in the Avizo Fire 9.0 software. Liming improved the soil chemical attributes only at layer A where it also produced positive effects on the soil porous system within a period of thirty months. We highlight the increase in soil porosity (P) and number of pores (NP) into which the main soil pore was separated, as evidence of such positive effects. For layer A, those pores were found to be longer, more elongated, and more connected for the limed site. However, changes in the pattern of the separated pores, with the formation of cylindrical pores in the horizontal orientation for the limed site, were observed at both soil layers, which can be attributed to stimulation of the soil fauna activity due to liming.

C1.1.3 - How to use micromorphology to understand palaeosols and polygenetic soils?

(5583 - 349) Fate of Co-containing phyllomanganate: Implications for Co sequestration

Zhongkuan Wu[1]; Xionghan Feng[1]; Hui Yin[1]; Wenfeng Tan[1]; Guohong Qiu[1]; Caroline L. Peacock[2]; Bruno Lanson[3]; Zhongjun Chen[4]; Lirong Zheng[4]; Fan Liu[1]
Key Laboratory of Arable Land Conservation (Middle and Lower Reaches of Yangtse River) Ministry of Agriculture, College of Resources and Environment, Huazhong Agricultural University, Wuhan, China[1]; University of Leeds, School of Earth and Environment, Leeds LS2 9JT, UK[2]; Univ. Grenoble Alpes, ISTerre, 38041 Grenoble, France.[3]; Beijing Synchrotron Radiation Facility, Institute of High

Energy Physics, Chinese Academy of Sciences, Beijing 100039, China[4]

The mobility and fate of bioessential metals, such as Co and Ni, are strongly controlled by their association with phyllomanganate (PMn) minerals. These minerals however, can transform to tectomanganate (TMn) minerals under certain environmental conditions yet. The fates of these transition metals during the transformation remain largely unknown. Here, the transformation from layered precursors containing various Co contents to tunnel structure minerals was investigated via using XRD, BET surface area analysis, HRTEM, EXAFS, FTIR and nitric acid treatment. We conclude that heterogeneous ions, without Jahn-Teller distortion, associated in the layered precursor, low Mn^{3+} content and inappropriate species in the interlayer of layered precursors, together with common environmental conditions will hinder this transformation or maintain the stability of PMn in nature, resulting a higher abundance over TMn. Particularly, under reflux reaction, precursors with no or low Co contents convert to minerals with incoherent tunnel dimensions (i.e. 3×*n*) along *a** direction as natural todorokite samples. While high Co contents lead to incomplete conversion, forming mixtures of todorokite analogues and 9.6 Å layered structure stabilized by islands of Mg (hydr)oxide in the interlayer, confirmed by nitric acid treatment, an innovative approach to differentiate 10 Å PMns and todorokite. The proportion of the todorokites decreases and that of layered structure increases as Co content increase. It is suggested that needle-like morphology or showing broad peak (around 7 Å) and slope (after 4.8 Å) in XRD pattern can be regarded as indicative features for the ideal todorokite structure with uniform 3×3 tunnel size. While trillings growth features reflect *a*-disorder todorokite with various tunnel sizes along *a** direction more likely. Here, we provide an insight to the fate of Co, demonstrating that adsorbed Co in layered precursor could incorporate into reflux product structurally, and the migration of structural Co to corner sites in TMn minerals contribute the increase of the ratio of coordination numbers of corner-sharing (CS) linkages to that of edge-sharing (ES) linkages for Co. Furthermore, Co could occur at sites with only ES linkages and sites containing both E/CS linkages in TMn minerals. Structural incorporation means a more stable Co uptake with respect to adsorption, and the transformation from PMn to TMn provides a sink for the more tight sequestration of Co.

(9378 - 1376) Features of Fe-Mn nodules in southern Indiana Loess with a fragipan horizon

Zhong-Xiu Sun[1]; Ying-Ying Jiang[1]; Qiu-Bing Wang[1]; Phillip Ray Owens[2]
Shenyang Agricultural University[1]; Dale Bumpers Small Farms Research Center, Booneville[2]

In this research, nodules were collected according to loess genetic horizons from Southeast Purdue Agricultural Center (SEPAC) and wet sieved into 4 groups, including 2-1 mm, 1-0.5 mm, 0.5-0.25 mm, and 0.25-0.1 mm. Physical, chemical, micro- and macro-morphological features of nodules and their soil matrix were determined as a function of soil depth. The Ap horizon was determined to contain the highest proportion of nodules. These were derived from the subsurface horizon due to high erosion in the past. The small sized nodules concentrated in the Ap horizon were predominantly related to high SOM. In addition to the Ap, the Btx1 and Btx2 also contained a large fraction of nodules. Additional observations and chemical composition analysis using scanning electron microscope (SEM) with energy dispersive X-ray spectroscopy (EDS) were conducted on 2-1 mm and 1-0.5 mm nodules. Different micro-morphological features, including a complex Fe-Mn-oxide matrix with mineral grains consisting of predominantly quartz and feldspar, were observed. Nodules were consistently grouped into rough and smooth types. Brown nodules have a low Mn/Fe value (< 1), whereas black nodules have a high Mn/Fe value (> 1). Micro-morphology of Mn-rich, Fe-rich, and Mn-Fe-rich regions were observed inside nodules from different horizons. Fe and Mn diffused and precipitated within the matrix with an extensive micro-pore system. Examination of soil thin sections from perched water zones showed brown spherical Fe-Mn nodules with sharp boundaries and more densely differentiated fabric.

(6764 - 954) Micromorphological description for final diagnosis of a non-lithified paleosol – a case in Brazil

Camila Fernandes Miranda[1]; Yuri Lopes Zinn[1]
Universidade Federal de Lavras[1]

Many paleosol studies identify and describe buried sequa or lithified soils constrained by geochronologically-dated rocks. If no buried A horizon, lithification or datable rocks occur, paleosols can only be identified by other morphological contrast with the overlying, current soil. However, such contrast can be highly variable and not always evident, and thus paleosol diagnosis is subject to a debate, in which Soil Micromorphology is a critical tool. Here, we describe a paleosol underneath a deep (2 to >5 m), reddish, very clayey gibbsitic Acrudox of fine granular structure developed from limestone, on a 3% slope in Ijaci, Minas Gerais, Brazil. A large excavation for a parking lot exposed this paleosol lacking a dark-colored buried A, with massive structure perforated by many faunal channels infilled by small granular peds, and marked by contrasting colors including red, yellow and white, not due to current redoximorphism. Under the microscope, the paleosol showed massive microstructure tending to fragment in weakly separated angular blocks, as noted by tapering planar voids. The c/f distribution was open-spaced porphiric. The b-fabrics was poro- and granostriated, but also circular striated, which aside with star-shaped vughs suggest that part of the massive structure was due to compaction and welding of fine granular peds. Coarse material was angular to sub-rounded quartz, often fractured but without fine material within the shards, consistent with the unusual macroscopic description of brittle, colourless gravel quartz. Pedofeatures included Fe depletion along preferential-flow paleochannels and planar voids, varying from yellowing to whitening of the reddish matrix. In addition, Fe and gibbsite nodules were also described, as well as clay coatings on pores. In contrast, the overlying Acrudox has fine to mid-sized granular microstructure, undifferentiated to speckled b-fabrics, and as pedofeatures, gibbsite/Fe nodules and excrements. We conclude that the clay illuviation coatings along pores confirms the paleosol diagnosis, since it is not compatible with the current Oxisol-forming processes. Also, XRD peaks for illite, absent in the Oxisol, further supports this conclusion. Probable evolution sequence is: 1-burial by current Oxisol material; 2-formation of faunal channels in buried paleosol; 3-hydration and deferrification along paleosol voids, 4) infilling of paleochannels and deposition of clay coats with material from the Oxisol above.

(9841 - 2969) Pedogenesis of Bt horizons in the Marília Formation (Bauru Basin Cretaceous), Brazil.

Diego Sullivan de Jesus Alves[1]; Francisco Sergio Bernardes Ladeira[1]; Alessandro Batezelli[1]
Universidade Estadual de Campinas[1]

Several studies have identified Bt horizons in the Marília Formation (Bauru Group - Bauru Basin), especially based on field morphology, possibly only in micromorphological analysis. This study aimed to

understand the paleopedogenetic processes involved in the formation of Bt horizons in the Marília Formation, trying to identify if these Bt horizons identified in the field really were genetic Bt horizons. The study areas are located in the states of São Paulo (Monte Alto municipality), Goiás (Itajá municipality) and Minas Gerais (Campina Verde municipality). This formation consists of sandstones, conglomerate sandstones, conglomerates, mudstone, siltstones and as calcretes and silcretes. It was deposited from an association of alluvial fan systems with torrential regimes, fluvial and ephemeral or as an eolian sand sheet, being dated Maastrichtian, in the Upper Cretaceous. Three paleosols profiles were selected, subdivided in the different study areas. Medium sand texture is predominant, c/f distributions (random and grouped; not referred and cutaneous; porphyritic, chitonic, quito-gefuric mixed, enaulic), birefringent fabric (crystallitic, granostriated and undifferentiated), ferriargilans (crescent, capping, pendent, link capping and typic; microlaminated; occasional to very abundant; strong and continuous), calcans (capping and pendent; abundant; strong and continuous), pedotubules (granotubules and isotubules) and nodules (iron oxides and carbonates; typic and crossed concentric; impregnated strongly). All paleosols profiles were identified in the Marília Formation but have markedly different micromorphological characteristics. In Monte Alto, the illuviation processes were dominant, considering the free/crescent laminates ferriargilans identified, which represent expressive conditions of landscape stability and greater availability of water in the environment, which allowed the movement and deposition of the oriented clay. In Itajá, clay minerals aggregates (enaulic regions) indicate well-developed paleosols, even if they present fractures due to compaction. On the other hand, in Campina Verde, the oxidic features absence along the predominance of calcareous and carbonate nodules suggests that the high carbonate accumulation obliterated the clay films and/or caused the clays flocculation and consequently illuviation decrease.

(1108 - 607) The unique fabric of pedo- and lithopedogenic gravels in Brazilian savanna soils: archives of soil polygenesis on tropical sedimentary terrains

Yuri L. Zinn[1]
UFLA[1]

Although polygenesis is the rule rather than the exception in soil genesis, evidences of former soil formation cycles are difficult to detect even using micromorphology, because most soil components (sand, silt and clay) fractions are small, unconsolidated and continuously mixed by bio- and pedoturbation. However, soil gravels and coarser particles (>2 mm), usually not considered soil materials and discarded, are in many tropical soils composed of ironstones or petroplinthites, which are pedogenic and thus can preserve features of past soil genesis cycles. Peds or clods indurated by other cementation processes may also occur, all here referred to as pedogenic gravels (as proposed by Zinn & Bigham, Soil Res. 54, 440, 2016). In addition, gravels of resistant parent materials, such as quartzite and shales, can become impregnated by soil Fe/Al oxides, and are named lithopedogenic gravels. In this work, we present a micromorphological description of gravels in a Haplustox formed from mixed Proterozoic sediments near Unaí, Brazil, not treated in the previous paper and perhaps never before observed, which can confound those who would casually find then in soil thin sections. Besides magnetic and non-magnetic ironstones, in which only quartz grains are not opaque, the most common pedogenic gravels found were peds indurated with massive Fe-Mn oxide impregnation. The most common lithopedogenic gravels were shale fragments, in which soil Fe-Mn oxides were later impregnated forming 6 different, outstanding patterns: reticulate, banded, undulated, massive (opaque and diluted), banded and globular. Near pure Al-oxide depositions were also found. In addition, chert and corroded-grain quartzite nodules, with separate Fe, Mn and Al oxide impregnations, associated with pores, occurred. The current soil shows Fe- and Mn-oxide nodules, although it is not hydromorphic. It may be interpreted that impregnation with Fe and Mn oxides occurred at different short-time scales with redoximorphism, but the Al impregnations are prima facies evidence of a different, aerobic long-term formation cycle. Such impregnation has enhanced preservation of the mica-rich shales in the warm, humid climate. Alternatively, the contrasting gravels suggest reworking and spreading of different parent materials, which would add another critical component to the space-time continuous nature of soil polygenesis. In any case, the potential of such gravels as indicators of polygenesis and paleosols is clear.

(3699 - 548) Analysis of a pedological transformation system of the Diamantina Plateau, MG.

Roberta Borges Parreira[1]; Cristiane Valéria de Oliveira[1]
Universidade Federal de Minas Gerais[1]

Studies regarding the interaction between soils and relief and/or, particularly, pedological processes involved in soil transformation and evolution of the landscape in the Southern Espinhaço domain (SdEM) are still scarce. In the Diamantina Plateau specifically, research is still rare and relatively recent. This paper seeks to evaluate a soil transformation system located at the Roda stream heads, on a high summit surface in the Diamantina Plateau based on morphological, physical and chemical parameters. For this purpose some laboratory analyzes were conducted, Granulometry, Dispersed Clay in Water (ADA), Determination of Organic Carbon (CO) content and Determination of iron (Fe) content extracted by Dithionite Citrate Sodium Bicarbonate (CBD) and Oxalate Acid Ammonium (OAA). According to the results, a significant loss of CO content was detected, especially when comparing the slope's hydromorphic environment to the areas presenting better drainage. The Fe contents were also low for the soils in environments that present or have already presented deficient drainage, suggesting that a loss of Fe occurred by leaching, due to the reducing environment. The change of soil colors was also considered according to its position in the slope, from a more yellowish color (lower slope) to a reddish one (medium and higher slope). As for the pedological structure of the materials found in the poorly drained portions there is no noticeable structure. However as the drainage conditions improve, the structural units become discernible. Thus, the morphological data showed an alteration in the pedological organization - as the slope of the terrain increases and the drainage in the slope improves. Thereby, it was possible to identify the following sequence of soils in the slope: Histosol (base), Gleysols (medium slope), Gleysolic Cambisol and Cambisol (medium and high slope). In this way, the following conclusions were reached 1) there is a cause and effect relationship between topography and soil distribution; 2) the organization of the horizons along the slope are resulting of the operation of an Histosol - Cambisol transformation system.

(7491 - 2630) Behavior of a pedological Oxisols-Ultisols system in the municipality of Terra Roxa Paraná, Brazil

Rafael Martins Sanches[1]; José Edézio da Cunha[2]; Vanda Moreira

Martins[2]
PPGG/UNESP/IGCE/DEPLAN/Rio Claro[1];
PPGG/UNIOESTE/CCHEL/MCRondon[2]

The study of the structure and the functioning of landscapes implies the comprehension of processes (both natural and antropic) which involve a certain segment of space. In this sense, there is a need for studies that provide insights into soil distribution in landscapes and its relations with relief forms. The investigations aimed to identify the causes and consequences of the potential and emergent fragilities in environments with soils of medium-sandy texture, derived from the alteration of sandstones from the Caiuá Formation (Kc). The researches about this thematic indicated the need for detailed studies in the areas with greater tendency for origin and evolution of water erosion, particularly in the sectors of valley floors with convergent concave declivity ruptures which foster the loss of fine fractions (silt and clay). The Structural Analysis of the Pedological Cover methodology, systematized by Boulet et al. (1982a), oriented phases of the research, whose central goal was the vertical and lateral morphopedological representation along a topographic section on the left hillside of Tamanduá stream. The spatial cut consists of a rural sector in the municipality of Terra Roxa, on the western region of Paraná state, Brazil. For this purpose, we carried out topographic survey, pedological reconnaissance, opening of trenches for macromorphological description of soil horizons and collection of deformed and undeformed samples for physical and chemical analyses. These proceedings allowed to confirm a pedological system with the presence of oxisols on the top and on the high and lower hillside. The occurrence of these soil classes happens because of a flat relief that is slightly corrugated, has a low degree of dissection, declivity up to 8%, and hillsides of convex-concave-convergent forms. As to pedological covers resulting from sedimentary rocks of the Caiuá Formation, the soils presented a medium-sandy texture, with a high rate of sand and a low rate of clay, being of friable nature, and consequently, susceptible to hydric erosion on the downstream. In this sector of the hillside, there is a predomination of soils of E horizon, which is extremely sandy (up to 86%), and impediment subsurface horizon (Btg and Bt). This pedomorphological organization indicates the existence of two transformation fronts: one in the medium-hillside (Bw/Bt) and another in the low-hillside (AB/E and E/Bt) where the erosive instability of the system is most evident.

(4092 - 2371) Development of some Mongolian soil types of Forest Steppe and Gobi Desert zones and their ecological evaluation

Undrakh-Od Baatar[1]; Karl Stahr[1]
University of Hohenheim[1]

Soil genesis is the study of the development of soils. Soil is a natural body, developing from rock at the Earth's surface through pedogenic processes (weathering and mineral formation, decomposition and humification, structure formation and various substance translocations) under a specific climate, specific litter-delivering vegetation, and population of soil organisms. Understanding the processes enables interpretation of the natural history of a soil and provides a starting point to evaluate how future changes will affect the soil resource. Combining landscape history with knowledge of principles of soil profile development allows for more precise and effective land use planning. The importance of this paper is to evaluate the Mongolian different type of soils ecologically in detail way and classify them according to the WRB Soil Classification. The soil profiles have been described in Mongolian Forest Steppe and Gobi Desert zones between 2012 and 2017. Soil chemical and physical parameters have been analyzed for each layer of the soil profiles. As Mongolian Soil Ecological Evaluation methodology has not been well developed yet, this work tried to introduce the International Methodology to the country. The calculations for soil ecological evaluation have been done using the method from Hohenheim University. The WRB soil taxonomy is presented based on chemical, physical, and morphological soil properties.

(9070 - 1367) Distribution and Formation Environment of Fe-Mn Nodules in the soils derived from Quaternary Loess-like materials in the North of China

Qiu-Bing Wang[1]; Zhuo-Dong Jiang[1]; Zhong-Xiu Sun[1]
Shenyang Agricultural University[1]

The distribution of Fe-Mn nodules plays an important role in interpretation of the formation mechanism of Fe-Mn nodules and soil classification. Soils existing Fe-Mn nodules at stable upland with deeper groundwater are found in Northeast China, which causes many problems in soil classification. The objectives of the study were to figure out distribution and explore the environment and mechanism of soil nodule formation in Northern China. The principles for selecting soil profiles were: (1) soils were situated at stable uplands with deeper groundwater table, indicated that soils are not affected by groundwater and without obvious evidence of erosion and deposition in the processes of soil formation; (2) soils developed from the Quaternary loess-like materials, ensure that soils were developed from the same parent materials as far as possible. A total of 345 soil profiles, including soil series prospecting results in 2010's and the legacy data of the Second National Soil Survey during 1980's, in 10 provinces in temperate zone of northern China were selected. The mean annual precipitation and temperature of each sampling site was recorded based on China Meteorological Science Data Sharing Service. The relationship between existence of nodules in soils and climate of soil-forming was analyzed. The result shows that nodules appear in seventy-four in 345 soil profiles, which is account for 21.5% of soil profiles in total. The soil profiles existing Fe-Mn nodules are mainly distributed 120.82 ~ 133.37° E 41.19 ~ 49.01° N, where humid temperate area with MAP 370.6-917.7 mm, and MAT 0.9 - 14.9°C. The common characteristics of soils is located in a climate of relative high precipitation with a long time deeply-frozen soil in winter, and an obvious period of alternation of freezing and thawing in spring. Soil water in lower part of soil profile moves up and concentrates in upper part of the soil in the early freezing reason, and thaws during the period of alternation of freezing and thawing in spring. The thawing soil water cannot moves down to the substrate soil because of the existence of freezing layer in it. This result in reducing environment close to freezing layer for a period of time before soil thaws throughout, which lays a solid foundation for the formation of Fe-Mn nodules. We conclude that the formation of Fe-Mn nodules in the soils at stable upland is closely related to the alternation of freezing and thawing in spring.

(8757 - 2823) Evolution of the São Pedro Cuesta Escarpment Foothills in São Paulo, Southeastern Tropical Brazil: Preliminary Results

Grace Bungenstab Alves[1]; Fernando Nadal Junqueira Villela[2]; Marcos Roberto Pinheiro[2]; José Pereira de Queiroz Neto[2]; André Mateus Barreiros[2]; Marcelo Reis Nakashima[2]; Sidneide Manfredini[2]; Beatriz Ferras Scigliano[2]; Cristiane Regina Michelon[3]
Federal University of Bahia[1]; University of São Paulo[2]; Federal

Institute of Santa Catarina[3]

The genesis of foothill landforms is attributed to the Neogene age with correlative deposits and in situ alterations. This paper presents the preliminary results of an analysis of the geomorphopedological genesis of the foothills at the São Pedro Cuesta, located between the Peripheral Depression and the Western Plateau in the State of São Paulo, southeastern tropical Brazil. Geomorphopedological genesis is approached through a multiscalar analysis, from the regional to the soil scale. A regional survey of forms, structures, and neotectonic features is followed by a structural analysis of the pedological cover. Macro- and micro-morphological, physical, chemical, and mineralogical properties of toposequence materials were analyzed in addition to dating by optically stimulated luminescence. The foothills are elongated hills in a sandstone area covered by shallow Quaternary materials. The soil toposequence is located at the gentle interfluve slopes of the foothills. The results show a pedological system with a sandy clay loam texture with less than 20% clay and minor variation in depth, except for the hillslope in the inferior sector where the texture changes suddenly. The pedological system is reddish at the top, with more clay, and becomes progressively yellowish, and coarser with more sand in the inferior sector. A weak acid pH, prevailing negative charges, low basic cation concentration, and Ki and Kr indexes greater than 0.75 suggest high degrees of weathering and leaching in these materials, with a predominance of kaolinite in the clay fraction. Although the materials show a high pedologic development, their ages are relatively young, between 22.5 ± 2.6 ka (at the top) and 27.45 ± 4.35 ka (in the inferior sector). Rock fragments (basalt, sandstone, silex, and ferruginous crust) are found at depth in the inferior sector. Magnetite and maghemite soil minerals are present in the upper sector. The preliminary results suggest the presence of allochthonous materials on the glacis surface, which would have been derived from Late Quaternary morphogenesis linked to the escarpment retreat. The current sculpture of the interfluve is a result of pronounced mechanical morphogenesis in the Upper Pleistocene, and more intense weathering and pedogenesis in subsequent wetter periods in the Holocene.

(5447 - 1703) Five decades in research on Vertisols: A bibliometric analysis

Lima Glêvia[1]; Corrêa Marcelo[2]; Ferreira Tiago[1]
Esalq/USP[1]; UFRPE[2]

The Vertisols present a wide world-wide occurrence, high productive potential, besides particular and dynamic features, which requires different management. Through the bibliometric analysis of publications, the objective was to analyze the dynamics and evolution of research on Vertisols between 1966 and 2015. The data were taken from the database (Scopus), using the words "vertisols" or "vertisol" in the search. "Vertosol" in the field of article title, abstract and keywords. The evaluated items of the documents were category, type of document, affiliation, language, country of publication, as well as frequency distribution of the words in the title, keywords and author keywords. The countries that published the most on Vertisols (1966-2015) were India, Australia, the United States, France and Ethiopia, which have extensive areas occupied by this soil except France. Thus, at the global level, they contributed the most scientifically to the progress of researches on Vertisols, as well as presenting the main publishing institutions on this subject, and Spain, Belgium and Mexico. The first publications indexed in the database come from the 60s, and reached the peak of production in 2014. This behavior expresses the scientometric model that followed a second-order polynomial growth pattern. A fifth of the publications came from 11 authors, although these were not responsible for the most cited articles. Articles are the main type of document and English is the predominant language of publications. Vertisols, Vertisol and Soil were the most used words. The country, elements and most frequent cultures were India; nitrogen, phosphorus, potassium, carbon, zinc; and sorghum, wheat, soybeans, rice, cotton, chickpeas. The studies focused mainly on effects, differences, productivity, growth and uses, aiming at the optimization of natural resources, their better use, as well as increased productivity. Subjects related to pedogenesis and microbiology were poorly explored.

(8778 - 2858) Influence of relief on mineralogical development in soil in the semi-arid region of Pernambuco, Brazil

Juliet Emília Santos de Sousa[1]; Alexandre Ferreira do Nascimento[2]; Marcelo Metri Corrêa[3]; Valdomiro Severino de Souza Júnior[1]
1Departamento de Agronomia, Universidade Federal Rural de Pernambuco, Rua Dom Manuel de Medeiros, s/n, Dois Irmãos - CEP 52171-900, Recife, PE, Brazil[1]; 2Empresa Brasileira de Pesquisa Agropecuária – Embrapa Agrossilvipastoril, Rodovia dos Pioneiros MT-222, Km 2,5, Zona Rural Caixa Postal: 343, CEP: 78550-970, Sinop, MT, Brazil[2]; 3Universidade Federal Rural de Pernambuco, Unidade Acadêmica de Garanhuns, Av Bom Pastor, s/n, Boa Vista - 55292270, Garanhuns, PE, Brazil[3]

Semi-arid environments occupy a large part of the terrestrial territory, are characterized by quite characteristic climatic conditions, with low rainfall and high temperatures. The soils existing in this landscape are categorically characterized as little weathered, and predominantly rich in bissialitic minerals, showing the climate as a preponderant formation factor, forgetting the importance of the others. From these theories, this study was carried out with the purpose of proving the fundamental influence of the relief and drainage condition on the formation of minerals in the semi-arid environment and consequent evolution of soils. Physical, chemical, mineralogical and petrographic analyzes were carried out, being proved the predominance of processes of monossialitization and bissialitization in the region. The studied soils are formed from materials of very similar composition, being of great importance for the mineralogical development of the same. All the chemical, physical and mineralogical characteristics are reflections of the materials of origin of the studied profiles. It is clear after all studies that the formation of minerals is directly linked to the position of the soil in the landscape, being the soils with greater drainage propitious to the formation of minerals 1: 1 (kaolinite), and the soils with less drainage conducive to the formation of minerals 2: 1 (smectite).

Keywords: kaolinite, smectite, hydrolysis, landscape, drainage.

(4954 - 2543) Legacy soil maps from Brazil: organizing and providing layers in an interactive WebGIS

Ricardo de Oliveira Dart[1]; Mario Luiz Diamante Aglio[1]; Hilton Luis Ferraz da Silveira[2]; Elaine Cristina Cardoso Fidalgo[1]; Margareth Gonçalves Simões[1]; José Silva de Souza[1]; Elaine Rodriguez de Souza[1]; Débora Pignatari Drucker[3]; Davi de Oliveira Custódio[4]; Claudia Regina de Laia Machado[1]; Maria Regina Capdeville Lafroet[1]
Embrapa Solos[1]; Embrapa Solos / INPE[2]; Embrapa Informática[3]; Embrapa Territorial[4]

Digital soil maps at appropriate scales are essential information for land use planning. Nevertheless, Brazilian soil information is scattered in several institutions and stored in several formats. In adition to that, this information have faced an interruption of its systematic soil

survey program, providing difficult access to decision makers. In order to organize and safeguard the spatial data produced at the Brazilian Agricultural Research Corporation (Embrapa), a spatial data infrastructure was developed (IDE-Embrapa) where thematic collections related to soil have been gathered and published in a web environment. The objective of this work is to present the initiative of organizing the spatial data of Embrapa related to soil information through the development of the IDE-Embrapa. In order to achieve this goal, the spatial data that were stored in a previous geoinformation infrastructure developed by Embrapa Soils were shifted to the IDE-Embrapa infrastructure. The implementation of the IDE-Embrapa was performed using open source software, based on the Open Geospatial Consortium standards. The IDE-Embrapa infrastructure uses GeoNode platform, which integrates a geospatial database (PostGis) with a map server (GeoServer) and a metadata catalog (PyCSW), and is controlled by a Content Management System in the Web environment. Currently, 100 information layers and 60 documents were catalogued in the IDE-Embrapa Soils (geoinfo.cnps.embrapa.br). These data and metadata are already available for download. Maps represented by various territorial boundaries and scales were registered. The main maps of Embrapa Soils are already catalogued and are available to the user with their own color pattern (styling) for each type of thematic map, allowed by incorporation of a file with the styled layer descriptor (SLD) format to each map. Soil maps, for example, are presented with the colors established according to the Brazilian Soil Classification System, which facilitates users to visualize the spatial distribution of soils in a given region. Currently, the IDE-Embrapa infrastructure is making available the Brazilian soil information available to any external user. This work is under construction and we hope soon to have all maps prepared by Embrapa Soils catalogued and available, in order to safeguard data and metadata, for ready use of these by society.

(8245 - 598) Pedo-ecotone as a specific soil-geographic unit

Hryhorii Moroz[1]
Peasant farm enterprise "Balkany"[1]

At the present stage of the development of geographic science, there has emerged a need to improve the conception of geographical ecotones as transitional bands between various natural systems. Within such territories, one type of landscape (soil) is changed by another, for example, the steppe – by the dry steppe (chernozems – by kastanozems). In the northwest of the Black Sea region, a distinct transitional stripe is the transition stripe from the middle to the dry Steppe, which at the same time is a peculiar transition from calcic chernozems to the gypsic kastanozems. At the present stage, the soils of this ecotone are affined to the gypsic kastanozems in the brownish color of the humus accumulative horizon, with clear signs of lessivage, very low sodic resistance, low buffer capacity and chemical signs of soil sodicity. A well-defined humus accumulative horizon, humus indexes, a broad ratio of carbon content in humic acids to the one in fulvic acids and indicators of the optical properties of humic acids characterize the soils of this ecotone as calcic chernozems. A characteristic feature of ecotones (and hence of pedo-ecotones) is the pronounced spatial streamlining of their internal structure. Accordingly, in the pattern of the soil cover of the researched area, three groups of soils, which form the local catenas, can be distinguished: the background soils of the plakors and narrow watersheds (sodic and residual-sodic calcic chernozems); the soils of the lower parts of the slopes and the soils of the reclined thalwegs of the hollows – are characterized by chernozem parameters; slightly xeromorphic and slightly eroded soils of the upper parts of the slopes – closer to gypsic kastanozems. It also confirms the transitional (ecotonal) status of the researched area. Thus, the transition stripe from the gypsic kastanozems to the calcic chernozems in the northwest of the Black Sea region should be defined as a medium-dry steppe pedo-ecotone – a peculiar soil-geographic unit. Actually, the pedo-ecotone should be defined as a dynamic spatio-temporal soil-geographic system, which is formed in the contact zone of certain types (subtypes) of soils and is characterized by relatively high gradients of properties and parameters, internal inhomogeneity and functional interconnection of the structural elements, among which both the objects of adjacent pedo-ecotone-forming bodies and specific for the given pedo-ecotone formations are found.

Keywords: Pedo-ecotone; chernozems; kastanozems; steppe.

(5260 - 2739) Relation of pedoenvironments with forms of nitrogen and phosphorus in semiarid soils.

Victor Junior Lima Felix[1]; Evaldo dos Santos Felix[1]; Bruno de Oliveira Dias[1]; Sebastiana Maely Saraiva das Chagas Sousa[1]; Vânia da Silva Fraga[1]; José Coelho de Araújo Filho[1]
Universidade Federal da Paraíba[1]

There are few studies related to the influence of the climatic gradient, mainly rainfall, on N and P dynamics in soils of the semiarid region of Brazil, being this information primordial for the planning of the soil management, since these nutrients are considered limiting for the production of biomass of the region. Eight sample areas were selected considering two climatic gradients (hot and semihumid, and hot and semiarid), which contained the three main orders of representative soils of the Brazilian semiarid region Planossolos, Luvissolos e Neossolos Regolíticos (Typic Albaqualf, Aridic Haplustalf and Typic Ustortent)). In these places trenches were opened, horizons were identified and samples were collected for analysis in all present horizons. The values of the fraction of P (P-Al, P-Fe and P-Ca) and mineral N (NH_4^+ and NO_3^-) were evaluated. The highest levels of P fractions were found in the Luvissolos (Aridic Haplustalf) region of the hot and semiarid climate, with predominance of P-Al and P-Fe fractions, which may be related to the reduced Ca^{2+} contents in this soil and the soil pH, since P-Al and P-Fe are more frequent in more developed soils and acids, while the P-Ca predominates in alkaline soils. As for mineral N fractions (NH_4^+ and NO_3^-), the levels were considered low in all soils and horizons, only the Luvissolos (Aridic Haplustalf) of the hot and semiarid climate had higher levels of nitrate. It was possible to conclude that with increasing rainfall there was an increase in P and N fractions in all Planossolo (Typic Albaqualf) and Luvissolos (Aridic Haplustalf) profiles, however, the source material influenced more than rainfall.

Keywords: pedogenesis, fractionation of P, NH_4^+ and NO_3^-

(3397 - 747) Soil fertility mapping: its transference to farmers by using GIS online tools

Bryan Alemán Montes[1]; Carlos Henríquez Henríquez[1]; Kenneth Largaespada Zelaya[1]
Universidad de Costa Rica[1]

The GIS helps to study the spatial variability of different characteristics on landscape and becomes an important tool for the adequate management under precision agriculture concept. The goal of this study was to use available *Online* tools in order to display the spatial variability of some soil chemical properties on field. In the project participated 235 farmers of CoopeTarrazú R.L. and CoopeLlanobonito R.L. cooperatives located at "Zona los Santos", Costa Rica and dedicated to coffee production. Cooperative Foment Institute (INFOCOOP) and University of Costa Rica (UCR) sponsored this study

in collaboration with the involved cooperatives. The farms were georeferenced reaching a total of 693 hectares; from this area, 142 soil samples for chemical analysis were taken and analyzed. Spatial autocorrelation analysis was carried out and interpolated maps were generated using Ordinary Kriging parameters with selected soil chemical characteristics data. The Effectivity Estimation Parameter was over 95% with the most of the features except with K (74%). Some critical characteristics as soil acidity were detected in some areas using the methodology. The interpolated data of each soil chemical feature was linked to georeferenced farm areas and uploaded at open source *Online* platform *QGIS-Cloud*. This allow viewing and consulting soil maps and linked data using mobile apparatus or computers with internet access. The work flow allow by this way to share and transfer the updated information related to coffee production to farmers stimulating the use of records and data base generated.

(3203 - 1477) Spatial variability of soils and its relation to plant biodiversity in fluvioglacial and lacustrine landscapes of South Karelia on a large scale

Igor Ilichev[1]
Lomonosov Moscow State University, Departments of Soil Science, Leninskie Gory 1-12, Moscow, 119991, Russia[1]

The research was conducted to identify soil heterogeneity of the fluvioglacial and lacustrine landscapes of South Karelia. Field studies were conducted in the Karelian Republic in the vicinity of the village Essoila. Two complementary methods were used: analysis of soil diversity and assessment of spatial variability of soils. Studies were carried out on two different landscapes: dissected fluvioglacial ridge with well drained moraine and fluvioglacial sands as parent materials (Site 1) and waterlogged plain on lacustrine-glacial clays (Site 2). At both sites one hundred soil pits were made and described. All soils were named according to the new classification of Russian soils and WRB. Typical soils for the Site 1 are Entic Podzols (Arenic) – 39 % and Albic Podzols (Arenic) – 27 %; for the Site 2 the dominant soils are Dystric Histic Stagnosols (Clayic) – 50 % and Umbric Stagnosols (Clayic) – 22 %. Soil diversity was characterized using the Shannon–Wiener index: for the Site 1 it equaled 2,36, for the Site 2 – 2,21. Variability of thickness of soil horizons was also calculated. It showed that despite close values of the Shannon – Wiener index, there were significant differences in the spatial organization of the two landscapes. Another aspect of the research was the consideration of the impact of soil variability on plant biodiversity. The degree of difference between plant communities were assessed by the Jaccard and other similarity indices. The research showed that soil variability has a significant impact on vegetation cover.

Keywords: pedodiversity, Podzols, Stagnosols, soil horizons thickness

(6019 - 2587) Volcanic island in the central part of Kurily Range: pedodiversity and Andosol properties

Sergey Khokhlov[1]
V.V. Dokuchaev Soil Science Institute, Pyzhyovskiy lane 7 building 2, Moscow, 119017, Russian Federation (khohlov2000@mail.ru)[1]

The Matua Island, 52.6 sq.km, a recent volcano with the highest point 1446 m a.s.l. and its neighbor – small and flat Toporkovyi Island 1.1 sq.km, 70 m a.s.l. are located in the center of Kuril Islands Arc. The volcano – Pik Sarycheva, is an active stratovolcano of explosive and effusive eruption activity, having produced during the Holocene stratified, mostly gravelly mafic pyroclasts, 5 to 7 m thick. Their top layer, about 500 years old and 140 to 65 cm deep, serves as parent rock for Andosols. Climate is cool: mean temperature of the warmest month is 10.8°C, that of the coldest one is – 5.3°C, MAT is 2.2°C, and MAP is 1223 mm. Meadows, small-shrub tundra and dwarf alder communities alternate with bogs. Volcanic soils are formed on stratified gravelly-stony tephra more than 60 cm thick, underlain by thin layers of volcanic slags, sands and transit ashes, some of them interstratified with buried soils; their deposition started 1.6 mln years ago. The most widespread soils were qualified in WRB-2015, for Umbric Vitric Andosols (Fulvic, Endoaluandic). In most soil profiles (total of 90 pits), main diagnostic properties of Andosols are identified, and the differentiation of the soil cover is due to topsoils, which properties well correlate with vegetation. In Russian classification system, there are special diagnostic horizons or diagnostic properties for them that only partly correlate with the WRB horizons. Thus, under tundra communities, a mucky – raw-humus horizon is formed, or the dry-peat one (10-17 cm thick) if soils are somehow disturbed. Meadows are related to a soddy horizon with features of the raw-humus one (10-35 cm), ferns – to peat or mucky-peat topsoil not deeper than 15 cm. It is worth noting that the whole pyroclastic thickness is pierced by fine roots. Shallow ash-stratified peat soils associated with raw-humus gley soils are confined to the sites of ground water discharge. The Toporkovyi Island is inhabited by birds – Fratercula cirrhata, responsible for the development of unusual ornithic soils occupying 35% of its area. They have a horizon with few traces of birds' artefacts, overlying the hard rock, or loose pyroclastic deposits. Thus, the soil survey performed on the Island of Matua confirmed the occurrence of young Vitric Andosols there, associated with several variants of Leptosols, having any combinations of qualifiers, Principal: Folic/Histic/Umbric, and Supplementary: Andic, Gelic, Gleyic, Ochric, Ornithic, Protic, Tephric.

C1.2.2 - Remote sensing applied to soil Science

(8670 - 2766) A combined gis-analysis of major forest-forming conifers, soils and climate distributions in central Siberia

Elena I. Parfenova[1]; Nadezhda M. Tchebakova[1]; Olga V. Trefilova[1]; Eugene G. Shvetsov[1]
Forest Institute of FRC KSC SB RAS[1]

Our goal was to determine relationships between major forest-forming tree species and ecological factors (climates and soils) in central Siberia and to apply these relationships to modeling and predicting their distributions based on climatic and soil GIS layers. In our regional SibForClim model, the input climatic layers were: 1. growing degree days, base >5oC; 2. negative degree days, base <0oC, and 3. annual moisture index, representing respectively summer warmth, winter cold and dryness stress conditions. Permafrost was explicitly taken into account. The output layers were: a major forest-forming tree species and its productivity (site index). This model was updated with soil types that were derived from the Soil Map of Russia (1988). Superimposing forest tree species distributions from the Map of Russia's forests (1990) and soil types using the GIS-techniques we concluded that probabilities of each tree species occurrence were associated with particular soil types. Thus, the tree species distributions are to be mapped using surface climate, soil and permafrost layers. The next step to extend the SibForClim model is to include the soil climate being a function of surface climate, soil morphology and local microrelief.

(9368 - 286) A novel technique for detection of shallow soils using remote temporal images in central Brazil

Wanderson de Sousa Mendes[1]; José Alexandre Melo Demattê[1]; Raúl Roberto Poppiel[2]; José Lucas Safanelli[1]; Caio Troula Fongaro[1]; Clécia Cristina Barbosa Guimarães[1]; Renato Zocco Belato[1]

Luiz de Queiroz College of Agriculture, University of São Paulo[1]; FAV, University of Brasilia[2]

Solum depth is controlled by soil forming processes and thus, play an important role in soil mapping, land use planning and agriculture. It is usually determined by field work (Dutch auger) and/or relief inferences, which implies on large budget to execute and requires a lot of time for evaluating the soil depth. Faster techniques are vital to evaluate the soil depth. However, solum depth are one of the most difficult tasks to be performed using sensing systems. The objective of this investigation was to create a technique to achieve area of soils with depth limitation using remote sensing temporal images. The study area is located in Central Brazil. It was collected 330 soil samples in 0-20 cm soil depth and granulometric analysis performed. The information was used to assess soil modelling with Geospatial Soil Sensing System (GEOS3)(Demattê et al., 2018). The technique allows to undercover soils using time series of images. Based on this image, we link the soil analysis with the pixel and predict sand and clay maps for the entire area. We constructed two datasets using images from the same months and different years, (a) in the wet season and (b) in the dry season. Handling the datasets, we used an algorithm in R to overlap all images and extract only the maximum Normalised Difference Vegetation Index (NDVI) of each pixel along the time series of each respective season. By the subtraction of the NDVI of the dry and wet seasons, we obtained an image which represents areas where had maximum differences in the pronounced natural vegetation. The areas with maximum differences indicated shallow or rocky soil at in-situ evaluation of the soil depth. Deep soils had higher pronounced vegetation. This was also correlated with the topsoil texture, which is an ancillary indicator of pronounced or non-pronounced vegetative areas. We suppose that shallow soils have the pronounced maximum vegetation in the wet season and minimum in the dry season because of water stress (Osakabe et al., 2014). Meanwhile, deep soils presented pronounced vegetation in both seasons. Therefore, this technique can assist soil management, classification, definition of soil zones and dataset, precision agriculture and land use planning.

(6565 - 2194) Analysis of hazard factors to risk desertification in the Amaime river basin, department of Valle del Cauca (Colombia - South America)

Diana Lucia Correa-Moreno[1]; Jeiner Yovany Buitrago Escobar[2]; Yolanda Rubiano Sanabria[2]; Andres Javier Peña Quiñones[3]

Colombian Corporation for Agricultural Research (CORPOICA)[1]; National University of Colombia. Campus Bogotá. South America.[2]; Washington State University. Prosser. United States of America.[3]

The purpose of this study was to estimate the hazards of desertification in the Amaime river basin in the department of Valle del Cauca (Colombia - South America), through indicators such as climatic, geomorphometric and soil cover. The analysis was carried out with basic primary and secondary information of risk analysis in regions prone to desertification (RARD), through a multifactorial approach, with standardized indicators according to criteria established in this area of research for tropical zones, and the estimation of indices of climatic hazard (NHclI), geomorphometric hazard (NHgI) and anthropogenic hazard (AnHI). Series of daily precipitation data between 1970 and 2010 were analyzed for the generation of a climatic index. The geomorphometric variables were obtained from the digital elevation model (DEM - STRM) with a resolution of 30 m. The anthropic index was obtained from RapidEye satellite images for classification of cover and land use according to the corine land cover - IDEAM methodology, and reclassification with criteria for quality attributes of the vegetation and intensive soil use. The indices were processed and spatialized for the elaboration of cartography at a scale of 1: 50.000, by applying a model in GIS that allowed grouping the RARDs that presented a similar level of hazard. The natural hazard index (NHI) allowed locate the area in the category of areas with medium hazard; while the anthropic hazard index (AHI) catalogs the basin with a high hazard. The basin in general presents a high hazard to desertification (1.45), and the areas with the highest probability of hazard are located in the flat area and in the central sector of the mountainous area, covering 63,878 ha (61.2%); Considering the factors analyzed in the RARD in the basin, it was established that the hazard to desertification is determined mainly by the climatic indicators: number of dry months and climatic aggressiveness; geomorphometric indicators: slope and topographic humidity index; and by anthropic hazard indicators: quality of vegetation and intensive land use. They express constant pressure in different parts of the basin due to the water deficit in a large part of the year, with a high probability of droughts and greater intensity of rainfall, which generate runoff, erosion and sedimentation processes in a natural way and which are exacerbated by the intensive use of soil under different vegetation cover in expansion in the basin.

(2504 - 2683) Analysis of the incidence of fires in different classes of soils and biomes in the state of Minas Gerais-Brazil

Eliana Elizabet dos Santos[1]; Elpídio Inácio F. Filho[1]; Liovando Marciano da Costa[1]; Márcio Rocha Francelino[1]

University Federal of Viçosa[1]

The study of the spatialisation of fires in the territory is an important way of knowing and understanding its potentiating factors in order to create measures that minimize its effects on the environment. In this sense, geoprocessing becomes an essential tool when it is intended to study large and difficult access areas that need a more comprehensive analysis. This study had as objective to evaluate the incidence of burnings in different types of soils in the state of Minas Gerais considering their different biomes. From the soil map of the state of Minas Gerais, soil classes were identified according to their second categorical level proposed by the Brazilian Soil Classification System (SiBCS). Hotspots were used for the period from 2001 to 2013 provided by the National Institute of Space Research (INPE). The hotspots were superimposed on the soil map and through ArcGis 10.1 program tools. It was possible to account for the number of hotspots sources in each type of soil and thus to analyze the density of points of fire between the different classes. This relationship was also made considering each biome (Atlantic Forest, Cerrado and Caatinga) in order to identify or not influence their characteristics on the spatialization and concentration of fires in the different soil types. When performing the spatialization of hotspots sources, it was observed that 57% of the outbreaks are concentrated in the Cerrado, 41% in the Caatinga and 2% in the Atlantic Forest. When related to soil type, Entisols Fluvents present a higher concentration of heat sources per area in the Caatinga biome, presenting 0.14 hotspots/km^2. In the Cerrado, there is a higher density on the group of Entisols Fluvents and Plinthosols Argilúvicos (0.60 hotspots/km^2) followed by the group of Gleysols Melanicos (0.52 hotspots/km^2). Finally, in the Atlantic Forest prevails over the group of Ultisols (0.33 hotspots/km^2). Physical characteristics such as depth and water storage capacity of each soil,

as well as the use intended for them, especially those related to agriculture can be important factors in this distribution, leading to a higher or lower incidence of fires in the environment, as well as bio characteristics of each biome.

(8929 - 1536) Assimilating satellite images and soil spectroscopy to model soil loss to evaluate crop residues removal for bioenergy

Bruna Cristina Gallo[1]; José Alexandre Melo Demattê[2]; Paulo Sergio Graziano Magalhães[3]; Marcus Vinicius Sato[2]; Caio Troula Fongaro[2]; João Luis Nunes Carvalho[4]
University of Campinas and Brazilian Bioethanol Science and Technology Laboratory[1]; University of São Paulo[2]; University of Campinas[3]; Brazilian Bioethanol Science and Technology Laboratory[4]

Mapping soil attributes provides support to agricultural planning and land-use monitoring such as agricultural residues removal. The crop residues has potential of renewable energy and soil and water conservation. However, there are no well-established criteria of agricultural residues removal, and the minimum coverage required to maintain soil integrity. This work aims to model soil loss by assimilating soil spectroscopy data from satellite imagery and establish the straw removal availability for bioenergy proposes. Here, we use Geographic Information System (GIS) to integrate the factors of the Revised Universal Soil Loss Equation (RUSLE) to model soil loss in a site of 515 ha cultivated with sugarcane in Piracicaba, state of São Paulo, Brazil. We estimate rainfall erosivity (R) using a time series data of 20 years, slope length and steepness (L and S) using a digital elevation model. Soil cover management (C) and control practices (P) using the land dynamic cover. Soil erodibility (K) using bare soil technique of multi temporal Landsat TM images based on soil spectroscopy to evaluate models of clay, sand and silt content. We define soil loss tolerance (T) as the potential limiting factor for straw removal, which indicates the maximum rate of soil erosion that can occur and still permit crop productivity to be sustained economically. Landsat images were efficient and suitable for modeling soil surface texture. Clay content prediction present good performance with R^2 of 0.75 and low error. Other attributes prove significant results, such as the positive correlation between sand content and reflectance. We found that the variance of soil loss across the site range from 0.3 to 133 Mg ha^{-1} $year^{-1}$. Here, we considered that T is 12 Mg ha^{-1} $year^{-1}$ as indicated by the literature, thus the potential straw removal that remained above the tolerance limit express 46% of the site. We also considered the average of 14 Mg ha^{-1} of straw availability in the site and an optimal quantity of 7 Mg ha^{-1} of straw that should remain in the field in order to maintain the agronomic and environmental benefits. Hence, the sustainable straw removal available represents 1778 Mg (25% of the straw production), which may provide 1251 MWh of bioelectricity production (15% of straw moisture, and 0.828 MWh per Mg of straw in dry basis). This study provides information based on soil erosion caused by runoff to guide the sustainable decision-making of straw removal for bioenergy production.

**(7138 - 3220) A comprehensive multiobjective sampling layout opti-
mization method**

Ziyue Chen[1]
Beijing Normal University[1]

Spatial sampling is one of the most important methods for soil survey and the sampling layout optimization draws a lot of concerns. In soil mapping, multiple variables and purposes are involved and multiple objectives should be optimized simultaneously. Due to the difference on measures, and quantities of objective functions, the implementations of methods that transform multiple objectives into single objectives are limited. In this paper we presented a comprehensive multi-objective sampling layout optimization method, named multi-paths SSA (MP-SSA), by extending the classic SSA method. The MP-SSA method optimizes multi-objective functions of different measures and quantities synchronously, and emphasizes important objective functions over less important ones. The performance of MP-SSA was examined in sampling optimization for concentration mapping and grades mapping of heavy metals in soils which have different requirements on sampling layout. The results suggest that MP-SSA can optimize multi-objective functions of soil mapping synchronously, and samples drawn by MP-SSA can improve the precision of concentration mapping and grade mapping. As a result, the MP-SSA is a promising tool of sampling layout optimization for multi-objective soil mapping.

(7850 - 2537) Building a spectral library for estimating soil texture in the Santa Catarina State, Brazil

Elisângela Benedet da SILVA[1]; Elvio GIASSON[2]; Alexandre ten CATEN[3]; André Carnieletto DOTTO[4]; José Alexandre M. DEMATTÊ[4]; Milton da VEIGA4[5]
EPAGRI[1]; UFRGS[2]; UFSC[3]; ESALQ[4]; UNOESC[5]

Soil properties characterization is required to inform and lead decision-makers into action. To achieve this goal, it is necessary to develop effective methods to soil measure and monitoring. Several soil databases have been used to build large spectral library for improving and facilitating the use of VIS-NIR-SWIR spectroscopy approach in a collaborative way. In this study, the performance of four multivariate statistical techniques (e.g., Partial least-squares - PLS, Support vector machine - SVM, Random forest - RF, Gaussian process regression - GPR) were compared to evaluated their ability to predict sand, silt and clay content (%) using a regional soil spectral library. A total of 1534 observations were collected throughout the State of Santa Catarina (SC). These observations were used as dataset for the calibration (n = 1151) and validation (n = 383) procedures. Soil spectra was obtained using the FieldSpec 3 (ASD) sensor in the VIS-NIR-SWIR range. The spectra were subjected to seven preprocessing techniques including raw spectra (RAW), first derivative (FD-SG), second derivative (SD-SG), continuum removed reflectance (CR), detrending (DT), normalization by range (NBR) and multiplicative scatter correction (MSC). The ranges of sand (1.0 to 99.0%), silt (0.0 to 83.0%) and clay (0.0 to 77.0 %) content are wide and their coefficients of variation are large, indicating great variability of samples as a result of different soil-forming factors. Our results showed that the best predictive validation models were obtained with FD-SG preprocessing and RF technique for sand content (R^2 = 0.68; RMSE = 11.56%; RPIQ = 2.42) and silt content (R^2 = 0.43; RMSE = 8.51%; RPIQ = 1.52) and with NBR and SVM for clay content (R^2 = 0.78; RMSE = 8.70%; RPIQ = 3.17). The Scott Knott test showed that there was no statistical difference between the RMSE values of PLS, SVM, RF and GPR for each soil property. However, when comparing preprocessing techniques used in this study, RMSE values for sand, silt and clay revealed statistical difference between the SD-SG and the others six preprocessing. The predictive ability of VIS-NIR-SWIR reflectance spectroscopy achieved

for soil texture using a regional soil spectral library was in line with those reported in international literature. On the other hand, SC soil spectral library needs to be improved adding more soil properties as well as partners to contribute in local and regional scale to obtain more soil representativeness.

(9223 - 2095) Comparative analysis of five digital elevation models: SRTM, ASTER, ALOS-PALSAR, UAV and Laser Scanner

Athos Alves Vieira[1]; Elaine Caliman Sposito[1]; Rafael Gomes Siqueira[1]; Elpídio Inácio Fernandes Filho[1]; Márcio Rocha Francelino[1]
UFV[1]

Digital elevation models (DEMs) and their derivatives has applications in many different studies, especially in models of representation of the Earth's surface, digital mapping of soils and studies from river basins. The potentiality of the different models of DEMs and its application are related to their spatial resolution, which determines the proper scale and area. The choice of a particular DEM depends on the purpose of the work, once its parameters may vary according to the origin of the data. In this study, five DEMs, from different sources (SRTM 90, SRTM 30, Aster, Alos Palsar, unmanned aerial vehicle - UAV and Terrestrial Laser scanner), were generated, compared and confronted with a total of 18 control points obtained by Global Navigation Satellite System – GNSS (L1, L2), in the hydrographic basin of the Equideocultura, in Viçosa – MG (Brazil). It aimed to assist the selection of the most suitable DEM to derive morphometric attributes. DEM acquisitions were performed through freely available data (SRTM, Aster and Alos-Palsar) and field data (UAV and Laser scanner). The mean square error (MSE) was calculated to estimate the accuracy of the images. The values obtained were: 1.10 for SRTM 90; 0.80 for SRTM 30; 0.93 for Aster; 0.27 for Alos Palsar; 0.09 for UAV and 0.01 produced for Laser Scanner. Therefore, DEM generated by the Laser Scanner and the UAV are recommended to detailed scales. However, they require more financial resources and fieldwork, so that the Alos Palsar DEM also representes a suitable option. DEM SRTM 30m resolution and DEM SRTM 90m resolution are suitable in studies that use smaller scales.

(8419 - 2754) Delineating soil nutrient management zones based on fuzzy clustering optimized by sPCA in a Colombian Oxisol.

Ruby S. Hernández S.[1]; Jaime H. Bernal R.[2]; Edgar J. Salcedo A.[2]; Orlando Arguello T.[2]; Nubia Stella Rodriguez[2]; Lina M. Moreno[2]; Miguel Arango A.[2]; Edwin F. Grisales[1]
National University of Colombia[1]; CORPOICA[2]

Crop management in the high plains of Colombia is based on generalized estimates of soil nutrients concentration, leaving aside the inherent soil variability, leading to low production efficiency and high risk of environment pollution. Delineation of soil nutrient management zones provides basis for variable fertilization technique and is the important link of variable fertilization management actualized in precision agriculture. After the spatial variability characteristics and structure of thirteen soil chemical parameters were analyzed, they were taken as the variables to delineate soil nutrient management zones. The fuzzy clustering algorithm optimized by spatial Principal Component Analysis (sPCA) was used to delineate management zones, and four indices were introduced to ascertain the reasonable number of management zones. According to the calculation, the reasonable number for the study area was 4. As single factor variance analysis was used to analyze soil nutrient data of the practical samples in each management zone, all soil nutrients show great differences among management zones on the confidence level of 87%. Zone 1 had the higher soil fertility and zone 4 had the lower. The delineation result indicated that fuzzy clustering optimized by sPCA had a good performance on delineating management zones and variable fertilization management was feasible in the study area.
Keywords: Precision Agriculture; Oxisol; Fuzzy k-means cluster; Management zone; soil nutrient spatial variability.

(3610 - 2760) Determination of potential soil management zones from soil electrical conductivity, DEM and yield data in an Oxisol of Colombia

Jaime H. Bernal R.[1]; Miguel Arango A.[1]; Nubia S. Rodriguez[1]; Lina M. Moreno[1]; Orlando Arguello T.[1]; Edgar J. Salcedo A.[1]; Jaime Gomez N.[2]; Yolanda Rubiano S.[3]; Luis J. Martinez[3]; Edwin F. Grisales C.[3]
CORPOICA[1]; CIAT[2]; National University of Colombia[3]

Field-scale characterization of soil spatial variability using remote sensing technology has a great potential for achieving the successful implementation of management zones in precision agriculture. The objectives of this study were to: (i) examine the spatial relationships between apparent soil electrical conductivity (ECa) and soil chemical and physical properties to determine if ECa could be useful to characterize soil properties related to crop productivity in a Colombian´s Oxisol; (ii) evaluate the effects of Digital Elevation Model on ECa mapping as a basis for characterization of soil spatial variability and as a data layer in cluster analysis as a means of delineating sampling zones; (iii) evaluate clustering approaches using different variable sets for management zone delineation to characterize spatial variability in soil nutrient levels and crop yields. Data were obtained in a 37 ha field in the high plains, Colombia, with a sampling grid of 225 points. Spatial measurements of ECa via electromagnetic induction (EMI) were compared with soil chemical and physical parameters using spatial correlation analysis. MULTISPATI-PCA was used to carry out for multivariate spatial analyses of soil attributes and yield data. The fuzzy clustering algorithm optimize by sPAC using sensor-based field attributes including horizontal ECa, DEM data, soil chemical and physical properties, yield data, and their combinations was performed to delineate management zones. Few strong direct correlations were found between ECa and the soil chemical properties studied, but some soil physical properties. The relationships of sensor-based field attributes as clustering variables to group soil test parameters and crop yields improve when the DEM data was included. The clustering data combinations effectively captured the within-zone variability of soil test parameters and crop yield. The results indicate that zones created by cluster analysis could provide a way to group and manage spatial variability of soil nutrients within fields.

(5871 - 2275) Determination of the P index for the watershed area of the Marrecas stream using geoprocessing

Joelma Divina Murliki[1]; Élvio Giasson[2]; Elemar Antonino Cassol[2]
PPG Ciência Do Solo UFRGS[1]; Departamento de Solos UFRGS[2]

In the quest to reduce the environmental liability caused by excess nutrients applied, there are no initial studies and development of methodologies to reduce the input of nutrients and simulations as they are transmitted to the system. Among the many nutrients that are applied, P (Phosphorus) stands out, mainly for being one of the responsible for the process of eutrophication. The objective of this work was to use the original P-Index (Phosphorus Index) to identify

areas of P contamination in the Marrecas Stram Watershed, in Caxias do Sul, Brazil. The methodology developed by Lemunyon and Gilbert (1993) was adopted and the parameters used in the original version are P soil content, soil erosion ($t.ha^{-1}.year^{-1}$), erosion by irrigation, ($P_2O_5.ha^{-1}.year^{-1}$), the application methods of mineral P and organic P (kg $P_2O_5.ha^{-1}.year.^{-1}$). The P-Index was obtained considering the transport factors and sources of P distributed in categories and weights based on the impact of this in the transportation of the P in the area. The equation of these parameters was performed using geoprocessing software, where maps of phosphorus content, soil use, soil type, runoff and soil loss were overlaid to generate the results. According to the application of the P-Index, it was verified for the watershed of the Marrecas stream that most of the watershed was classified as having a low risk of P contribution due to the type of land use predominant in the watershed, with extensive livestock farming in the natural pasture. The areas with the greatest potential risk were those in which soils are used more intensively with annual crops and without the adoption of conservation practices or degraded areas. Thus, the application of the P-Index presents a good potential to be used as a tool for the management of water resources, contributing to the identification of areas of risk of diffuse pollution and, thus, making possible the most efficient planning of the actions to be carried out for improvement of the quality of water resources.

(1437 - 2211) Digital elevation based soil mapping method for hilly areas built up of unconsolidated sediment

Károly Kovács[1]; Endre Dobos[1]; Péter Vadnai[1]; Diána R. Bertóti[1]

University of Miskolc[1]

The relative influence of each soil forming factor varies through the geographical landscape. Geomorphology of hilly regions built up of unconsolidated sediments is defined by the physical properties of the deposits. Relief is shaped accordingly the stability and stratigraphic position of the sediments. Thus within the landscape the primary soil forming factor is the parent material, and the geographic distribution of the parent material can be modelled based on the relief. The study site is of the northern piedmont of Bükk mountains (NE Hungary). The geological landscape is set up of Eocene - Miocene piedmont, tidal, alluvial and estuarine sediments, some volcanic tuff from the same age and quaternary colluvium, alluvium and aeolic deposits. The diverse parent materials form soils of different texture from gravel to heavy clay and its amalgamations of different portions. Soils chemical properties vary from extremely calcareous to strongly leached acid pH. The two geological formation characterising an area that covers 300 square kilometres, which can be mapped in high resolution with the elaborated method. The high resolution soil mapping was implemented for growing site assessment purposes to guide local authorities' land use management. The rural area is adjacent to heavy industry, mapping had the purpose of revealing soil contamination too. The 500 hectares' study site was explored by 25 soil pits and another 30 auger samples. Soil samples were analysed for texture, BS, CEC, OM, carbonates, complete available nutrient analysis and 14 toxic elements. All profiles were classified, WRB RSGs and diagnostics defined. Based on field experiences and laboratory data we delineated areas were parent material is certainly homogenous. We used these polygons as training polygons for classification of a layerstack consists of geomorphologic metric raster images derived from DEM. The obtained polygons delineate uniform soil forming environment, they are not soil type units, RSGs are divided by the most important diagnostics. The resulted stratification of the area gives those homogenous soil landscape units in which soil properties vary the least, thus predictions can be made in changes of toxic element, OM or nutrient content, water regime or pH.

(2481 - 2214) Discriminatory performance of data obtained by unmanned aerial vehicle in soil-plant systems

Filipe Castro Felix[1]; Fabio Arnaldo Pomar Avalos[2]; Wellington de Lima[3]; Wesley Soares de França[4]; Marx Leandro Naves Silva[5]; Ronaldo Luiz Mincato[6]

Federal University of Alfenas, UNIFAL / ICN, Alfenas, 37130000, Brazil (filipecfelix@gmail.com)[1]; Federal University of Lavras, UFLA / DCS, 3720, Lavras, 37200000, Brazil (fa.ingeo@gmail.com)[2]; Federal University of Lavras, UFLA / DCS, 3720, Lavras, 37200000, Brazil (tomdelima@yahoo.com.br)[3]; Federal University of Lavras, UFLA / DCS, 3720, Lavras, 37200000, Brazil (wesley.franca@engagricola.ufla.br)[4]; Federal University of Lavras, UFLA / DCS, 3720, Lavras, 37200000, Brazil (marx@dcs.ufla.br)[5]; Federal University of Alfenas, UNIFAL / ICN, Alfenas, 37130000, Brazil (ronaldomincato@gmail.com)[6]

The soil-plant system represents the interaction of countless physical, chemical and biological soil attributes, which are responsible for the dynamic and complex plants process in the ecosystem. The understanding of these processes enables the rational management of certain soil conditions, can improve plants productivity. Like this, the objective of this study was to check the discriminatory performance of data obtained by an unmanned aerial vehicle (UAV) in relation to these systems. For this, 250 soil samples from the superficial layer (0 to 20 cm) were collected during the 2017's winter, in the municipality of Lavras, Minas Gerais. The collections occurred in five distinct vegetation cover areas that were considered as soil-plant systems. From the samples were analyzed attributes such as texture, organic matter, and soil temperature and soil moisture of the five systems: coffee, eucalyptus, pinus, native forest and cerrado, which were characterized according to indirect ordination by principal component analysis. In the same period, UAV flights were conducted to capture images, in the visible spectrum, of each vegetation cover. Subsequently, several vegetation indexes based in this spectrum were calculated, as well as the generation of a digital surface model. The images in the visible and the digital surface model were segmented to get new variables, based on these segments, like shape index, homogeneity and entropy. The discriminative capacity of the soil-plant systems as retrieved by UAV data was evaluated by linear discriminant analysis. Principal component analysis indicated a high association between vegetation types and soil attributes, which allowed us to consider vegetation type as an indicator of soil condition. The first two discriminant functions distinguished 91.35% of the data among vegetation covers (71.85 and 24.5%), which emphasizes the capability of UAV digital photogrammetry to obtaining and monitoring environmental data. It should be noted that the research is in progress, and our main objective is the seasonal monitoring of the five soil-plant systems, assessing the vegetation indexes and soil variability throughout the years 2017 and 2018.

(4714 - 882) Evaluation of agricultural land potentiality for mechanized agriculture in the state of Acre

Glailson Barreto Silva[1]; Alves, Washington Santos.[1]

IBGE[1]

The potentiality of the classes of soils is expressed in the form of

schematic map and percentages represented in the form of cartogram, histograms and pizza graphics, representing the percentage of each class of potential in relation to the area of the State. The studies are based on a map of soils of the RADAMBRASIL Project. Classes were defined as follows: Good, Constrained, Inappropriate. The methodology uses information contained in the map of soils. Potentially similar individuals from the perspective of their potentialities and constraints, expressed by its natural and edaphic characteristics, were divided into three groups according to your suitability for mechanized agriculture: Inappropriate, Regular and Good. Inappropriate: group of soils with severe restrictions to the development of mechanized agriculture, represented by *Gleissolos Tiomórficos*, *Organossolos*, *Neossolos Litólicos*; soils with salic and natric properties; soils with stony, rocky and eroded phases; land types (mangrove soils, rock outcroppings). Regular: group of soils with moderate restrictions for mechanized agriculture, including the *Planossolos* (except the natric ones); *Gleissolos* (except the *Tiomórficos*); *Plintossolos*; *Vertissolos*; *Espodossolos*; *Cambissolos Flúvicos*; *Neossolos* (except *Litólicos*); hydromorphic soils (suborder and large groups); soils with intermediate characteristics or not (subgroups) as the *plínticos*, *planossólicos*, *gleissólicos*, *neofluvissólicos*, *solódicos*, *lépticos* and *salinos*, *líticos*; sandy soil with textural class; soils with gravel and much gravel fractions. Good: group of soils with slight constraints for mechanized agriculture, including classes of soils with texture different of sandy (in whole soil); soils without impediment from a physical point of view (not rocky, not stony, without gravels); deep soils; not hydromorphic soils; other soils that do not comply with the previous groupings. These three groups were crossed with the *topography* resulting in the three land capability classes for mechanized farming, namely: Good: land with soils with minor restrictions, in plan and soft wavy relief; Restricted: land with soils with moderate restrictions, in wavy relief; Inappropriate: land with soils with severe restrictions, at any kind of relief.

(4071 - 1411) Generation of exposed soil composites based on Landsat imagery (1984-2014) for large regions

Uta Heiden[1]; Simone Zepp[2]; Derek Rogge[3]; Marianne Jilge[1]; Julian Zeidler[1]

DLR Oberpfaffenhofen[1]; LMU München[2]; Spectral imaging[3]

Large scale monitoring of soils in high spatial and temporal resolution is crucial to analyse soil development and to detect soil degradation. Nevertheless, monitoring large areas with a high temporal frequency is still a challenge. A promising approach is to use multitemporal Earth Observation data to increase the area of exposed soils that can be observed and to account for the temporary vegetation cover (e.g. agricultural areas). The Soil Composite Mapping Processor (SCMaP) is an operational infrastructure that been developed which makes use of Earth Observation time series imagery to generate reflectance per-pixel composite images suitable for the analyses of the spatial distribution and changes of exposed soils. The objective of this presentation is 1) to test the suitability of the SCMaP methodology across several geographical regions and 2) to present the resulting SCMaP products with an emphasis on large scale exposed soil development. First, the SCMaP was developed primarily for regions that are dominated by agriculture. The different climatic conditions, land use characteristics and agricultural practices of regions across Europe can have an influence on the vegetation index thresholds used within SCMaP to differentiate between exposed soils and other land cover types (e.g. vegetation, urban, water). The influence of climatic conditions in Europe is analysed in the North-South direction representing predominantly a climatic shift and in the East-West direction, where the climatic shift is not as dominant. The results emphasise the transferability of the SCMaP to other regions, and the needs for continental product generation. Second, the different regional products (spectral composites and additional statistical information) are compared by analysing the coverage and development of the exposed soils within the time period 1984-2014 using 5 year composites. It gives a first estimate about the development of intensively used agricultural areas across Europe. Additional statistical information related to soil use and intensity show areas, where soils are especially prone to soil erosion due the duration of exposure in the time period. In future work, the statistical results will be validated against statistical surveys of the specific regions. The composites will undergo an in-depth data quality check to prepare the reflectance composites for more detailed soil parameter analyses. A first validation concept for both product suites will be outlined.

(4506 - 2928) Geo-environments of the southern part of Sempre-Vivas National Park, Espinhaço, Minas Gerais, Brazil

Raphael Wakin de Araujo[1]; Carlos Ernesto Gonçalves Reynaud Schaefer[1]; juliana Costa Baptista Barreto[2]

Universidade Federal de Viçosa[1]; Universidade Federal de Juiz de Fora[2]

The Nacional Park of Sempre-Vivas (PARNA-SV) is located in the Espinhaço Range in the northern of Minas Gerais State, Brazil. The Park was created in December of 2002 as part of the Brazilian policy for conservation and protection of biodiversity, its landscape is essentially built on top of quartzite rocks from the Galho do Miguel Formation (Espinhaço Supergroup). In order to support the resources administration of this protected area, this study has identified, mapped and described the geo-environments, found in the southern sector of the most representative and diverse area of the PARNA-SV. For the mapping process, Rapideye images were used to stratify the geo-environments, considering the characteristics of the soils, the geomorphology and the vegetation type associated with each unit encontered in the field. Fifteen soil profiles, of the most representative soils of southern sector, were collected, described and classified in accordance to the Brazilian Soil Classification System. During the field visits, the identification *in locus* of the mean botanical families, genus and species of each unit were conducted. Fourteen geo-environments were identified and described. The mapping allowed to separate 20 different geo-environments units and its associations. The ecotonal landscape of PARNA-SV shows the coexistence of forests, grasslands and savannas in highland conditions, revealing an important characteristic of this sector of the Espinhaço Range, where the great richness and diversity of plants and environments are controlled by the geomorphology and the influence of the soil aspects. For each geo-environment mapped according to its particularities, an interpretative discussion was elaborated, in order to support the management plan for protection and conservation of PARNA-SV.

(8591 - 2528) How to address the lack of soil mapping in the semiarid Chaco, a case in Santiago del Estero, Argentina

Cristina Angueira[1]; Gustavo Cruzate[2]; Eduardo Zamora[3]; Guillermo Olmedo[4]; José Sayago[5]; Manuel Sanchez de la Orden[6]; Isabel Castillejo González[6]

INTA EEA Santiago del Estero, Santiago del Estero, Argentina[1]; INTA-CIRN, Buenos Aires, Argentina[2]; INTA EEA Manfredi, Córdoba,

Argentina[3]; INTA EEA Mendoza, Argentina[4]; Universidad Nacional de Tucumán, INGEMA, Tucumán, Argentina[5]; Universidad de Córdoba, Dept. Ingeniería Gráfica y Geomática, Córdoba, España.[6]

The semiarid Chaco is an ecosystem shared by Bolivia, Paraguay, Bolivia, Brazil and Argentina where land use change from woodland and grassland to commercial agriculture and the social conflicts have been intensive since the beginning of the 21st century. These changes and the lack of reliable soil information at suitable scales a re threatening the sustainable development of the region. In order to reduce the knowledge gap, a geopedologic survey was carried out with the application of a system approach, intense use of geomatic techniques and GIS for the management of generated information. The approach was considered an appropriate due the large area, geomorphology and soil diversity, high demand of soil mapping, limited funding and lack trained staff. The study area of 4,800 km2 (27°30' - 28°35 ' S and 63°45'-64°35' W) is in Santiago del Estero province, Argentina. Data were obtained from maps and reports, remote sensing as SRTM 90 and 30m, satellite images Landsat, CBERS and SAC-C, field observations and laboratory determinations. ArcGis 9.3, Imagine 9.3.1 and SAGA softwares were used. The survey was divided into eleven steps: compilation of background information; digital processing of remote sensing data; general survey of the area; geospatial analysis; elaboration of preliminary cartography; soil profiles description, physical-chemical laboratory data, interpretation and soil classification; control of boundaries of physiographic units; a hierarchical legend of geoforms to define soil landscape relationships; geo-referenced database of soil properties; final geopedological cartography. Map units and geopedologic legend were determined based on the integration of geoforms and soils, knowledge of landscape and soil forming factors, 176 georeferenced soil profiles, and laboratory determinations. Three main landscape units were recognized and the soils associated: (1) a fluvio-eolian Chaco plain including a megafan with Haplustolls and Torripsamments, (2) the Rio Dulce valley with Torripsamments, and (3) the alluvial migratory plain of Río Salado with Torripsamments, Ustifluvents, and Natraqualfs. The used approach helped speed up the soil information collection at appropriate scale for land use planning, and other disciplines as geostatistics, precision agriculture.

(7216 - 203) Integrating multitemporal satellite image and laboratory surface spectral data for mapping soil classes using multiple endmember spectral mixture analysis

Raúl Roberto Poppiel[1]; José Alexandre Melo Demattê[2]; Marilusa Pinto Coelho Lacerda[1]; Manuel Pereira de Oliveira Jr[1]; Caio Troula Fongaro[2]; Rodnei Rizzo[3]

FAV/University of Brasilia[1]; ESALQ/University of São Paulo[2]; CENA/University of São Paulo[3]

The Earth is under severe pressure. Long-term projections show that to ensure food security by 2050 (> 9 billion people) current production must increase by 110%. Thus, there is an urgent need to know well and assess the best soils for agriculture. Less than a third of the world has been mapped on a scale of 1:1 M or greater. In Brazil, most states have soil maps at scales of about 1:0.5 M or less. In front of these overview, data obtained by satellite and laboratory spectral sensing can help in the soil mapping and management, although many of the areas are with vegetation, straw or clouds, hindering the use of satellite images. The objective of this work was to digitally map soil classes by means of a multitemporal satellite image (MSI) of bare soil and laboratory surface spectra (SS) from 350 to 2500 nm. In a 143 km^2 study area in the Central Plateau of Brazil (Federal District), 25 soil points in three toposequences were described collecting samples for chemical and physical analyses. The soils were classified up to the 4th categorical level of the Brazilian Soil Classification System (SiBCS). SS from A horizon were registered in aboratory and used for grouping soils with similar attributes by cluster analysis. The average SS (patterns) within each one of ten clusters was calculated and were convoluted for the Landsat bands. These patterns, representative of soils of the studied area, were used to spatialize the soils in unknown locations using the MSI at the 2nd level (suborder). 19 Landsat images were selected from 1984 to 2016; the atmospheric effects were eliminated and data was transformed into surface reflectance to generate the MSI. To obtain the digital soil map (DSM), the MSI was unmixed using convoluted SS and multiple endmember spectral mixture analysis (MESMA). Posteriorly, 80 field validation points (field truths) were used to build the error matrix. The clustered soils were similar, mainly in terms of color, textural class and organic matter content. The SS unmixed 98% and 100% of the MSI (80% of bare soil) with higher than 0.691 and less than 0.025 of average endmember fraction and root mean squared error (RMSE), respectively. This good performance was achieved because the MSI presented only bare soil for modeling. The DSM presented Kappa coefficient of 78%. This work demonstrates the high potential of remote sensing techniques for soil mapping. This strategy is important for mapping large and diverse areas, such as Brazil and Africa.

(1249 - 2172) Land use and occupation of the urban sub-basins of Ilhéus, State of Bahia, Brazil

Samuel de Amaral Macedo[1]; Pedro Enrico Salamim Fonseca Spanghero[2]

Universidade Estadual de Santa Cruz[1]; Universidade Estadual de Campinas[2]

Researches related to the dynamics of land use and occupation are relevant because they help the elaboration of public policies of territorial planning, because it allows to understand the varied forms of occupation of the territories and how this influence in the natural environment. The objective of this work was to characterize land use and occupation of the urban sub-basins of Ilhéus city, state of Bahia, Brazil. Geoprocessing and Remote Sensing techniques were used in ArcGis 10.2.2 software, which enabled the digital processing of the Landsat 8 image and acquisition of the expected results. Sub-basins 1 has a population of approximately 2,221 inhabitants distributed in 1,021,045 m² (94%) of urbanized area, 10,196 m² (0.9%) of vegetation cover and 52,109 m² (4.1%) of the beach. Sub-basins 2 presents the highest area ratio for vegetation cover, with a total of 134.753 m² (92%) of its area, the other 12,037 m² (8%) are occupied by anthropized areas. Sub-basins 3 is located in the industrial district of Ilhéus city, has 432,578 m² (35%) of anthropized area, 62,106 m² (6%) of urbanized area and 713,140 m² (59%) of vegetation cover. Sub-basins 4 has 2,012 inhabitants for the area of 0.34 km, in which 58% is urbanized area and 42% of vegetation cover. Sub-basins 5 presents 166,056 m² (10%) of urbanized area, 1,484,269 m² (89%) of vegetal cover and 1% (3 083 m²) of maguezal. Sub-basins 6 has 281,696 m² (82%) of urbanized area and 61,014 m² (18%) of vegetal cover. Sub-basins 7 presents 386,927 m² (81%) of urbanized area and 87,240 m² (19%) of vegetal cover. Sub-basins 1, 4, 6 and 7 have larger urban areas and there were greater conflicts of use and occupation, mainly in permanent protection area (riparian forest and top of hill). Sub-basins 2, 3 and 5 have greater vegetation coverage and less environmental conflicts. Geoprocessing and remote sensing techniques are indispensable in studies of this nature. It is hoped that the present study will assist in more detailed surveys of land use and occupation of Ilhéus city urban watersheds.

(7591 - 1594) Local-scale soil organic carbon prediction in Southern Brazil

Diego José Gris[1]; Ricardo Simão Diniz Dalmolin[1]; Jean Michel Moura-Bueno[1]; Nicolas Augusto Rosin[1]; João Pedro Moro Flores[1]; Taciara Zborowski Horst[1]

UFSM[1]

Soil is one of the most important carbon (C) reservoirs in the environment. Depending on how it is managed, it can act as a sink or source of C to the atmosphere. In face of the current scenario of climate change, C sequestration in the soil may be one of the ways to reduce the increasing amount of CO2 in the atmosphere. Mapping soil organic carbon (SOC) is fundamental for the development of spatial information that can be used to understand how it is distributed throughout the landscape, enabling more studies that can establish the correct management in order to use soil as a sink for C. Therefore, the objective of this study was to map SOC using a prediction model based on environmental variables. SOC data consisted on 261 samples from 0-5 cm in an area of 940 ha in the Planalto region of Rio Grande do Sul, Brazil. Eleven environmental variables were used as SOC predictors, including a land use map, soil adjusted vegetation index (SAVI) derived from a 30-m Landsat 8 image, and nine terrain attributes derived from a 30-m Topodata digital elevation model: elevation, slope, LS factor, horizontal curvature, vertical curvature, terrain ruggedness index, topographic wetness index, direct insolation and diffuse insolation. SOC content was predicted for the whole area using a Boosted Regression Trees (BRT) model in R environment, adjusting model parameters for the best performance. Model accuracy was evaluated using 10-fold cross validation. SOC content in the area varied from 1.74 to 5.64 %, with the highest values in low and poorly-drained parts of the landscape and lowest values in more elevated areas where annual crops are grown. The BRT model was able to predict SOC content with moderate accuracy (R2 = 0.68, RMSE = 0.63 %, RPIQ = 1.64) and was used to produce a 30-m resolution map of SOC over the area for the 0-5 cm layer. Diffuse insolation, land use and slope were the most important variables used by the model to predict SOC content. The SOC map produced in this study might be useful for future studies that demand SOC information in this area. The procedure used to develop this study can be applied to other similar areas to produce prediction models for SOC, considering the satisfactory results achieved.

(3016 - 355) Mapping of native mate herbs in the northern plateuau of santa catarina state using gis and remote sensing techniques.

Ludmila Nascimento Machado[1]; Arcângelo Loss[1]; Denilson Dortzbach[2]; Ivan Luiz Zilli Bacic[2]

Universidade Federal de Santa Catarina - UFSC[1]; Empresa de Pesquisa Agropecuária e Extensão Rural de Santa Catarina - Epagri[2]

The Northern Plateau of Santa Catarina State (PNC) is one of the main producing regions of mate herb in Brazil. It is also one of the few regions of the country with significant native production, that is, yerba mate produced in the forest. According to the Brazilian Institute of Geography and Statistics (IBGE), while in 2010 just about 34.83% of the Brazilian yerba mate was produced in native forests, in PNC the production derived from native herbs was responsible for 89.76% of the total production. The yerba mate produced in native forest, is currently more valued than those of planted herbs, because it has a softer flavor. Usually it presents an overprice of up to 30%, thus, the product of the region has been disputed by mate industries from the south of the country and even from abroad. Important tools have been used to map the areas where mate is produced, with emphasis on GIS and remote sensing techniques. These mappings are of extreme importance for environmental planning and control, since improper use can have negative consequences on the environment and even reduce productivity. Thus, the objective of this work was to identify, classify and quantify land use and cover in PNC, with emphasis on native mate, in a total area of 1202486.2126 hectares. For this purpose, the China-Brazil satellite images Cbers-4 were used, whose spatial resolution is 5m (panchromatic).For this mapping, the images were processed in the ArcGis 10.0 software and the identification of these areas was performed by automatic interpretation in the Erdas software, with subsequent visual analysis of the images using RGB colored compositions with different bands. The results showed that 44% of the PNC area is covered by natural forest, 18% with forestry (pinnus and eucalyptus), 21% occupied with agriculture, 14% with field / pasture, 1% water body, 1% floodplain and 1 % urbanized area. Thus, it was evident that native mate can be an important stimulus for the conservation of the Mixed Ombrophilous Forest that predominates in the PNC due to its occurrence in the sub-forest and its significant economic value, which gives value to "standing" forest, contributing to the conservation of forests through traditional management of these native mate herbs. It is worth to notice that in addition to monetary value, native mate herb have a high cultural significance for local populations.

(5441 - 2606) Multi-temporal relationship between soil moisture in the root zone in *Coffea arabica* (L.) and the plant vigor obtained by images of UAV

Diego Armando Amaro da Silva[1]; Geraldo César de Oliveira[1]; Marx Leandro Naves Silva[1]; Wellington de Lima[1]; Fabio Arnaldo Pomar Avalos[1]

Universidade Federal de Lavras[1]

Brazil is the largest producer and exporter of coffee beans in the world, with the south and center-west of Minas Gerais accounting for 31% of total production. However, the lack of water at crucial moments, together with the acidic soils of the Brazilian Cerrado has been shown to be the major limiting factor of the coffee crop. In this context, this work will aim to verify the relationship between soil profile moisture (up to 80 cm) and vegetative vigor (accessed by UAV images), measured by different vegetation indices of the visible spectrum (RGB), to identify the effective depth of water absorption by the plants, thus to evaluate the plant vigor response time for moisture at different soil depths. The experiment is located in the municipality of Nazareno, MG, Brazil (7º14'2 "S, 44º33'14" W), with an average altitude of between 960 and 1,060 m, and climate Cwa (tropical of altitude), with average rainfall of 1,200 to 1,500 mm year^{-1} and average temperature between 18 and 19 ºC. The dominant vegetation of the site is a transition between Semideciduous Seasonal Forests and Cerrado biome. The experiment site has 1,920 m^2 (24 x 80 m), and belongs to the commercial area of the farm Frade. The soil was classified as a Cambissolo Háplico latossólico of clay-loamy texture for horizons A and B, with wavy topography and maximum slope of 12%. For the monitoring of soil moisture, TDR EC - 5 ECH2O sensors were installed, the readings of which will be stored in the data logger Em5b, both of the company DECAGON DEVICES ®, providing soil moisture values stored every 60 minutes. The sensors were fixed at depths of 35-40 cm, 55-60 cm, 75-80 cm, corresponding to furrow aperture depths, or three sensors around each point. The points are represented by the central plant of the line crop of each treatment,

that will be arranged forming a gride, with distances assimarated between the points. The DJI Phantom 2 Vision + quadricopter UAV will be used to collect a set of aerial images at three flight altitudes (30, 60 and 90 m) on the coffee crop, coupled with a Phantom Vision FC200 camera (resolution 4384 x 2466 cells, and 5 mm focal length) with the aid of the GPS and its waypoint navigation system, and subsequently vegetation indices using the RGB bands using ArcGIS 10.2 ®. It is expected that with this work it will be possible to define the most important root depths for water and nutrient absorption by the coffee tree, giving greater support to the regional coffee grower.

(9468 - 987) Open soil surface dynamics as a factor for efficient soil mapping based on remote sensing data

Prudnikova E.Yu.[1]; Savin I.Yu.[1]

Soil Science Institute[1]

Open surface of arable soils significantly changes during the warm season of the year. These changes occur mainly due to the influence of meteorological conditions and agricultural practices. Three-year field observations and one-year model experiment confirmed that during the vegetation season soil surface follows the same stages of transformation. From one agricultural practice to another the surface smoothing takes place, soil clods are destroyed by the agricultural machines and/or rain, in-between surface drying results in the formation of the crust separated by cracks. This process is accompanied by the accumulation of water-stable components (water-stable humus aggregates, washed sand grains or the combination of both) on the crust surface. If heavy rain interferes, the transformation cycle starts again. During this cycle spectral reflectance of the surface changes as the relative contribution of properties affecting it alters. Thus, it was founded that the spectral reflectance of the crust determined mainly by the amount and mineralogical composition of silt fraction differs from the reflectance of untransformed surface which highly depends on organic matter content. Significant differences were observed between spectral reflectance of water-stable components and mixed soil samples. Besides, the effect of sand grains on the general spectral reflectance of the open soil surface is lower than the contribution of water-stable humus aggregates. So, the spectral curve becomes more informative for the estimation of soil properties as the masking effect of organic matter decreases and the contribution of clay and silt fractions, and mineralogical composition of soil to its spectral reflectance increases. Determined in the research parts of the spectrum where the surface dynamics influence is more pronounced can be used for the development of soil surface dynamics model. The application of this model in the digital mapping of soil properties with satellite data can increase the accuracy and ensure the reliability of obtained maps. For these purposes, spectral libraries have to be created for open soil surface instead of libraries of soil samples spectrum acquired in laboratories. Additionally, as the impact of surface transformation on the relationship between spectral reflectance and soil properties varies, the possibilities of the application of the dynamics model and the accuracy of modelling results will also depend on the estimated soil characteristics.

(2409 - 1936) Predicting soil organic carbon content in farmland using Fourier transform decomposed variables

Lin Yang[1]; Min Song[2]

Nanjing University[1]; [2]

Mapping the spatial distribution of soil organic carbon has been of great interest. Most of the current soil organic carbon mapping employs natural environmental covariates. However, human activities have become an important impacting factor for soil organic carbon, especially for agricultural soils. Crop rotation impacts the amount and spatial variation of soil organic carbon, but has not been considered for mapping soil organic carbon in farmlands. In this study, we generated environmental variables indicating crop rotation using Fourier transform on HJ-1A/1B NDVI time series data, and explored the effectiveness of crop rotation type and the Fourier decomposed variables in predicting topsoil organic carbon content in farmland of a study area in Anhui province, China. Four main crop rotations were obtained through field investigation in 2010, and 68 samples were collected. One-way analysis of variance (ANOVA) for topsoil organic carbon content in the four crop rotation groups was performed. Importance of 36 environmental variables including parent lithology, climate, terrain, NDVI, crop rotation type, seven Fourier decomposed components were calculated by Random Forest. Different combinations of environmental variables were developed according to the variable importance for predicting topsoil organic carbon content using Random Forest. A cross validation was conducted to evaluate the prediction accuracies. The results showed that crop rotation types had significant impacts on topsoil organic carbon content. Crop rotation type, the 2nd harmonic amplitude and the 3rd harmonic phase are among the most important environmental variables for topsoil SOC in our study, and are more important than single NDVI time series image. Adding crop rotation information into the natural environmental variables improved the SOC prediction accuracy. Using the three variables indicating crop rotation obtained a similar accuracy with using only those important natural environmental variables, which shows the strong prediction power of crop rotation information. This study demonstrates the usefulness of human activities in digital soil mapping and thus indicates the necessity for human activity factors in digital soil mapping studies.

(1257 - 1066) Quantifying forfeited wheat yield due to soil sodicity in high, moderate and low rainfall conditions in the northern grains region of Australia

Yunru Lai[1]; Matthew Pringle[2]; Peter Kopittke[1]; Neal Menzies[1]; Thomas Orton[3]; Yash Dang[1]

The University of Queensland[1]; Queensland Department of Environment and Science[2]; The University of Queensland & Queensland Department of Environment and Science[3]

Soil sodicity is a major constraint to wheat production in Australia. Obtaining an estimate of the impact of sodicity on wheat has historically been difficult due to the interactions of climate, management and disease. In this study, we have estimated the forfeited wheat yield due to sodicity in the northern grain-growing region of Australia (referred to herein as “NGR”). We considered three different approaches for estimation: (i) “calculate-then-model”; (ii) “model-then-calculate”; and, (iii) “no-interpolation”. In (i) we used an empirical yield-prediction model (linking Landsat satellite imagery to limited yield-monitored data) to estimate wheat yield over 17 years (2000-2016) at available soil-sample locations. The predicted yield was then used as the response variable, to model yield as a function of soil properties, climate, and farm-management practices. We estimated the potential yield at each data location assuming improved sodicity conditions and different rainfall scenarios. The forfeited yield at soil-sample locations was derived and subsequently interpolated across the study region. In approach (ii) we used the same yield-prediction model to first estimate wheat yield for NGR. We regarded consistently low yielding regions as limited by soil constraints. The

sodicity-related soil attributes were interpolated to the same raster grid as yield. Foregone yield was then estimated by comparing the yield and soil properties of the constrained areas to those of the unconstrained areas. Approach (iii) served as a quality-assurance by pairing actual yield-monitored data with soil data at sample locations, to investigate the direct impact of sodicity on wheat yield. This approach, however, is limited by the number of locations, where both yield-monitored data and soil samples were available. We compared the three approaches to determine if they were in reasonable agreement, and if the methods gave fair assessments of uncertainty. The simplicity of (i) means that it might be favoured when a large number of soil samples with multiple sodicity-related attributes are available. However, when the sample locations containing all the relevant attributes are limited, yet the total number of soil samples is large, then (ii) may be a useful alternative. This is particularly helpful when financial constraints do not allow collection of new soil samples, but data from past soil-sampling campaigns are available.

(7149 - 2865) Reflectance spectroscopy applied to identification of pedological attributes: Chernosols of the Bahian semi-arid in question

Deorgia Tayane Mendes de Souza[1]; Gustavo de M. M. Baptista[1]; Washington de Jesus Sant'Anna da Franca Rocha2[2]
UnB[1]; UEFS[2]

The study of soils associated with analytical techniques enhances the rational management and the forms of adequate appropriation for this feature. Being an object of study of high complexity, since it involves several natural systems in its formation, this approach constitutes a technological challenge. Within the instrumental alternatives, reflectance spectroscopy applied to soil science has been reaching prominence among the researchers for producing accurate analyzes at low cost and with high potential of identification of pedological attributes. Soils, depending on their composition, have varied spectral responses and each target has a distinct spectral signature. The chernosols present peculiar attributes that determine their classification: the horizon A Chernozemic and / or incipient B with predominance of organic matter and a carbonic or calcium C horizon, are characteristics that can be identified by reflectance spectroscopy. The present work aims to analyze the spectral responses of Chernosols with different source materials and to evaluate the capacity of separation by pedological attributes using multivariate analysis. Three profiles were described in the field located in the municipalities of Juazeiro, Curaçá and Angico, state of Bahia / Brazil, where the semi - arid climate predominates. The spectral curves of the profiles in the C horizon in the SWIR range showed spectral similarity, due to the predominance of calcite in the samples. The horizons A and Bi of the Juazeiro profile exhibit a concentration of the organic matter, and the absorption of minerals 2: 1 can be identified in the VNIR range and in the SWIR range. However, the profiles of Curaçá and Angico emphasize a greater depth of feature in the VNIR range due to the concentration of iron oxides. It was applied a principal component analysis - ACP, using 15 reflectance bands of 125nm in width, covering the range of 400 to 2400nm. The results of the ACPs were satisfactory since occurred a clustering of the horizons C of all profiles, a separation between the horizons A due to the presence of organic matter and a grouping between the horizons A and Bi between the profiles, being able to affirm that the ACPs separated the spectra by mineralogy and by profiles.

(3570 - 637) Soil Conditioners in Land Use and Land Cover in the Lagoa Formosa county, Minas Gerais, Brazil

Ligia Faria Tavares de Souza[1]; Liovando Marciano da Costa[1]; Elpídio Inácio Fernandes Filho[1]
Universidade Federal de Viçosa[1]

Lagoa Formosa county has three soil classes directly correlated to the pattern of land use and land cover. This study aims to show this influence crossing information from soil map obtained from IBGE and land use and land cover map generated with Random Forest algorithm in the R software. Pasture is the most expressive land use in the region, responsible for 53.7% of the total area. Agriculture occupies 33.13%, 8.05% is composed of riparian forests and 3.40% shows exposed soil. The remainder corresponds to lakes and urban area. From the soil classes, we have Red Latosols corresponding to 48.48% of the county area, followed by Haplic Cambisols with 27.30%, and Litholic Neosols occupy 24. Red-Yellow Latosols correspond to the remaining 0.22% but it is irrelevant to explain land use patterns in the area. Pasture and agriculture are in almost 90% of the total area of Red Latosols, where 21.51% is cultivated. Pasture prevails because of relief conditions. From the total of exposed soil in the county, only 0.76% are in Latosol area. These deep soils developed over Tertiary and Quaternary deposits in plain terrain, which explains its depth, water storage capacity and vegetation development. In Cambisols area, 60% correspond to pasture. Again, the relief associated with this soil explains the predominance of this land use. The exposed soil area is bigger on those soils, corresponding to 1.07%, and it is a consequence of the most common land use. Exposed soil in Neosols occupies 1.57% of the area of the county. Vegetation on this soil is underdeveloped due to its small depth. This is related to the mudstone deposited horizontally, making water infiltration difficult and, therefore, slows pedogenesis. We can conclude that Latosols are primarily used for agriculture, and Cambisols and Neosols are used for pasture. Erosion prevails in Neosols as a result of the steep relief and small depth of those soils. Latosols developed in plain areas less disturbed by geological events, such as the magmatism in the Cretaceous. The Cambisols are on the edge of the relief and its structure is friable and less resistant to erosion. Neosols also show less resistance to erosion due to the lack of development of those soils.
Keywords: R software; geology; erosion

(1570 - 1609) Soil use in the hydrografic basin of Ribeirão Jataizinho, PR and implications for erosion processes.

Rosana Kostecki de Lima[1]; Pedro Rodolfo Siqueira Vendrame[2]; Fernanda Leite Ribeiro[2]; William Renan Piva dos Santos[3]; Rafael Calore Nardini[2]
Universdade Estadual de Londrina[1]; Universidade Estadual de Londrina[2]; Universidade Federal do Paraná-Setor Palotina[3]

The hydrografic basin of Ribeirão Jataizinho is located in the north of Paraná State of, southern Brazil. Its area is approximately 11,138.14 hectares (or 111.38 km²), comprised between the geographical coordinates 23º 14 '00' 'at 23º 20' 00 '' latitude S, and 51º 01 '27 "' at 50º 50 ' 00 "W longitude. The basin is inserted in an area of intense agricultural activity. There are numerous problems related to environmental degradation, including the intensive and inadequate use of the soil by agriculture, removal of native forest for livestock activities in inappropriate areas, that cause the acceleration of erosion processes and consequently the silting of rivers . The objective of this work was to identify and measure current land use, as well as to form a database to serve as a diagnostic tool for the hydrografic basin of Ribeirão Jataizinho. The Geographic Information System- IDRISI Selva, to distinguish land use through the unsupervised Isoclust classification from satellite images provided by INPE with the support of Google Earth for the visual interpretation of vegetation cover areas. Also used were images of the LANDSAT 5 satellite, 2011 pass and IBGE

topographic charts. The classes identified were native forest (16.5 km²), temporary crop (64.64 km^2), pasture (18.06 km^2) urban mesh (2.14 km^2), reforestation (0.4 km^2) fruticulture (2,0km^2), lakes, dams and related (0.12 km^2). It was observed that 64% of the total area of the basin is used for temporary crops, often associated with the intensive and degrading use of the soil. Regarding the soil classes, it was possible to identify the presence of Neossolo Regolítico eutrófico, Nitossolo Vermelho eutroférrico, Latossolo Vermelho eutroférrico, e Gleissolo Háplico (Bhering & Santos, 2008). The presence of less developed soil classes (Neosols) and hydromorphs (Gleissolos) suggest caution in the use of these soils for temporary crops. In this way, it is concluded that the studied basin deserves attention in relation to the use of the soils and the information to the producers is of paramount importance to mitigate the degradation of those soils and other environmental damages.

(3358 - 254) Spatial relationship between soybean crop and soil properties in a Colombian oxisol

Sergio Tovar-Hernandez[1]; Loren J. Sanchez-Cuesta[1]; Mauricio Castro-Franco[2]
Grupo de Investigación en Agricultura de Precisión, Ingeniería Agronómica, Universidad de los Llanos[1]; Consejo Nacional de Investigaciones Científicas y Técnicas CONICET[2]

Determine the variability of the soil within agriculture fields facilitates the implementation of site-specific management of agricultural inputs. In this report two hypotheses were tested: (*i)* the spatial variability of soil properties within agriculture fields in a Colombian Oxisols determines the spatial yield pattern in soybean crop and (*ii)* digital soil mapping (DSM) techniques allow the delimitation of potentials zones for precision agriculture. The study was carried out in three agricultural fields located in Puerto Gaitan, Meta (Lat: 4°19'; Lon: -71°58') from January to August 2016. The soil is a typical Oxisol with high acid levels and low organic matter contents. The terrain is flat with maximum slope of 3-4%. DSM techniques were applied through soil spectral indices based on a satellite image Sentinel 2A. The used indices were: (i) Clay-Mineral Rate (CMR), (ii) Iron-Mineral Rate (IMR) and (iii) Iron-Oxides Rate (IOR) to delimitate zones. A sampling scheme of 40 subsampled at 0-30 and 30-50 cm depth were implemented using conditioned Latin hypercube (cLH) within each field. Texture, CEC, pH, OC, N, P, K, Mg, Ca, Al and Na were determined. Also, Interception of radiation (IR), Leaf Area Index (LAI), Dry Matter x m^{-2} (DM), Number of nodules x m^{-2} (NN), Weight of nodules x m^{-2} (WN), Numbers of grains x m^{-2} (NG) Weight of grains Weight x m^{-2} (WG) were measured during V6, R2, R6 and R8 phenology stages. A classification of importance of soil properties was established using Random Forest. Finally, the zone delimitation was validating by soil type for soil properties and soybean yield components using a mixed lineal model. The results suggest that the soil spectral indices capture a high variability in each field. Adjacent fields do not present similar spatial patterns. cLH was effective to capture the spatial variability and distribution of all spectral indices. Crop properties such as WN and NN were highly influenced by N and OC. Chemical soil properties such as Al, CEC and pH had more importance for NG, WG and DM. IMR was more effective to determine spatial patterns of soil properties. IMR present proportionally inverse spatial relations with IOR. Two results could stand out: (*i)* there is a considerable vertical and horizontal variability of chemical and physical soil properties between fields and depth and (*ii*) our results support the implementation of zones to apply a variable management of lime amendments and soybean crop fertilization.

(6002 - 2882) Spatio-temporal Land Use Dynamics and Soil Organic Carbon in Swiss Agroecosystems

Felix Stumpf[1]; Armin Keller[1]; Karsten Schmidt[2]; Andreas Mayr[3]; Andreas Gubler[1]; Michael Schaepman[4]
Agroscope - Swiss Soil Monitoring Network[1]; University of Tuebingen, Germany[2]; University of Innsbruck, Austria[3]; University of Zuerich, Switzerland[4]

Land use change strongly affects soil organic carbon (SOC), which is a critical driving force for soil quality and soil services. However, the influence of detailed land use dynamics on SOC remains an active research field. We investigated the impact of long-term grass-/cropland conversion dynamics on SOC for the Swiss agroecosystem (8`500 km^2). In Switzerland multi-temporal SOC observations are sparse, while the spatio-temporal resolution of available land use data is inadequate to capture small structured and dynamic land use. Thus, we stratified one-time SOC observations of two periods ($n_{1995-1999}$ = 1096; $n_{2011-2015}$ = 502) into typical land use classes of grass-/cropland conversion regimes to analyze states and trends of SOC. First, based on spectral imagery and auxiliary variables, we established a Random Forest classifier to detect annual grass-/cropland distributions in a spatial resolution of 30 x 30 m for 2000 to 2015. Second, we used the annual land use maps to derive classes of typical land use dynamics based on a pattern description of conversion regimes. Third, we comparatively assessed the SOC covariate importance (IMP) and SOC sample representation of land use dynamics using terrain and climate covariates. Subsequently, we statistically analyzed SOC across land use dynamics and two periods. The land use classifier shows an Overall Accuracy of 86%, while the annual land use maps deviate by 6%-11% from census data. 46% of the farmland underlies frequent grass-/cropland conversions. The SOC covariate importance of land use dynamics is increased by at least 2.4 times compared to the SOC covariates. The SOC observations consistently represent land use dynamics across SOC covariates. In both periods, SOC increased as the grassland share within the land use regimes increased. The mean SOC for permanent grasslands is 35 g kg^{-1} and 17 g kg^{-1} for permanent croplands. Areas of land use conversions where grassland is dominant show increased SOC (29-30 g kg^{-1}) compared to areas where cropland was dominant (23-25 g kg^{-1}). The mean differences of SOC between the periods and classes are statistically not significant except for permanent cropland, for which the SOC is decreased by 5.2 g kg^{-1}.

(9777 - 296) Spectral attributes selection based on data mining for bare soil detection in remote sensing images

Marilusa Pinto Coelho Lacerda[1]; Raul Roberto Poppiel[1]; José Alexandre Melo Demattê[2]
University of Brasilia[1]; University of São Paulo[2]

The soils, as the main source of energy that supports earth life, are considered a non-renewable and increasingly scarce resource. Rapid population development and growth and mismanagement overburden soil capacity resulting in their degradation. To conserve of soils, they needs to be known and mapped, at an appropriate scale, to guide public policies, management and planning. Therefore, it is

necessary to develop technologies that provide quality information fast at low cost. The objective of this work was to define a methodology of data mining (DM) using decision tree in WEKA program for bare soil (BS) detection in remote sensing images, aiming at aiding the digital soil mapping (DSM). An image acquired on August 22, 2016, by OLI on Landsat 8 satellite, orbit 221 point 71, over the Cerrado (brazilian savanna) region, was transformed to surface reflectance. In addition to the seven OLI bands, images were highlighted by calculation of spectral indexes (NDVI, EVI and MIDII), differences between bands (3-2 and 4-3), Principal Component Analysis (PCA) and spectral mixing models (MESMA) in ENVI program. From a representative area of the image, samples of defined classes were collected and imported into WEKA for DM. The J48 was the most promising WEKA algorithm tested, since it yielded a decision tree with high Kappa (99%) and structure compatible with ENVI. These rules (threshold values) were extracted and applied (extrapolated) in the complete scene, using the ENVI decision tree classifier. From this classified image, were masked out all objects distinct to soil for obtaining the BS satellite image. For the set conditions, were selected by J48 algorithm to separate BS from other objects the next spectral attributes: OLI bands 1, 3, 5, 6 and 7, PCA1, difference between bands (3-2), NDVI, EVI and MIDII. This resulted in a decision tree trained by 14 specific rules for BS detection in ENVI. The final image yielded 30.8% of BS areas, whose spectra and soil line were in agreement with the standards of bibliographies. In this way, the use of DM improved time spent by eliminating subjectivity in the decision rules implementation, commonly generated by the analyst's knowledge. The proposed method showed good separation between BS and other objects in the image, improving its quality in terms of the representativeness of BS, when compared to other techniques. Thus, DM can be used as a powerful tool in DSM.

(1452 - 617) Strategies on Pedological Mapping: from traditional to digital

Fellipe Alcantara de Oliveira Mello[1]; José Alexandre Mello Demattê[1]; Caio Troula Fongaro[1]; José Lucas Safanelli[1]; Wanderson Souza Mendes[1]

Escola Superior de Agricultura Luiz de Queiroz - USP/ESALQ[1]

Soil maps have been more required as the need for agriculture improvement and environmental conservation increases. Assuming that a high detailed soil map is a difficult and expensive product to construct, technology took on the role of providing information to identify soil characteristics. In the last decade, the main goal of pedology was to use these technology advances to make the best soil map. Soil science has been developing strategies to achieve a better way to identify soil attributes since there is not many high detailed soil maps in the world. This work aims to create and present some strategies, since traditional until digital, to reach a high detail soil map. The study area is located in the state of São Paulo, Brazil (2500 ha) and six parent materials. Through geoprocessing, we obtained the drainage patterns, geological map, elevation model, bare soil satellite image and a geomorphometric map. We performed several soil maps with different techniques for comparison as follows (S=strategies). Using a legacy map constructed by traditional technique, the S1 (1:10.000) and S2 (1:50.000) were used as base validation. A detailed drainage network using stereo pair orthophotos with digital 3D visualization served as basis to an empirical/tacit mapping method on photopedology (S3). S4 map was based on bare soil satellite image. S5 was constructed from geomorphometric information. S6 used relief models to identify soils and S7 overlapped all of them and reached a unique soil map. We evaluated the number of polygons related with soil mapping units to identify witch one indicated the best delineation and umber of soil units. The S1 and S2 maps were used as base for validation. S3 reached the higher number of polygons. S4 indicated less number, but created polygons on places not indicated in S3. S5 created an extremely high number of polygons, but not related with soil map units. S6 presented a relatively important number of polygons and similar to S3. S7 reached the best map. Indeed, photopedology indicated polygons where could not see differences on colors due to vegetation. At this moment, bare soil image gave its assistance as also indicated the quantified soil texture. Relief gave more strength while complemented variation on relief not detected by photopedology. Thus, the best technique is to integrate all information related with every information from field, since relief until color, shapes and features.

(8045 - 858) Surface soil moisture: point measurements, tower and satellite – voyage through the scales

Mateusz Lukowski[1]; Radoslaw Szlazak[1]; Lukasz Gluba[1]; Edyta Rojek[1]; Jan Slominski[2]; Jerzy Usowicz[3]; Boguslaw Usowicz[1]

Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland[1]; Space Research Centre, Polish Academy of Sciences, Warsaw, Poland[2]; Torun Centre of Astronomy of the Nicolaus Copernicus University, Poland[3]

The water contained in the soil is one of the most important components of the environment. Without it, any growth or development of plants would be impossible. Water in soil affects the dynamics of the energy and mass transfer for a very wide range of spatial and temporal scales. The measure that quantifies water content is called soil moisture. In this study, the examined test-site was Bubnow wetland in Poland (Europe), chosen due to its nearly undisturbed hydrological conditions and importance of wetlands in climate change issues. Soil moisture data from three sources, covering almost 2 years, were investigated. Starting from point-scale, the soil moisture has been measured using hand-held TDR devices and then extrapolated via geostatistical methods. To catch the broader context, the ELBARA (European Space Agency L-band Radiometer), mounted on a 6.5-meters-high tower was used. ELBARA measures brightness temperatures at 1.4 GHz, the frequency that is sensitive to the presence of water and may be transformed into the soil moisture using L-MEB model. In order to proceed with an increase in scale size and find which land-cover type on Bubnow may be treated as representative for the entire area, the brightness temperatures measured by ELBARA were compared with Soil Moisture and Ocean Salinity (SMOS) satellite. Despite the difference between single ELBARA footprint area (25 m^2) and SMOS DGG pixel (approx. 200 km^2) is huge, the comparison of the time-series shown some important relations. Firstly, it turned out, that only a few footprints decreased in brightness temperatures after rain, what is characteristic for strong precipitation interception effects. Analyses revealed that the lowest ELBARA-SMOS agreement is for the cultivated field, which may be caused by modification of this area through plant cultivation, mowing and ploughing. Wetland, which according to the literature is often problematic land-cover, also in the Bubnow case shows only a partial agreement. On the meadow, the best ELBARA-SMOS match is observed, what may be interpreted as a consequence of meadow-agricultural land cover domination in the examined SMOS pixel. The general conclusion is that the soil moisture moderately influence measured brightness temperatures, which are also governed by many other factors. Nevertheless, even locally it was possible to specify a representative land-cover for the whole region corresponding to the SMOS map pixel.

(2745 - 2784) Temporal and spatial expression of water deficit evaluated through SPI and SPEI indices in mediterranean central Chile

Elizabeth Ramírez[1]; Mauricio Galleguillos[2]; Oscar Seguel[1]

Universidad de Chile, Facultad de Ciencias Agronómicas[1]; Universidad de Chile, Facultad de Ciencias Agronómicas. Centro de Estudios del Clima y la Resiliencia CR2[2]

Considering the effect of climatic change on potential crop production, in this study we evaluated the water deficit in four Communes of Central Chile (1700 km2 in O'Higgins Region, ≈500 mm precipitation and 7-8 dry months in summer), using two dryness indices: SPI and SPEI, based on the temporal distribution of precipitation and precipitation+potential evapotranspiration, respectively. The indices were calculated (each 3 and 12 months) from CHIRPS and MODIS satellital products, and validated with meteorological stations databases, using the period of 1985-2015 and 2000-2015 for SPI and SPEI, respectively. Then we calculated for both indices the magnitude of drought events and the sensibility; finally the results were separated according to soil cover and soil properties. Both indices are useful to understand the climatic variability of the study site, with the maximum dryness in 1999-2000 season (SPI ≈ 4.0). The validation was carried out through the Pearson correlation coefficient (r), shown better results when 12 months analysis are performed compared to 3 months analysis, and the higher spatial sensibility was found with SPEI index. High variability and no differences between annual and perennial crops were found, but forest plantations shown a high stability in time, while bare soil shown the lowest indices of dryness. SPI index was sensible to soil properties, with the highest dryness magnitude in shallows soils and lowest dryness magnitude as the clay content increased; SPEI was no sensible to soil properties. In the future, we will continue monitoring the dryness indices in a higher surface, looking for a better spatial sensibility for soil cover depending on new soil attributes.

Keywords: Water deficit, SPEI, SPI

(4854 - 713) The use of the spiking methodology for the improvement of global prediction models for total aluminium, iron and silica contenent in soils from Paraná State

Aline de Carvallho Gasparotto[1]; Marcos Rafael Nanni[1]; Everson Cezar[1]; Franciele Romagnoli[1]

Universidade Estadual de Maringá[1]

The conventional chemical analysis to obtain total Fe_2O_3, Al_2O_3 and SiO_2 levels of soils modifies the system and the balance between the phases of the soil, not considering its complexity, besides being expensive, time consuming and dangerous to the handler, by the use of acids for the extraction of chemical elements. The use of remote sensing, such as spectroradiometry to generate predictions of these total soil contents, don´t modify the soil system, takes into account the complexity, and is a safe, fast and inexpensive technique. Predictions of chemical attributes by spectroradiometry provide better predictions on a local scale than on a global scale, due to the homogeneity of data and soils. Thus, in this work, the use of vis/NIR/SWIR spectrodiometry in the prediction of total contents of Fe_2O_3, Al_2O_3 and SiO_2 of the soils at a local scale (Lobato-PR municipality) and at a global scale (Paraná-BR state), the use of local samples inserted in the global set to improve global predictions was also studied. Spiking numbers (10, 20, 40 local samples), spiking site (along, center, periphery of PCA and cluster) and set weight (0, 5, 10 and 20 copies). In addition to the overall set size with 100% of the samples (n = 650), 50% of the samples (n = 325) and 25% of the samples (n = 162), as alternative methods to improve the global predictions and to generate predictions similar to those of local scale. Thus enabling its use on a global scale without losing the quality of the model, enabling an improvement in soil surveys in developing countries, which are still insufficient. The ASD FieldSpec 3 was used for acquisition of soil reflectance, the Unscrambler software was used to perform calibrations and spiking recalibrations for the total Fe_2O_3, Al_2O_3 and SiO_2 by PLSR and the Sisvar Software with the Scott-Knott test, to study the differentiation of the qualities of the models found. In the prediction of the total SiO_2 and Al_2O_3 contents, the spiking methodology for all global sets (100%, 50% and 25%) improved prediction of the models, but weren´t better or similar to the local set models, the size of the overall initial set had little influence on the results found. In order to predict the total Fe_2O_3 levels, the use of the spiking methodology for all global sets improved the prediction models providing results similar to the models of the local set, the best spiking strategy found was with the use of 40 samples selected at the center of the PCA (10 copies).

(3292 - 2287) Unmanned Aerial System (UAS) as a tool to quantify conventional and conservation tillage crop treatment effects.

Murilo Maeda[1]; Akash Ashapure[2]; Jinha Jung[2]; Andrea Maeda[1]; Junho Yeom[2]; Anjin Chang[2]; Juan Landivar[1]

Texas A&M Agrilife Research, 10345 Hwy 44, Corpus Christi ,TX, 78406, USA[1]; Texas A&M University-Corpus Christi, 6300 Ocean Dr., Corpus Christi, TX, 78412, USA[2]

Recent advances in Unmanned Aerial System (UAS) and sensor technology are now making it possible to accurately assess overall crop growth and health status with fine spatial and high temporal resolutions previously unobtainable from traditional remote sensing platforms, at a relatively low cost. When properly equipped with remote sensors, UAS enable fast and accurate data collection throughout the growing season. The combination of these technologies (UAS + sensors) with state-of-the-art image processing algorithms, visualization techniques, and geospatial data analysis offers an innovative opportunity for the development of high-throughput phenotyping system and precision agriculture applications. Here we present a novel approach to use multi-temporal UAS data for the comparison of conventional and conservation tillage treatment effects on cotton production. The parameters considered for the comparison were: canopy height, canopy cover, canopy volume, and Normalized Difference Vegetation Index (NDVI). Measurements were extracted grid-wise from high resolution UAS data captured during the growing season. A one-tailed test hypothesis was used to compare tillage treatments. Experimental results indicate that there is a significant treatment effect on the plants' responses, for all dates compared. Overall, UAS-based measurements demonstrated that conservation tillage significantly improved plant growth, development, and yield in this study.

(2352 - 429) Use of Lidar derived Digital Elevation Maps and Principal Component Regression to Scale up Topographic Models of Soil Properties

Greg McCarty[1]; Xia Li[2]

USDA ARS Hydrology & Remote Sensing Laboratory[1]; Unviversity of

Maryland, Geography Department[2]

Landscape processes are critical components of soil formation and are important determinants of the distribution of soil properties on the earth surface. Thus, strong topographic relationships to observed distributions are expected. The recent availability of large-scale, high-resolution topographic information through application of a rapidly evolving Lidar technology holds promise that useful large-scale maps of soil properties can be routinely derived from topographic models. We explored the use of Principal Components (PCs) for characterizing the topography of land surfaces and the use of Principal Component Regression (PCR) to scale-up soil property prediction models at watershed or regional scales. Evidence shows that PCR models are more robust than ordinary multi-parameter regressions models for scaling up topographic prediction models at larger settings. This evidence supports the hypothesis that PCR models are better tuned to a larger setting because the underlying PCs that are used can be directly derived from analysis of the topography of the larger setting. Additionally, use of PCs removes the often-strong collinearity between individual topographic parameters and the associated dimensionality reduction diminishes the risk of overfitting the prediction model. This work advocates for a new approach for sampling and modeling of soil properties at various scales.

(9285 - 1236) Using multi-temporal polarimetric Sentinel-1 data to monitor soil moisture over winter crops

Miguel Eduardo Zabala Rodrgiuez[1]; Marisa Domenech[2]; Maria Jimena Berriollo[2]; Mauricio Castro-Franco[3]

UNILLANOS[1]; INTA[2]; CONICET[3]

The implementation of site-specific crop management demand techniques that allow an accurate spatio-temporal monitoring of topsoil moisture at field scale. The aim of this study was to develop and test an approach to improve the estimation of surface soil moisture over winter crops based on multi-temporal polarimetric Sentinel-1 data. Two agricultural fields located in the Argentine Pampas (Long 60º 14,264´W; Lat 38º 19,178´S) were used for this study. Wheat and oat were sown in field 1 and 2, respectively. ECa and elevation were previously determined using VERIS 3100 soil sensor and DGPS. Based on this information, two standard digital soil mapping (DSM) techniques were applied. First, a coupled spatial Principal Components and Fuzzy K-means (sPCA-FK) was used to delimitate three homogeneous zones per field. Second, 11-sampling points were determined per field using conditioned Latin Hypercube (cLHS). Ten Sentinel-1 images were acquired during the period August-December 2017 through crop growing season. All images were in dual-polarization modes (VH and VV) and were calibrated. Also, VH/VV rate was calculated. The coefficient of variation (CV) and the mean of radar backscatter within each field were calculated for all polarization modes along time serie. Volumetric soil moisture (VSM) content at 0-5, 5-10 and 10-15 cm depth was measured for each sampling point, simultaneously with Sentinel-1 image acquisition. All measurements were coupled with zone delimitation within field. A lineal model per zone between polarization modes and VSM was adjusted and validated. The results suggest that the zone delimitation was efficient to define the differences in the CV and mean radar backscatter for both fields. Also, cLHS was efficient to establsih representative sampling points. Lineal regression model results suggest that previous zone delimitation and the use of cHLS could improve the prediction of VSM. In this work, we demonstrated that the approach proposed was effective to improve the estimation of VSM based on multi-temporal polarimetric Sentinel-1 data.

(2115 - 1010) Attributes of Planossolos in different physiographic regions of Rio Grande do Sul State, Brazil.

Paulo César do Nascimento[1]; Luis Fernando da Silva[1]; Ana Paula Barbosa Lima[2]

Universidade Federal do Rio Grande do Sul[1]; Universidade federal do Rio Grnade do Sul[2]

Planossolos constitute a soil class established in the Brazilian System of Soil Classification. The main diagnostic attributes are the occurrence of the diagnostic subsurface horizon “B plânico”, with characteristics such as influence of aquic moisture conditions and abrupt transition (especially abrupt textural change) in relation to surface horizons. In the other hand, they show great variability in relation to morphological, physical, chemical and mineralogical attributes. In Rio Grande do Sul State (RS), southern of Brazil, these soils comprise about 12% of the territory, with widespread occurrence in different regions, and economic and environmental importance. The aim of this study is to characterize and evaluate the influence of the environment of occurrence in Planossolos of four different physiographic regions of RS. Regions chosen were the alluvial plain of “Jacuí” river -JAC (east), alluvial plain of the “Vacacaí” river - VAC (center), the North Coastal region - NOC (northeast) and “Serra do Sudeste”- SSU (southeast) for the prospection, description and sampling of soil profiles. It were chosen three profiles in each region, apart one profile from other 500 to 5000 m. After morphological description and collection of samples of the main pedogenic horizons, samples were submitted through analysis of pH in water, elements contents and active and potential acidity, allowing determining cationic exchange capacity (CEC) and bases saturation (V). It were also determined granulometry (clay dispersed in water and total clay, with calculation of degree of flocculation); and levels of iron (Fe), aluminum (Al) and silicon (Si) in oxidic forms, extracted by means of sulfuric attack. For this study, we considered, in each profile, results obtained in “B plânico” subsurface horizons, specifically in subhorizon of greater thickness, to avoid the influence of soils use and management. The results indicate variations between the environments, such as higher levels of clay, iron and cation exchange capacity in JAC profiles; higher bases saturation in VAC profiles; while NOC profiles showed lower contents of clay and occurrence of the B horizon in greater depth. Results analysis by means of multivariate analysis will be performed in next steps of the work, allowing determining in more detail the differences between Planossolos of different regions occurrence.

(1160 - 1448) Change of soil pH in a long-term experiment of Detritus Input and Removal Treatment

Katalin Juhos[1]; István Fekete[1]; Zsolt Kotroczó[1]

Department of Soil Science and Water Management, Szent Istvan University[1]

Climate change affects both the productions of detritus and soil moisture and temperature as well. These parameters alter the physical, chemical and biological properties of soils. We examined how to change the soil pH in the Detritus Input and Removal

Treatment sites a decadal time scale. The experimental site is located North Hungary at 320-340 m altitude (N 47°55' E 20°26'). According to the FAO World Reference Base, the soils are Luvisols. The site has Quercetum petraeae-cerris community. The permanent plots were established in November 2000. Six treatments were established: Double Litter, Double Wood, Control, No Litter, No Roots, No Inputs. Each treatment plots is 7m×7m (49m2), and each plot is in three replicates. During the long-term experiment, the pH was monitored seasonally at 0-15 cm depth of soils. In several years, soil samples of the depth of 0-5, 5-15 and 15-30 cm were analyzed as well. The pH was measured in a 1:2,5 soil/H2O mixture. The variance analysis (Tukey's range test) show that the soil pH of no litter (mean pH 5.30), no roots (mean pH 5.36) and no inputs (mean pH 5.36) treatments are significantly ($p<0.05$) lower than that of the control (mean pH 5.67). There is no significant difference in soil pH between double wood (mean pH 5.70) and control plots. Significantly the highest pH was measured for double litter treatment (mean pH 5.99). The pH at 0-5 cm soil layer in the double litter, double wood treatments and control are significantly higher than in deeper soil layers. This difference cannot be measured in the litter removal plots. Soil pH decreased in the litter removal plots presumably because litter removals reduced Ca2+ and Mg2+ inputs. The decreased soil cation content and decreased soil organic matter content decreased soil buffering capacity in the top layer, making soils less able to neutralize acidic substances from decomposition. Increased detrital inputs in the double litter and double wood treatments increased soil organic matter, Ca2+ and Mg2+ input, which resulted in a higher soil buffering capacity and soil pH. The seasonal change in the pH follows the rate of litter decomposition.

(4222 - 589) Clay and iron profiles of E, G, soft plinthic B, and prismacutanic B horizons described during the land type survey of South Africa

A. Stolk[1]; C.W. van Huyssteen[1]

University of the Free State[1]

Humans classify their environment, including soils. With soil classification the challenge is, however, to consistently differentiate between soils. This study was therefore initiated to ascertain to what extent pedologists succeeded in differentiating between E, G, soft plinthic B, and prismacutanic B horizons during the land type survey of South Africa. A total of 1181 soil profiles, comprising 299 Sterkspruit, 331 Estcourt, 49 Katspuit, 257 Kroonstad, 103 Westleigh, and 142 Longlands soils were extracted from the land type data base and used in the analysis. Based on the analysis, we propose the following criteria be used to quantitatively differentiate between the studied horizons: E horizons have <1.0% Fe and <16% clay; with practically no change in either Fe or clay content from the overlying horizon. Soft plinthic B horizons have ≥1.0% Fe and <25% clay; the clay increase from the overlying horizon is >1.5 times. G horizons have ≥1.0% Fe and >25% clay; the clay increase from the overlying horizon is >1.0. Prismacutanic B horizons have ≥1.0% Fe and >25% clay; the clay increase from the overlying horizon is >2.5.

(4025 - 397) Consequences of land use change for soils in peri-urban environments.

Kalinina Olga[1]; Dolgikh Andrey[2]; Goryachkin Sergey[2]; Novák, Tibor József[3]; Giani Luise[1]

CvO University Oldenburg, Germany[1]; Institute of Geography, Russian Academy of Sciences, Russia[2]; University of Debrecen, Hungary[3]

Urban areas are likely to increase worldwide due to a number of factors such as economic growth, population increase, rising living standards, availability of cheap agricultural land, inner city problems, increased wealth per household, and enhanced personal mobility. Since the mid-1950s, the total surface area of European cities has expanded on average by 78 % while the population has grown by just 33 %. An analysis at the 1-km^2 grid level shows that the most pronounced sprawl in peri-urban areas is in wide circles around city centers, along large transport corridors and along many coastlines. About 80 % of newly developed urban land consists of settlement areas. The majority of newly developed urban land was previously used for agriculture. The relative contribution of agricultural land to uptake by peri-urban land is about 73 % in Europe (46.2 % arable land and 26.7 % pastures), 84 % in Germany (63 % arable land and 21 % pastures), and 91 % in Hungary (69 % arable land and 22 % pastures). Furthermore, Europe's agricultural land continues to decrease at an average rate of 0.1 Mio ha per year. The same trend can be observed in developing countries at a rate of about 0.5 Mio ha per year. Most affected by urban sprawl during the 20th century was Russia, where about 64 Mio ha of former agricultural land around the cities was converted into urban land. Thus, urban expansion on arable land is a typical pattern of land use change in human history worldwide, with an increasing impact at present. Conversion of agricultural land to peri-urban land is an important challenge that has received little attention thus far. Trends in carbon balance and potential of soil carbon sequestration, soil properties and soil functions after such land use change needs to be assessed. It is expected that newly initiated pedological processes and inputs of new materials due to human activities, that occur in peri-urban areas simultaneously, will result in changing soil morphology, carbon sink functions, and biological activities. Additionally, the formation of new human-natural bodies, from which classification problems will likely arise, require resolution. First investigations are in progress in Hungary (Debrecen area), Germany (Oldenburg area), and Russia (Belgorod area) and will be presented at the congress.

(5573 - 1017) Diversity of pedogenetic processes in Southern Crimea

Agadzhanova N.[1]; Krasilnikov P.[2]

Lomonosov Moscow State University, Leninskie gory, 1, Moscow, 119991, Russia (nel.agadzhanova@yandex.ru)[1]; Lomonosov Moscow State University, Leninskie gory, 1, Moscow, 119991, Russia (pavel.krasilnikov@gmail.com)[2]

Complexity and diversity of soilscape is usually assessed either as taxonomic diversity or diversity of functions. In the first case it means a diversity of separate soil classes in systems but it is limited by the frames of classifications under used. In the second case the assessment of diversity is based on specific soils properties, but the set of these properties might differ for different areas. Soil diversity evaluation based on the diversity of pedogenetic processes may be a possible to the approaches listen above. The concept of pedogenetic processes (PP) coined by A. Rode in Russia and R. Simonson in the USA considers movement and transformation of matter in soil profile as a complex of phenomena occurring simultaneously or sequentially. The processes cannot be observed directly but they could be supposed on the basis of available morphological properties or hypothesis base on soil-forming factors. Diversity of PP was studied in two sites in Southern Crimea, a mountainous area with Mediterranean climate. The soils of the first in Nikitsky Botanical Garden were formed on

shales and limestone under introduced arboreal vegetation. Young underdeveloped soils prevailed on this site due to perturbation and terracing. The soils of the second site, reserve Cape Martyan, were formed on limestone under natural xerophytic vegetation. There are both deep well-developed terra rossa and shallow, stony soils. In Nikitsky Garden the following set of processes was identified: humus formation, litter accumulation, weak clay illuviation, formation of aggregate structure, leaching of carbonates and bases, physical and chemical weathering, lateral soil erosion. Because of young age of soils the properties are weakly developed. In contrast, the Cape Martyan's soils are formed in stable conditions for a long time and were not affected by anthropogenic impact. The processes observed in the above mentioned soils are: humus formation, litter accumulation, chemical weathering, rubification, carbonate leaching, karst process. Our pilot research showed that the same processes at different stages of their development produce different morphological products. Relict processes should be also carefully separated from current processes, which affect soil-related ecosystem services.

(2514 - 2050) Effects of land use change on soil acidification and organic matter storage in tropical forests

Kazumichi Fujii[1]; Warsudi[2]; Sukartiningsih[2]; Taakeshi Toma[1]
Forestry and Forest Products Reseach Institute[1]; Mulawarman University[2]

Soils are exposed to drastic land use change in tropical forests. We compared rates of soil acidification and organic matter decomposition between primary forest, *Macaranga* natural secondary forest, *Acacia* plantation, *Imperata* grassland, and oil palm plantation in Bukit Soeharto Experimental Forest in East Kalimantan, Indonesia to extract the optimal scenario to minimize forest degradation. Experimental items include (1) litter bag tests using root and leaf litters and cellulose filter papers, (2) 30 year monitoring of soil carbon stocks under different land use change series (forest- grassland, forest-grassland-forest), and (3) analyses of proton budgets associated with plant uptake and solute leaching in plant-soil systems. The litter bag tests showed that land use changes to grassland and acacia or oil palm plantations can increase microbial activity to decompose cellulose in the Ultisol soil studied. Leaf and root decomposability depends strongly on plant traits, with faster turnover of oil palm and grass litters. Land use change from forest to grassland exhibited the greater soil C storage for initial 10 years due to considerable root litter inputs, while net increase in soil C storage during 30 year land use changes is greater for forest-grassland-forest scenario due to low decomposability of forest litters. Soil acidification rates caused by nitrification were greater in Acacia and oil palm plantations than in *Imperata* grassland and natural forests. These data suggests that *Imperata* grassland can contribute to build-up of soil organic matters in short-term fallow (< 10 years), while changes to natural secondary forests can maximize soil C storage and mitigate soil acidification in longer fallow period. Acacia and oil palm plantations have the greater risk to increase soil acidification, but proton budgets can provide minimum N application or lime requirement in acacia and oil palm plantations to ameliorate soil acidity.

(1138 - 587) Impact of pedogenetic factors on the content of organic matter in Vojvodina soils (Serbia)

Jovica Vasin[1]; Milorad Živanov[1]; Jordana Ninkov[1]; Stanko Milić[1]; Vladimir Ćirić[2]; Ljiljana Nešić[2]; Milivoj Belić[2]
Institute of Field and Vegetable Crops, Laboratory for Soil and Agroecology[1]; University of Novi Sad, Faculty of Agriculture[2]

The region of Vojvodina (coordinates of the geographical center - 45º24'05" N, 20º04'53" E) administratively belongs to the Republic of Serbia (northern part), while its geomorphological position is in the southern part of Central-European Pannonian Plain. Besides other pedogenetic factors (parent material – mostly loess, relief – mostly flat, climate – semiarid, with mean annual temperature of 11°C and the period i.e. duration of pedogenesis), the formation of soils in this region was affected mostly by biota and human activity. Natural environment affected the formation of soils through natural herbaceous vegetation represented by steppe grassland (*Festuca sulcata*, *Agropyron sp.*, *Andropogon ishaemum*, *Stipa pennata* etc.), which leaves a large amount of well-distributed alkaline organic matter in soils, causing the development of soil types well-supplied with organic matter (with the natural humus content above 5%) at 75% of Vojvodina surface. The main soil-forming process was humus accumulation. The obtained soil types are chernozem (FAO soil type Chernozem) and humogley - hydromorphic black soil (FAO soil types Vertisol and Gleysol). The effect of man as a pedogenetic factor was visible in the last 100 years. Deep tillage was performed during the period of intensive agriculture, along with soil aeration and intense mineralization of soil organic matter. Mineral fertilizers were preferred over organic fertilizers, which disturbed the natural cycling of soil organic matter, resulting in significant decrease of its content. Many systemic soil analyses have been carried out since 1950s in order to determine the dynamics of soil organic matter content in the region of Vojvodina. During 1950s and 1960s, analyses were conducted for the purpose of constructing a pedological map at the 1/50.000 scale. The network of soil samples covering the territory 4x4 km in size (over 1300 samples) was established in early 1990s, while sampling and analyses were repeated in early 2010s. Research results revealed the decrease in organic matter content by about 0.38% until 1990s, and henceforth by an additional 0.5%, depending on different soil types. The significance of organic matter content to soil fertility created the need for increased future application of organic fertilizers, as well as more rational soil tillage, higher amounts of applied green manure, etc.

Keywords: pedogenetic factors, soil types, organic matter

(6132 - 1567) Long-term effects of litter input change on carbon content in the soil of a Central European deciduous forest

Istvan Fekete[1]; Katalin Juhos[2]; Marianna Makádi[3]; Ibolya Demeter[3]; Imre Berki[4]; Zsolt Kotroczó[2]
Department of Soil Science and Water Management, Szent Istvan University, 29-43 Villányi St., Budapest, 1118, Hungary; Institute of Environmental Sciences, University of Nyíregyháza, Nyíregyháza, Sóstói út 31/B Hungary[1]; Department of Soil Science and Water Management, Szent Istvan University, 29-43 Villányi St., Budapest, 1118, Hungary[2]; Research Institute of Nyíregyháza, University of Debrecen, Westsik Vilmos utca 4-6, 4400 Nyíregyháza, Hungary[3]; Institute of Environment and Earth Sciences, University of Sopron, Ady u. 5, 9400 Sopron, Hungary[4]

Changes in temperature and precipitation patterns that are predicted under scenarios of global climate change will have profound effects on species diversity and forest productivity resulting in alteration of the quality and quantity of detritus inputs to soils. These changes can influence decomposition, thereby altering soil organic matter (SOM) content and dynamics. Our research at the Síkfőkút Forest (founded in 1972) and Síkfőkút Project DIRT (Detritus Input and Removal Treatments) (founded in 2000) effort to explore how changes in the quality and quantity of detritus inputs affect biological activity but

especially SOM content. We studied carbon dynamics of a Northeast Hungarian deciduous forest that has been subject to significant increases in temperature and decreases in precipitation and over the last 4 decades. The decline in sessile oak stand, which was 71% due to primarily aridification increased the organic material to the soil, thus the organic carbon content of soils also significantly (with 28%) increased in the upper 25cm. In the DIRT project, we studied how changed the carbon content of the Double Litter (adding (by doubling) of leaf litter (DL)), No Litter (NL) and Double Wood (adding of wood debris including branches, twigs, bark (DW)) in comparison with the control treatment in the upper 25 cm soil layer over 12 years. DL was 10.9%, DW 6.1% higher, while NL was 32.1% lower than control. According to variance analysis, there is a significant difference between the groups. The results show that decrease in litter production had a greater effect on soil carbon content than on its addition. Litter production and climate change have been able to influence the carbon storage capacity of the soil over a shorter period over a few years.

(3455 - 2330) Magnetite and maghemite: genesis, geochemistry and magnetism in Fe-rich Rhodic Oxisols in the Minas Gerais State, Brazil

Luiz Aníbal da Silva Filho[1]; João Carlos Ker[1]; Maurício Paulo Ferreira Fontes[1]; José Domingos Fabris[2]; Luciano de Moura Guimarães[1]; Luis Carlos Duarte Cavalcante[3]

Universidade Federal de Viçosa[1]; Universidade Federal de Minas Gerais[2]; Universidade Federal do Piauí[3]

Magnetite and maghemite may influence significantly the chemical, mineralogical and magnetic properties of several soils; however, they are commonly found in Fe-rich Rhodic Oxisols, which occupy around 5% of the Brazilian territory. These soils are worthy of attention because they present expressive magnetization and a high potentiality to the agricultural use. Therefore, we evaluated the occurrence and distribution of magnetite and maghemite in fine-grained fractions (sand, silt and clay fractions), which make up the air-dried fine earth, in order to determine their contribution as reserve of trace elements (Co, Cu, Ni V, Zn, Mn and Cr) and for magnetization of the soil mass. Five samples of Bw horizons at 0.8 and 1.0 m depth were collected from Rhodic Oxisols originating from basalt (2 samples), tuffite (2 samples) and itabirite (1 sample) in Minas Gerais State. The contents of Fe and Al extracted from the clay fraction with 1.8 mol L^{-1} H_2SO_4, acid ammonium oxalate and Na-citrate-bicarbonate-dithionite were determined. Mass specific magnetic susceptibility and total trace element contents in the sand, silt, clay and sand magnetic concentrated by hand magnet, were also determined. Magnetite and maghemite were identified by X-ray diffractometry, as well as by Mössbauer and Raman spectroscopy. The morphology of the grains composing the sand magnetic fraction was observed by light microscopy. So it was possible to say that magnetite is inherited from the parent material and its oxidation leads to maghemite formation. An evidence of the magnetite-maghemite-hematite transformation was observed on the surface of magnetite grains in sand magnetic fraction. In addition, Raman spectra indicated a strong signal associated with magnetite compared to the signal related to maghemite for the sand fraction, whereas the other hand, the Mössbauer spectroscopy detected only maghemite. It suggests an advanced degree of oxidation of the magnetite grains; furthermore the presence of other minerals in the sand fraction would have decreased the efficiency of magnetite and maghemite distinction by Mössbauer spectroscopy. For the clay fraction, the null values of magnetic susceptibility after H_2SO_4 1.8 mol L^{-1} extraction and Mössbauer analysis indicated maghemite as the only magnetic mineral. In general, the higher trace and magnetic susceptibility found for in the sand and silt fractions are attributed to the magnetite predominance in relation to maghemite in the soils.

(6781 - 1239) Map of the soil surface color of Rio Grande do Sul obtained by diffuse reflectance

Priscila Vogelei Ramos[1]; Alberto Vasconcellos Inda[1]; Keyrauan Taha[1]

Universidade Federal do Rio Grande do Sul[1]

Diffuse reflectance spectroscopy (DRS) represents a technique widely used in the scientific environment, and, in recent years, has been more explored and popular in soil science. The DRS presents advantages to determine an expressive variety of soil proprieties in comparison to traditional techniques. The reflectance spectra are obtained quickly, inexpensively, accurately, non-destructively way and do not produce residues. According to the mathematic treatment done in the visible spectra wavelength possible to obtain information regarding the type and abundance of iron oxides. In addition to the effect on soil physical and chemical properties, iron oxides influence soil coloration. The strong pigmentation effect of iron oxides is the reason why most soils are brown, red and yellow. This work aimed to determinate the soil surface real color of the state of Rio Grande do Sul (RS), Brazil, using the soil reflectance technique on visible wavelength. For this, we measured the spectra of 579 soil samples from the layer of 0-0.20 m representing all RS territory. A VIS-NIR spectrophotometer was used that covered the wavelength range of 350- 2500 nm. To calculate and obtain the soil real color the visible wavelength has been selected (350–770 nm). By means of the selected range it has been possible to obtain the tristimulus values x, y and z, which have been converted into other color parameters such as hue, value, chroma and RGB (red, green, blue). According to Munsell parameters, hue values vary between 3.41-9.76 YR, value vary between 4.99-6.11, and chroma between 1.31-4.69. For the values validation obtained by conversion, values of hue, value and chroma were compared with the same parameters manually obtained in others research, which have been verified that the reflectance obtained parameters were more accurate. RGB values of the analyzed soils were assigned the mapping units of the RS soil map, generating a map with the actual color of the soil surface. Future studies may relate the color parameters obtained in this research with physical (e.g. soil drainage) and chemical attributes (e.g. soil adsorption) of RS soils. The elaboration of this map proves the potential that reflectance has, with appropriate treatment, to obtain the real color of the soil.

(9413 - 1506) Prospecting of soils in topossequences in Southwestern Mato Grosso – Brazil

Ana Paula Barbosa Lima[1]; Paulo César do Nascimento[1]

Universidade Federal do Rio Grande do Sul[1]

The surveying and classification of soils has undeniable importance in the agricultural context. Knowing the processes and factors involved in the soils formation is an important step in defining their suitability for usage. Pedological studies in topossequences allow observe the differences between the formation processes and the soils that occur in different positions of the landscape. Because it is a set of soils in

different levels in the relief (higher or lower altitude, higher or lower slope), the influence of the formation factors such as climate, parent materials and relief occurs at different levels, forming different soils in the same sequence topography. The objective in this work is to characterize, classify and evaluate the influence of soil formation factors and processes in two topossequences: Chapada dos Parecis, formed from sandstone and located in counties Campo Novo dos Parecis and Tangará da Serra, and Serra Tapirapuã, formed from basalt, located between counties Tangará da Serra and Nova Olímpia, MT, Brazil. Observations were made in thirteen points, from the top of the Chapada dos Parecis to the foothills of Serra Tapirapuã. It was observed that in flatter regions there are deeper, well drained and weathered soils such as Oxisols and Ultisols. In the more inclined positions of the topossequences, the tendency is to form less weathered soils, like Entisols, and outcrops of the parent material. In some areas, despite of sloping relief, the formation processes advanced, with the formation of relatively deep profiles. There is evidence of podzolization in Serra dos Parecis, with the formation of soils with characteristics of Spodosols; also lessivage in the Serra Tapirapuã, with the formation of Molisols and/or Alfisols, classes that are not mentioned in the soil charts of the region. The discrepancy between the distribution of soils present in small-scale surveys and the field observations is normal, due to the small scale of available pedological maps, reinforcing the need for detailed survey for classification and mapping with larger scale. The sequence of the works, with complete morphological descriptions, sample collection and laboratory analysis will allow the characterization and classification of these soils, as well as to estimate the formation processes involved and establish standards in the soil-landscape relationship.

(8001 - 323) Researches on the Evolution of Red Yellow Soil on the Earth

Zhongjie Ye[1]

Zhejiang A&F University, China[1]

I am a retired 90 years old professor from Zhejiang A&F University in China. I have been dedicated my entire career in the research and education of soil science, especially in the area of the genesis and evaluation of red yellow soil. In 1986, a few years after China opened up its door to the outside world, I was fortunately selected, through a rigorous competitive screening process, as a member of a delegation participating in the 13th World Congress of Soil Science (WCSS) in Hamburg, Germany. At the 13th WCSS more than 30 years ago, I presented a paper "The Contribution of Forest and Catastrophic High Temperature to the Formation of Yellow Red Earths". New research results and additional evidences were presented related to the formation of red soil and evaluation of yellow soil at subsequent 14th to 20th WCSS. In this paper, I would like to emphasis some of my view points. Oxisol, a widely used higher level category substance including latosol, were thought to be evolved from high degree of weathering in the tropical areas. Based on the research and analysis it would be more reasonable to believe that Oxisol was derived from the weathering of basalt. Oxisol can be found widely in the basalt stratum from the Quaternary period, from low and high latitude regions. The evolution of Oxisol has no closed relationship with the hot and humid climate in the tropic areas.

(8501 - 1307) Saline sodic cryoturbated soils at Barguzin Depression and processes of their formation

Vasiliy Ubugunov[1]; Nikolay Khitrov[2]; Vera Ubugunova[1]; Anna Zhambalova[1]

Institute of General and Experimental Biology, Ulan-Ude, Sakhyanovoy str. 6, Russia[1]; V.V. Dokuchaev Soil Science Institute, Moscow, Pyzhevskii per. 7, build 2, 119017, Russia[2]

Soil cover pattern included alluvial, swampy, saline, alkaline, cryoturbated soils occur within peculiar landscape at the northern-eastern part of Barguzin Depression that is a part of Baikal Rift at the north of Asia (Buryatia). The landscape is characterized by unusual combination of endogenous and exogenous soil-forming factors been chanced at small distance, namely, existence of surface and subsurface thermal spring relieving in swampy-alluvial plain with insular permafrost sediments near the surface at the bottom of intermountain Barguzin Depression with rainless extra continental climate. Thermal springs are the main source of soluble salts and a cause of formation of local thermic "windows" in the landscape with insular permafrost. Upper soil horizons have symptoms of cryoturbation and long-term reducing conditions. Lateral flow of soluble salts above permafrost layer promotes hydrogenic accumulation of gypsum, carbonates and salts in the solum. Eluvial-illuvial clay differentiation is a result of weakly expressed solonetzic process.

(1263 - 322) Soil covers variability as an indicator of intraplate base level change: an example from the San Francisco Craton, Minas Gerais, Brazil.

Renata Jordan Henriques[1]; Roberto Célio Valadão[1]

Federal University of Minas Gerais - Geosciences Institute - Belo Horizonte - Brazil[1]

The investigation of intraplate crustal movements demands a series of indicators and techniques to evince how this movements condition the earth's surface and its processes. In this context, the main objective of this work is to present the hypothesis that soil coverings may be able to reveal indicators of crust mobility. The study area is a drainage basin of 50km² localized in San Francisco Craton. The Sujo stream is the main tributary that drains this basin and flows to Mata River, an important tributary of Velhas River in Minas Gerais. This drainage basin comprises a regional geological transition between the Neoproterozoic sedimentary basin of the Bambui Group and the Belo Horizonte Complex, which is an Archaean granite-gneiss basal complex. This kind of geological transition is consider as an area of most sensibility intraplate crustal perturbations, which in this case is motivated especially by the continental drift E-W of the South-American plate. As a research methodology this work involved principally fieldwork observation of spatial distribution of soil covers and its characteristics. By this way, these coverages were categorized according to their structural organization and textural aspects. To represent each type of soil cover was also developed a regional topographic section to insert their respective position on the surface. As a result, the soil covers reveals significant allochthonous contribution, which their materials vary according to the topographic position. These coverings correspond mainly to heterogeneous materials composed by clay minerals and coarse fragments of sub-rounded quartz. In upstream of the drainage basin investigated were found a lot of thin allochthonous coverings (about 0,3m in thickness) upon saproliths from the sedimentary rocks and the basal complex. Downstream these covers have thicknesses ranging from 0.3m to more than 6m and also indicate, in some places, that they have been incorporated into a river dynamics, which was responsible for reorganized the quartz gravels and clays. The investigation of these coverings allows suggesting that there are two main moments; the first involves a more lowering of the base level that mobilized the

thicker fragments, and another later moment responsible for deposition of fine clays and crystallizations of iron oxides in some places. Notably, this variation in the basal level may also be conditioned to karsts process because of the carbonates from the Bambui Group.

Doutor Sylvio Menicucci 1001, Kennedy, Lavras, MG, 37200-000, Brazil[5]

In order to develop a sustainable and economically feasible agricultural production capable of maintaining its soils, it is necessary to know the features of different types of soils and their distribution over the landscape. This research categorizes the soils of high quality coffee crops and their distribution at the municipality of Carmo de Minas, as a sample of the region of Serra da Mantiqueira (Mantiqueira Mountains), state of Minas Gerais, to provide data for a Geographic Indication (IG) seal in the Designation of Origin (DO) modality. Field activities led to selecting the curvature and pedological profiles of significant soil classes, in order to produce a complete morphological description and characterization, and to collecting lab samples as an input for the Brazilian Soil Classification System (SiBCS). This research also assessed the morphometric parameters of the terrain, e.g. declivity, hypsometry and curvature, in relation to its soil classes, and found that in altitudes higher than 1,000m, curvature classes linked to a specific declivity class control the variability of soil classes in the region. Hapludox from previous epochs in geomorphological flatlands were preserved in convex slopes with a declivity of up to 45%; Oxic Hapludult occur in transitional convex-concave terrains within a declivity range of 45-75%; and Hapludept occur in concave landforms with a declivity higher than 75%. The linkage between these soils and quality coffee crops is related to the long evolution and depth of these soils in rugged terrains and to their preserved oxic features, which facilitate the existence of coffee crops. The frequent occurrence of thick umbric horizons also contributes physically and chemically to coffee crops in this region.

In tropical soils, the proportion of goethite-hematite and kaolinite-gibbsite indicates the landscape dynamic helping to understand the relationship between soil and landscape evolution. The objective of this work was to characterize the soil-landscape relationship, based on mineralogical characteristics in different landscape positions in a slightly dissected plateau at Jardim River Basin, Central Brazil. This region is well known by extensive agricultural occupation for at least four decades. Topossequences were selected along the landscape: two were performed on soft undulated ramps and two on partially dissected channels along an interfluve. Soils were sampled at 10 to 20 cm depth intervals up to 80 cm. They were air-dried and sieved with a 2 mm mash. Soil color was verified with the Munsell book to estimate the proportion of Hematite and Goethite. The presence of iron oxides was evaluated by magnetic susceptibility (SM) and the proportions of kaolinite and gibbsite were determined with a Thermogravimetric Analyzer (ATG). The lowest kaolinite and gibbsite ratios were found in the headslope of the basin. There was a decrease in SM values from the headslope to the bottom with hue color ranging from 5YR to 7.5YR. At the ramps the soils are more reddish, 2.5YR, and more kaolinitic. The results showed that in a slightly dissected plateau in a neotropical savanna region the dissection of the landscape changed the mineralogical dynamics where higher levels of gibbsite did not mean greater stability and the soil enriched with kaolinite in the ramps represent an old pedogeneses deposits rich in iron oxides.

Keywords: Magnetic Susceptibility, Thermogravimetric Analysis, landforms, iron forms, kaolinite-gibbsite ratio.

(6450 - 356) Urban soils in the Metropolitan Region of São Paulo (Brazil) and their role in the provision of ecosystem services

Wagner Sousa Gomes[1]; Icaro de Sena Almeida[2]; Sheila Aparecida Correia Furquim[1]

Universidade Federal de São Paulo - UNIFESP[1]; Universidade de São Paulo - USP[2]

The Metropolitan Region of São Paulo (MRSP), the biggest of Latin America, comprises 39 counties and approximately 20 million people. This region experienced a significant process of soil alteration due to intense and mostly unplanned urban expansion, accelerated during the XX century. Although the environmental role of the MRSP soils has been highly neglected, they are probably able to provide ecosystems services, as other urban soils in the world, even if affected by higher anthropic influence. In this work, field descriptions and laboratory analyses (pH, exchangeable cations and particle-size) were performed in five soil profiles (a, b, c, d, e) of two vacant lots (L1 and L2) located in developed urban sites of the MRSP, in order to determine their capacity to provide ecosystems services. The profiles are divided in two main sets: upper horizons developed in embankment materials and lower horizons that represent the original soils. The upper horizons are mainly brownish and reddish at L1 (10R to 10YR) and reddish at L2 (10R to 5YR). The surface horizons of L1a, L1b, L1c and L2d profiles present low values (1 to 2), indicating presence of organic matter (OM). All the upper horizons of both profiles have a high heterogeneity due to the abundant presence of volumes with different colors, many of them composed by construction residues. These horizons are majority acid (pH<5.0), clayey, highly compacted and massive, although some of the horizons of L1 (a, b, c) and L2 (d) present granular or blocky structure. The lower horizons at L1 are saprolite materials, mainly reddish (5R or 10R), clayey and massive,

developed by Pre-Cambrian granite weathering. At L2, the *in situ* horizons are black (10YR 2/1) or grayish (7.5YR 5/1), very clayey and massive, developed over Quaternary fluvial sediments. Despite the clear disturbance provoked by anthropogenic activities, such as high compaction, heterogeneity and mix with human artefacts, most of the studied soils have OM accumulation and incipient structure. These characteristics reveals the action of pedological processes, which enable the studied soils to better exert ecosystem services such as mitigation of floods, carbon storage, local climate regulation and soil biological activity. Thus, the definition of the future use of sites in the MRSP should consider their soil functions in order to develop more sustainable cities.

Av Pádua Dias 11, 13418-900 Piracicaba, SP, Brazil[6]

Thick and deeply weathered tropical soils are the basis for the most diverse ecosystems worldwide and an important pillar of global food production. Under today's increasing pressure on soils, the understanding of soil formation and its rate are essential. There is remaining debate if in-situ processes can sufficiently explain the genesis and distribution of thick tropical soils, or if additionally, allochtonous components transported by e.g. water or wind have to be taken into account. Luminescence dating is a promising tool of Quaternary research and increasingly recognized in soil science. Mainly regarded as tool to date sedimentation, it can also be used to evaluate rates of soil turnover by bioturbation. In this presentation, we present first luminescence ages from > 4 m thick Ferralsols near Piracicaba, SP, southeastern Brazil. Preliminary data point to a Late Pleistocene to Holocene age of the dated material. We discuss the significance of these ages to understand the formation of these soils and the implications for the paleoenvironmental development and present land-use.

(2776 - 2378) Vegetation produces but pedotubation decides where carbon is allocated in soils: Assessing O and A horizon thicknesses across the forest-prairie biome transition in Minnesota, USA

Adrian A. Wackett[1]; Kyungsoo Yoo[1]; Nicolas A. Jelinski[1]

University of Minnesota - Twin Cities[1]

The paradigm surrounding humus forms and thicknesses across forest-prairie biome transitions suggests that these morphological distinctions arise from intrinsic vegetation characteristics. The cumulative effects of growth, senescence, and decay of deeply rooted grasses is thought to cultivate a roughly 1:10 ratio of organic matter cycling through above (1) vs. belowground (10) reservoirs in grasslands, resulting in thick A horizons wherein minerals and organic matter are intimately mixed. Alternatively, in forests, plant and litter biomass is concentrated above-ground and the above:below-ground reservoir ratio approaches 1:1. This partially explains the thicker O horizons found on forest floors. In such systems, organic and mineral layers are often stratified and un-associated with one another, in the absence of agricultural land use or the introduction of bioturbating agents such as earthworms. Here, we use the U.S. state of Minnesota as a natural laboratory to test the hypothesis that the modes and magnitude of pedoturbation is critical to explaining the observed trends in litter (O horizon) vs. topsoil (A horizon) thicknesses within and across soil landscapes. Capitalizing on the ternary intersection of grassland, deciduous and coniferous forest ecosystems within Minnesota, we use the U.S. Soil Survey Geographic Database (SSURGO) to extract O- and A-horizon thicknesses at the component level. From these mapping exercises, we estimate A:O horizon ratios that far exceed the anticipated 1:10 ratios for grasslands and fall far below the anticipated 1:1 relationship in forests. Under intensive agriculture, these ratios converge and are independent of vegetation type, reflecting the role of tillage as an efficient soil mixing process. These results may suggest that pedoturbation (or a lack thereof) may play a significant role in establishing and maintaining the form and thickness of humus across soil-mantled landscapes. These thickness relationships and ratios are also compared with biogeographical maps of pre-settlement vegetation and pedoturbation derived from multiple datasets, which permit additional qualitative assessment of the interplay between humus form/thickness, soil mixing agents (both natural and anthropogenic), and vegetation type. Our findings reveal that the mechanism and magnitude of bioturbation should be considered as a significant regulatory factor in setting the type and thickness of humus forms across grassland and forested ecosystems.

(1682 - 1837) Weathering sequence of clay-size minerals based on weathering index and silicic acid activity

Tetsuhiro Watanabe[1]; Han Lyu[1]; Shinya Funakawa[1]

Kyoto University[1]

Changes in clay-size minerals during soil formation (i.e., weathering sequence) have been reported in case investigations and summarized in various schemes. In case investigations, however, effects of soil forming factors on the composition of clay-size minerals are difficult to compare with those in other regions. It is also difficult to relate actual soil forming factors to the composition shown in summarized schemes. This is likely because of the complexity of combinations of soil forming factors. In this study, we propose that soil weathering index and H_4SiO_4 activity (Si activity) can be used to relate soil forming factors and clay-size mineral composition, and demonstrate the effects of soil forming factors on changes in mineral composition. Soils formed under different parent material, climate, and time conditions were collected from B horizons in Japan, Thailand, Indonesia, Cameroon, and Tanzania. The samples were from volcanic soils to strongly weathered soils. Mineralogy of the clay fraction was determined by X-ray diffraction, differential thermal analysis, and selective dissolution methods using sodium pyrophosphate and acid ammonium oxalate solutions. Total contents of Ca, Mg, K, Na, and Fe and dithionite citrate extractable Fe content were determined to calculate the weathering indices (i.e., total reserve in bases and crystalline Fe oxide ratio to total Fe). Si activity was determined in soil water extract. For transformation of 2:1 type minerals, mica was commonly found in soils derived from felsic and sedimentary parent

materials; it weathered to vermiculite under the lower pH conditions of the udic soil moisture regime and less weathered under higher pH conditions of the ustic moisture regime. For neoformation of minerals, in weakly weathered soils, higher Si/Al ratio nanocrystalline minerals were found in soils with high Si activity, whereas lower Si/Al ratio nanocrystalline minerals were found in soils with low Si activity. In moderately weathered soils, smectite was detected in soils with high Si activity and gibbsite with low Si activity; gibbsite was found in soils with low Si activity in strongly weathered soils. Kaolinite was widely found in weakly to strongly weathered soils. The pH and Si activity, which were affected by precipitation, and weathering indices, which were affected by parent material, time, topography, and temperature, were found to be good indices for describing the weathering sequence of clay-size minerals.

C1.3.2 - Soil pedogenesis and diversity in extreme environments

(4588 - 3009) Characteristics and genesis of profiles developed from Amphibolite complex rocks in Southwestern Nigeria.

Sikiru Adekoya MUDA[1]; Temitope Abayomi OKUSAMI[1]; Oladipo OMOTOSO[2]

Obafemi Awolowo University, Ile-Ife, Osun State, Nigeria[1]; Suncor Energy Inc.P.O. Box 2844, 150 - 6 Avenue S.W. Calgary, Alberta Canada T2P 3E3[2]

Limited data have been published on the nature of deeply weathered soils in humid tropical soils of Southwestern Nigeria. The study evaluated the characteristics and formation of weathered soil profiles in rain forest region of Southwestern Nigeria. The soils developed from mafic rocks (Amphibolite and Talc). Results revealed that the soils have generally similar morphological characteristics, particularly in terms of colour (2.5 YR-10 R), and structure (granular to subangular blocky), although the Mokuro profile has higher clay content than the other profiles. The soils have similar chemical properties (e.g. acidic, low exchangeable bases) except that the Ajindo profile has higher CEC values and higher exchangeable Ca content, resulting in a higher base saturation in the upper horizons. The soils also have high dithionite-extractable Fe contents and very low oxalate/dithionite ratios. They are dominated by kaolinite, goethite, hematite, and quartz in the clay fraction. Apparently as a result of their more weatherable mafic parent rock and more stable geomorphic surface, the Mokuro, Wonu 1 and Wonu 2 profiles show more advanced weathering and soil development than the Ajindo profile. The Mokuro profile has higher Ti and Cr contents inherited from its mafic parent material. The study revealed that on the deeply weathered humid tropical soils of Southwestern Nigeria, the characteristics and genesis of the soils are greatly affected by the geochemical characteristic of the parent rock material.

(9145 - 1001) Characterization and classification of soils under native forest in the Western Amazon, Brazil

Andrei Dobner[1]; Luís Antônio Coutrim dos Santos[1]; Fabrício de Araújo Pedron[1]; Catiusca Peretto[1]; Jessica Rafaela da Costa[1]; Uilson Franciscon[2]; Mariana Coutrim dos Santos[2]

Federal University of Santa Maria[1]; Federal University of Amazonas[2]

The Amazon region covers a vast area of land, some areas are cleared for agricultural or livestock use, but the quality of the soil in relation to the sustainability of these practices is inefficient, so it is very important to know the soil attributes of this region. The objective was to characterize and classify two Amazon soils of the native forest. The soils are located in the municipality of Apuí, southern region of the state of Amazonas. The morphological characterization was carried out, and the samples were collected by horizons for the physical and chemical characterization. Were realized physical analyzes of soil bulk density (BD), granulometry and water dispersed clay (WDC) and chemical analyzes of pH, Ca, Mg and Al exchangeable, available P and K, total organic carbon (TOC) and oxides extracted by means of sulfuric attack (SiO_2, Fe_2O_3, Al_2O_3), low crystalline iron (Feo) and Pedogenic Fe (Fed). The soils presented a horizonal sequence described as A, AB, Bw1, Bw2, Bw3 and BC, darker coloring in the surface horizons (10 YR 3/3) due to the higher organic matter contents. Both soils have a very clayey texture and a silt/clay ratio of less than 0.7, possibly indicating a higher degree of weathering. The surface horizons of both soils had WDC ranging from 211 to 314 g kg^{-1}, while for subsurface B horizons the values were 0 g kg^{-1}, which resulted in a flocculation degree of 100%. The BD presented ranging from 1.1 to 1.3 g cm^{-3}, with the lowest values for horizons A, justified by the higher TOC levels and biological activity. The pH varied from 4.5 to 4.9. The exchangeable bases (Ca, Mg, K, and Na) were very low, resulting in base saturation of less than 14%, while the higher Al contents resulted in Al saturation of 46 to 96%, common aspects for soils of the region. The highest TOC in horizons A, are due to the higher contribution and incorporation of organic matter in the surface caused by the Amazonian forest. The Ki index ranging from 1.6 to 1.8, and the Kr index always higher than 0.75, shows the moderate weathering stage and indicates the dominance of the kaolinite mineral in the soil. The Feo/Fed ratio presented values ranging from 0.02 to 0.08, showing the predominance of crystalline iron oxides. Soils were classified in the world reference base as Haplic Ferralsol (Alumic Clayic). Both studied soils present acidic reactions and low levels of exchangeable bases and configure the chemically poor nature of the Amazonian soils.

(6779 - 309) Clay minerals formation in a Solod soil in the Brazilian Pantanal wetland

Thiago Tavares Vidoca[1]; Sheila Aparecida Correia Furquim[2]; Gabriel Ramatis Pugliese Andrade[3]

Universidade de São Paulo, São Paulo, SP, Brazil (thiagovidoca@usp.br)[1]; Universidade Federal de São Paulo, Diadema, SP, Brazil (sacfurquim@gmail.com)[2]; Universidade Estadual do Norte Fluminense Darcy Ribeiro, Campos dos Goytacazes, RJ, Brazil (gabrielramatis1@gmail.com)[3]

The Nhecolândia subregion, located in the Brazilian Pantanal wetland, is distinguished by the existence of thousands of freshwater lakes, brackish lakes and alkaline-saline lakes. Recent researches showed that the brackish lakes have been formed by the progressive decrease in water salinity of alkaline-saline lakes, due to atypical freshwater flows from the floods that reach the wetland during the summer. These geochemical changes are responsible for the transformation of Saline-Sodic soils, typically formed by solonization around the alkaline -saline lakes, into Degraded Sodic Soils (Solodized-Solonetzes and Solods) around the brackish lakes, which are submitted to solodization process. In the present work, the identification and crystal chemistry of clay minerals in the fine clay fraction of a Solod soil were investigated by XRD, XRD modelling by Newmod II and STEM techniques, in order to understand the mineral genesis related to the replacement of solonization by solodization in the Nhecolândia soils. Previous works showed that the Saline-Sodic soils are mainly composed by iron-enriched mixed layered phases, majority kaolinite-illite (K-I, 53%) and illite-smectite (I-S, 34%). Both these phases are strongly dominated by illite layers, with proportions of 91% and 81%

of illites in the K-I and I-S crystals, respectively. In the Solods, our data revealed mainly kaolinite-illite (K-I, 20%), illite-smectite (I-S, 38%) and kaolinite-smectite (K-S, 19%) minerals. These phases are still iron-enriched, but the illite layers are no longer dominant in the crystals. The K-I is formed by 95% of kaolinite whereas the I-S and K-S phases have 53% and 54% of smectite layers, respectively. Thus, the more acidic conditions promoted by solodization have been responsible for the transformation of illite into smectite and kaolinite layers in the crystals, which is evidenced by the lower presence of illite in the assemblages and the high content of iron in the kaolinite and smectite layers in the Solod. Hence, iron-enriched mixed-layered illites, initially formed in soils associated with the alkaline-saline lakes, appear to remain only transiently in brackish lake soils, since the environmental conditions responsible for their formation and maintenance are incompatible with the geochemical conditions created by solodization.
Keywords: kaolinite-illite; illite-smectite; kaolinite-smectite; brackish lakes; solodization.

Campus Universitário, Avenida Peter Henry Rolfs - s/n, Viçosa, Minas Gerais, CEP 36570-900, Brazil[2]; Universidade Federal de Roraima, Department of Soil and Agricultural Engineering. Campus Cauamé, BR 174 - KM 12, Boa Vista, Roraima, CEP 69300-000, Brazil[3]; Instituto Federal de Educação, Ciência e Tecnologia do Amazonas, Av. Sete de Setembro - 1975, Manaus, Amazonas, CEP 69020-120, Brazil[4]

Monte Roraima is a morphological table-shaped feature (tepui), which is a characteristic of the Guianas Plateau, with an altitude of approximately 2,734m. They are characterized by heterogeneity of habitats under the control of diverse edaphoclimatic factors. This work aimed to evaluate the chemical characteristics of the soils of three geoenvironments in an area of a Rupestrian Grassland (Campo Rupestre) complex developed on Quartzitic rocks located at Monte Roraima, Brazil-Venezuela Border. Three geoenvironments were studied: Bonnetia roraimae Rupestrian Shrubby Grassland (CRB); Rupestrian Grassland on Organosols (CRO); and Open Rupestrian Grassland on Sandy Neosols (CRN). Soil samples were collected at twenty distinct points for each geoenvironment in the 0-0.1 m layer for the following chemical analyses: potential of hydrogen (pH), potassium (K^+), sodium (Na^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), exchangeable aluminum (Al^{3+}), and potential acidity (H + Al). From these analyses, the following soil sorption complex characteristics were calculated: base sum (SB), potential cation exchange capacity (T), effective cation exchange capacity (t), and base saturation (V%). In addition, the soil organic matter content (OM) was determined. A variance analysis (ANOVA) was performed to evaluate the differences between soil chemical variables among the three geoenvironments, followed by the Tukey test at 5% probability. Differences were observed in all characteristics, except for pH in water. The geoenvironment CRO was superior to the other geoenvironments in the characteristics K, Na, Al^{3+}, H + Al, T, and OM. However, for the variables Ca, Mg, Al, SB, t and V%, the CRO environment did not differ from the CRB environment. For all chemical characteristics the CRN environment presented the lowest values, except for Na, Al and MO, where it did not differ from CRB. The soil classes found in the geoenvironments are determinants of the chemical composition found. The CRO geoenvironment presents greater chemical wealth than the other geoenvironments.

(6829 - 2988) Genealogic Hypothesis of Semi-Arid Brazilian Ultisols and Inceptisols

Aderson Stanrley Peixoto Santos[1]; José João Lelis Leal de Souza[2]; Bartolomeu Israel de Souza[3]; Eduardo Rodrigues Viana de Lima[3]
Universidade Federal da Paraíba, João Pessoa/PB, 5045, Brasil (stanrleys@gmail.com)[1]; Universidade Federal do Rio Grande do Norte, Natal/RN, Brasil.[2]; Universidade Federal da Paraíba, João Pessoa/PB, 5045, Brasil[3]

Previous studies described Caatinga biome in Brazil as dominated by Entisols and Luvisols. However, us hypothesis is that wetter sites in Caatinga could conduce the formation of more developed soils. In this context, the work aims to highlight the taxonomic hypothesis of pedo-genealogy of the Inceptisols and Ultisols in the Brazilian semiarid. For this, nine profiles were described and collected in sites with different local and regional topographical conformations (between 400 and 1010 m above sea level). Physic-chemical soil properties were determined according to established tropical soils methods. The data were compared with the regional dynamic, climatic, geological and geomorphological conditions, with support from SRTM and GOES 13 and METEOSAT 12 satellites. As a result, the indication of genetic tendency in the formation of the Inceptisols in areas to the leeward of the regional relief, along the syncline portions of the residual masses of the outcrops, whose concavity or relief invoice allow the sedimentary stability and relative pedogenic changes that configure them. The existence of these soils occurs along the heights of 400 to 800 m of altitude, where the influence of a topographic amplitude does not occur in a representative way, in the retention of the humidity of adiabatic difference of relief, as in the environments where the Ultisols. On the other hand, Ultisols are observed in above 800 m (Θ = 20%). Contiguous regional valleys favored a zone of influence and convective systems and moisture retention of moisture, which reduced the daily thermal gradient. Therefore, we conclude that both the Ultisols and the Inceptisols present preponderant distinctions, caused by topographical (and locational) and climatic conditions, which together influence their distributions.

(5883 - 1483) Highly Weathered Soil Development in the Southeastern U.S.A.

J.N. Shaw[1]; B.F. Hajek[1]; T. Knappenberger[1]; E.A. Brantley[1]; B.V. Ortiz[1]
Auburn University[1]

Highly-weathered soils of the southeastern U.S. occur in upland, well-drained environments of the Piedmont and Coastal Plain. By Soil Taxonomy, these soils are commonly Ultisols with kandic horizons or subactive CEC activity classes. Kandic horizons possess low activity clay dominated by kaolinite, hydroxy-interlayered vermiculite and sesquioxides, and share certain characteristics with argillic (relatively finer textured subsoils) and oxic (low activity clay) diagnostic horizons. These highly weathered properties are mostly due to a warm, humid climate, landscape stability due to a predominant backwearing development, and recycled sedimentary parent materials. Improved quantification of clay minerals, thermodynamic modeling, and fluvial chronosequences illustrate that clay mineralogy

systematically varies with soil development in this region. Chronosequence studies (35 pedons) in Alabama (U.S.A.) (climatic, aggradation terraces from Holocene to late Pliocene age) have illustrated the presence of vermiculite and smectite and the relative absence of hydroxy-interlayered vermiculite within the solum of Holocene terraces, but the presence of hydroxy-interlayered vermiculite with systematic depth trends on significantly older (>50,000 ybp) terraces. Pedogenic indicators including depth of solum, clay content, dithionite extractable iron, and CEC/clay ratios indicate highly weathered soils and mineralogical suites develop on the scale of 10^4 to 10^5 years in this environment.

(6161 - 1615) Modelling of water balance dynamics of a Technosol on an abandoned mine site in northern Québec (Canada)

Yves-Dady Botula[1]; Touria Ben Khouya[1]; Bruno Bussière[2]; Marie Guittonny[1]; Abdelkabir Maqsoud[1]
UQAT-Polytechnique Research Institute on Mine and Environment (RIME)[1]; UQAT-Polytechnique Research Institute on Mine and Environment (RIME) / NSERC-UQAT Industrial Chair on Mine Site Reclamation[2]

Acid mine drainage (AMD) is responsible of soil and groundwater pollution in most mining countries such as Canada, and represents a major environmental concern for the mining industry. It originates from oxidation of sulfide minerals in the mine wastes with sharp decrease of pH and increase of heavy metals concentration in drainage water. Until 2008, the Manitou mine site was considered as one of the most polluted abandoned mine sites in northern Québec (Canada) with acid-generating mine wastes covering an area of approximately 190 ha. Recently, a part of this site (identified as Tailings Storage Facility TSF 2) was reclaimed with a cover made of Goldex non-acid generating mine wastes of 1.2 to 1.8 m thick combined with an elevated water table. Half of the cover was revegetated with herbaceous plants. The main objective of the reclamation approach is to maintain a high level of water saturation in the reactive Manitou tailings and the cover made with non-reactive Goldex tailings material. This water saturation allows to limit oxidation of sulfide minerals and inhibit the production of AMD. The Manitou acid-generating tailings and the Goldex non-generating cover material above with or without vegetation can be referred as a Technosol since its properties and pedogenesis are dominated by its technical origin. Pedological properties and hydrogeological dynamics of the engineered soil cover and its colonization by plants (e.g. grasses, legumes and willows) are critical to maintain tailings at high degree of water saturation and allow successful reclamation of the abandoned Manitou mine site in the long term. The objective of our research is to model the water balance dynamics in the experimental plots of the TSF 2 and to compare it with monitoring and field observation of water balance parameters. From 2015 to 2017, volumetric water content, matric suction, soil temperature and groundwater level were monitored on 8 instrumented stations of the Manitou site. Complementary laboratory analyses were performed to determine hydrogeological properties of the cover material used to reclaim the site. Additionally, a monitoring of natural vegetation species that successfully established on the site was conducted. A one-dimensional water balance modeling was performed with Vadose/W (GEO-SLOPE International, Ltd., 2016). The aim was to evaluate the ability of this numerical model to adequately simulate the water balance while including the effect of the vegetation.

(7325 - 3063) Pedogenesis in a semi-arid wetland

Evaniely Sayonara Dos Santos Costa Gualberto de Sá[1]; Valdomiro Severino de Souza Júnior[1]; Artur Henrique Nascimento da Silva[1]; Juliet Emília Santos de Sousa[1]; José Coelho de Araújo Filho[2]
UFRPE[1]; EMBRAPA[2]

The Convention on Wetlands of International Importance - RAMSAR is an intergovernmental treaty that establishes frameworks for national actions and for cooperation among countries with the aim of promoting the conservation and the wise use of wetlands in the world. These wetlands include environments with natural or artificial, permanent or periodic water. These wetlands are also found in arid and semi-arid environments, such as temporary ponds, which are generally small and shallow, intermittently flooded, and pass through a period of annual drying with no surface water. They are of great importance to the environment because they are responsible for a high biodiversity and productivity. There are many studies about these lands in the fields of biogeochemistry, ecology and botany. However, no significant studies were found regarding the pedogenesis of these soils. Thus, the purpose of this work is to identify the pedogenetic processes and to classify chemically, physically and morphologically the soils. The study was carried out in four soil profiles (P1, P2, P3, P4) distributed in a dry lagoon in Parnamirim City, Pernambuco, Brazil, taking into account the position of the points in the landscape and the absence of anthropic interference. The profiles were morphologically described and the horizons evaluated for physical, chemical and mineralogical properties. The profiles P1 and P2 were classified as Vertisols, with a gray color typical of gleation processes, as well as vertization: presence of slits, slickensides and argiloturbation. P3 was classified as Gleysol with gley horizon; and P4 classified as Planosol with presence of B textural. Soils also have kaolinite, smectite and strong feldspar minerals.

Keywords: temporary ponds, wetlands, semiarid, pedogenesis.

(8226 - 689) Pedogenic forms of iron and manganese and its implication on soil genesis over a lithosequence in Nigeria.

Babalola, Temitope S.[1]; Fasina, Abayomi S.[2]; Shittu, Olubunmi Samuel[3]; Ogunleye, Kayode S.[2]; Kadiri, Wasiu O. J.[1]; Ilori, Augustus O. A.[3]
Kabba College of Agriculture, Division of Agricultural Colleges, Ahmadu Bello University, Nigeria.[1]; Department of Soil Science and Land Resources Management, Faculty of Agriculture, Federal University Oye, Oye-Ekiti, Nigeria.[2]; Department of Soil Resources and Environmental Management, Faculty of Agricultural Sciences, Ekiti State University, Ado-Ekiti, Nigeria.[3]

Citrate-bicarbonate-dithionite extractable iron and manganese oxides (Fe_d and Mn_d), Oxalate extractable iron and manganese oxides (Fe_{ox} and Mn_{ox}) and Sodium pyrophosphate extractable iron and manganese oxides (Fe_p and Mn_p) were studied on soils from two agro ecological zones in Nigeria. The active iron and manganese oxide ratios ($Fe_{ox/d}$ and $Mn_{ox/d}$) and Clay/dithionite iron ratio (clay/Fe_d) were evaluated in the soils derived from schist and older granite to establish influence of parent material on soil development and identify major pedogenic processes in the study area. Significant differences were observed in means of most of the properties studied between the parent materials with exception of means of Fe_d and $Mn_{ox/d}$ that were not significant. There were higher values of Fe_d, Fe_{ox}, Fe_p, Mn_d, Mn_{ox} and Mn_p (2.276, 0.511, 0.350, 0.085, 0.017 and 0.016%) respectively in soils formed on schist. Significant differences were observed in the means of Fe_d between horizons with subsurface

horizons having higher mean values than the surface. There was correlation between the forms of iron and manganese with gravel, clay, pH and exchangeable cations. This study revealed that parent materials influence pedogenesis in the soils studied and the extent of pedogenesis varied on the lithosequence. Furthermore, co-translocation of Fe with clay by elluviation and illuviation, plinthization and co-migration of clay with Mn_d were the major pedogenic processes in the soils.

Keywords: Iron, manganese, older granite, parent material, pedogenesis and schist.

(3785 - 338) Physical properties of salt-affected soils surrounding saline and brackish lakes in the Pantanal wetland, Brazil.

Flávia de Oliveira Damaceno[1]; Sheila Aparecida Correia Furquim[1]; Juliana Gardenalli de Freitas[1]
UNIFESP[1]

The Nhecolândia subregion, located in the central-southern portion of the Pantanal wetland, presents hundreds of saline lakes that are not commonly reached by the seasonal floods. However, recent studies showed that some of these saline lakes have been transformed into brackish lakes due to the input of freshwater from the inundations, provoked by the erosion of the saline lake surroundings. Consequently, the Saline-Sodic soils formed around the saline lakes have been converted into Sodic (Solonetzes) and Degraded Sodic soils (Solodized-Solonetzes and Solods). In this study, the hydraulic conductivity (K) and bulk density (BD) of one Saline-Sodic, two Solonetzes, one Solodized-Solonetz and two Solod profiles, the former associated to a saline lake and the last three associated to brackish lakes, were determined in order to understand the consequences of the salt-affected soils transformation in these physical properties. K and BD were determined, respectively, by the falling head permeameter test and the clod method. K has the lowest value in the Saline Sodic soil ($4.5x10^{-4}$ cm s^{-1}), increases in the Solonetzes ($1.2x10^{-3}$ to 2,8 x 10^{-3} cm s^{-1}) and tend to decrease again in the Solodized Solonetz ($8.0x10^{-4}$ cm s^{-1}) and Solods ($9.3x10^{-4}$ to$1.3x10^{-3}$ cm s^{-1}). Also, the Saline Sodic soil present the lowest SD (2.8 g cm^3), whereas no clear pattern was verified from the Solonetzes (2.9 to 3.6 g cm^3) to the Solodized Solonetz (3.5 g cm^3) and Solods (2.9 to 3.4 g cm^3). These results do not corroborate the assumption that the progressive decrease of soil sodicity correspond to an increase of K and decrease of BD values, especially due to a higher colloid flocculation and the consequent structure and pore development. Our results are likely related to the formation of nodules (Mn, Fe, silt and clay-enriched) around the brackish lakes, which tend to generate higher bulk densities and prevent significant K increasing in the evolution of the salt-affected soils. The lower K in the Solonetzes is probably associated with a higher presence of silt and clay-enriched nodules and a less abundant presence of Mn/Fe nodules, which probably allows the production of a more connected porosity. Because the formation of the Mn and Fe nodules is common in salt-affected soils, the interpretation that the decrease of sodicity improves soil physical conditions is not always valid.

(9017 - 1666) Salt distribution and organization in Soils from Arid and Hyperarid environments, northern Chile

Davi Feital Gjorup[1]; Carlos Ernesto G. R. Schaefer[1]; Marcio Rocha Francelino[1]
Universidade Federal de Viçosa[1]

Many soils in desertic zones shows soluble minerals accumulation. Low information is available about distribution and organization of these minerals in arid-hyperarid soils. We present the distribution and organization of soluble minerals in 10 soils from arid and hyperarid zones of Atacama Desert, Northern Chile. Samples were characterized chemically and physically. Soluble minerals were extracted in soil solution (1:1 soil:water), and anions were determined by ionic chromatography (NO3, SO4, Cl) and titration (CO3 and HCO3). Micromorphological descriptions of selected horizons were performed. Soluble minerals accumulation is the main pedological process in the study area. At hyperarid zones, salt redistribution is closed to soil profile, and losses are negligible; accumulation is high and very soluble minerals is an important component. At arid zones, accumulation and losses coexist, and vary due to landscape position. Well drained arid soils are subject to leaching losses. Poorly drained soils receipt soluble minerals from other zones, and accumulation is intense. Landscape transport of soluble minerals in arid landscape vary due to mineral solubility and landscape position. Pedogenic carbonate accumulation is widely distributed, but incipient. Present-day climate is not favourable to pedogenic carbonate reorganization. Extensive carbonate pedofeatures were attributed to past hydrologic conditions. Gypsification is general in study area, and all stages of the process were detected. The process vary due to precipitation and landscape position. In extreme hyperarid zones pedogenic sulphate reorganization were not detected. Some soils were subject to a almost complete gypsification, with volumetric gain, to the extent that the original soil constituents become of secondary quantitative importance. Salt accumulation is associated with proximity to salt sources, or very low precipitation. Some organization forms indicate climatic variation with aridity intensification. Lowland soils shows higher saline content in any climatic system, due to high solubility and landscape mobility of saline minerals. Micromorphological study of soils subjected to a intense soluble minerals accumulation requires conceptual and methodological development. In this study, possible mineral alterations were detected in thin sections, due to hydratation or solubilisation of instable minerals.

(8183 - 2832) Soil relations and landscape in ferruginous geosystems: The example of the Tableland of Canga, in Minas Gerais, Brazil.

Anna Paula Vilemberg Botelho[1]; Cristiane Valéria de Oliveira[1]; Henrique Amorim Machado[1]
Universidade Federal de Minas Gerais[1]

Ferruginous soils and ferruginous outcrops are among the most threatened ecological systems in Brazil due to their restricted distribution, associated with the country's main iron ore deposits, harboring an endemic biodiversity, providing a high relevance geoenvironmental heritage such as water recharge areas. Therefore,the objective of this work was to understand the soil and landscape relationships of ferruginous environments with the landscape of the Tableland of Canga, inserted in the Fonseca Basin, located in the extreme east of the Quadrangle Iron. It should be emphatize the influence of two distinct geomorphological units: a dominant topographic positioning (Montain of Caraça), formed by itabirites and supported by quartzites and a relief of aplaine (tabuliform), formed by sedimentary depositions, originating from the Fonseca Basin formation, presenting fluvial dissection in the less resistant areas, superimposed by a ferruginous bed. As a méthod of analysis of the soils present in the Tableland of Canga, particle size and particle density analyzes were used, in which it was possible to infer the existence of the domain of the lithostructural control of the geological material of itabirite source, with high density and high degree of magnetization, resulting in shallower soils in the upper portion of the Tableland of Canga and deeper soil in the areas of depression near the drainage head, on the left margin of the

Piracicaba River, where it is inferred that this lower altimetric level portion suffered preteritally the influence of alluvial fan formation, generating soils of greater thickness and with ferruginous characteristics.

(4030 - 502) Typical and extreme Vertisols in space and time

Irina Kovda[1]
1- Institute of Geography RAS; 2 - V.V. Dokuchaev Soil Science Institute[1]

Typical Vertisols (WRB, 2015) are churning, heavy clay soils formed on parent material with a high proportion of swelling clays. They have deep wide cracks when dry, and occur in depressions and level to undulating areas, mainly in tropical, subtropical, semi-arid to subhumid and humid climates with an alternation of wet and dry seasons. Typical vegetation is savannah, grassland and/or woodland. They may have a gilgai microrelief. Vertisols are recognized by vertic horizon with wedge-shaped aggregates and slickensides starting ≤ 100 cm from the soil surface. The aim of our research is to evaluate the extreme environments for Vertisol formation i.e. the full range of possible climate (MAAT and MAP), vegetation, geomorphology, parent material and time, where they occur. We also aimed to estimate the change of leading soil forming factor and its impact on shrink-swell process and formation of vertic features in the extreme cases, and to find the special attributes, characteristic for each extreme case. Most Vertisols occur in semi-arid tropics with MAP 500–1000 mm/yr. Meanwhile they are known in extremely dry (50 mm) or wet (3000 mm) climates. The MAAT in Vertisols areas is generally in between of 15-26 ^{o}C. But they occur in areas with MAAT 30 ^{o}C, and have been recently found in Siberia with MAAT –4.2 ^{o}C. Typically Vertisols are montmorillonitic. At the same time kaolinite (in Australia, Hawaii, Cambodia, Salvador, Sudan), illite (Australia, Bulgary) and polymineral (Trinidad) Vertisols also occur. Gilgai indicating strongest shrinking, swelling and shearing vary in lateral size from 3-4 up to 20 m, have amplitude from 5-30 up to 100 cm, and a range of forms. The most common gilgai are rounded. Tank, melon-hole, wavy, lattice, dendritic gilgai also occur. Extremal gilgai in Australia having an amplitude > 240 m and wavelength ~120 m was named giant. The age of Vertisols is known from < 100 yrs to ~2.5 billion yrs. Extreme Vertisols (i.e. formed in atypical environment or having atypical attributes) may be the result of various combinations of texture, mineralogy, geomorphology, and hydrothermic conditions. On the other hand, extreme Vertisols can be associated with the history of soils and landscapes development being in fact relic soils (exhumed or non-buried paleosol), or initial Vertisols started to shrink/swell due to climatic changes (drying, wetting, warming) or at a next appropriate stage of the climatic cycle.

(3925 - 615) unity of soils evolution during time

Tskhovrebov V.S.[1]; Faizova V.I.[1]; Novikov A.A.[1]
Stavropol State Agrarian University[1]

The process of soil formation is uniform for all corners of the land and there are no soil-forming processes. There are specific features in the direction of soil formation, due to the composition and quality of the parent rocks, climate, and relief. The essence of soil formation is in the biological weathering, accumulation and transformation of weathering products of mineral and organic matter. In evolutionary development, soils sequentially undergo stages from birth on the rock to their natural death (neo-breed). The first stage is the beginning of soil formation. There is a settlement of vegetation on the initial soil-forming rock. The second stage is accelerated soil formation. The formation of the upper genetic horizons begins and the main soil features and differentiation of the profile appear. The third stage is slowed down soil formation. All genetic horizons of soils continue to form and the profile capacity and fertility level increase. The fourth stage is mature soil. The formation of the soil profile and all genetic horizons is completed. It is used to call this stage climacteric when the stage of equilibrium functioning comes and all the processes take place within the framework of relatively stable biochemical cycles. But is it possible to achieve equilibrium and constancy in open biological systems with constant inflow and outflow of matter and energy? The weathering of the mineral base, the alienation of the elements of nutrition continues and the depletion of soils is inevitable. The fifth stage is the aging of the soil. Further weathering of minerals leads to a significant difference in their qualitative composition between the soil and the soil-forming rock. The amount of organic matter and elements of nutrition is reduced. Soil fertility decreases. The sixth stage is the death of soils. The mineralogical composition of soils and soil-forming rocks is radically different from each other. The bulk is made up of poor in chemical composition of newly formed minerals. Soil can no longer satisfy the needs of plants in the elements of mineral nutrition. Depending on climatic conditions, the first four stages can last from ten to one hundred thousand years, the fifth stage from one to two million years. The given scheme of evolution can be successfully applied only in the wet zone. Naturally, in conditions of dry or moderately damp climate of steppes, the duration of the stages is longer and it is impossible to expect the death of soils.

(5933 - 1924) Weathering of metamorphic rocks and formation of planosols in semi-arid environment, Brazil

Valdomiro Severino de Souza Junior[1]; Laércio Vieira de Melo Wanderley Neves[1]; Jean Cheyson Barros dos Santos[1]; José Coelho de Araújo Filho[2]; Marcelo Metri Correa[1]; Luís Felipe Inácio da Silva[1]
Universidade Federal Rural de Pernambuco[1]; Embrapa Solos[2]

In the Brazilian semi-arid region, the evolution of the surface tends to the flattening with monotonous landscapes of smooth undulating relief where large expanses of Planosols occur. The action of the time, with perpetuation of the aridity conditions, results in the formation of shallow soils, physical and chemical denudation with loss of the superficial layers, water regime with evapotranspiration that exceeds the precipitation, making these areas naturally susceptible to degradation. However, recent studies of soil genesis in the region have shown that the lithology of felsic rocks is the main factor that leads to the Planosols pedogenesis imposing on the soil the main physical, chemical and mineralogical attributes. The objective of this work was study the evolution of the weathering front in gneiss saprolites (felsic rocks) in two profiles of Planosols under different levels of severity of degradation (point 1 incipient degradation and point 2 degradaded area under desertified area in Pernambuco. In order to deepen the knowledge of the role of the source material in the intrinsic characteristics of the soils. The primary assembly and pedological features were determined using optical microscopy techniques in thin sections of the R / Cr horizon. The variability in the contents of the series albite up to anorthite was determined by the Michael-Levy diagram, as well as the domains of primary mineralogy and accessory minerals. The secondary assembly was identified by X-ray diffractometry, coupled with complementary techniques such as SEM / EDS scanning electron microscopy, thermogravimetric and differential (DTA /GT), vibrational analyzes using InfraRed (IR). The results showed that felsic rocks present great variability in types and proportions of alkali and plagioclase feldspar, including perthites, with alteration routes and quite different secondary products. Point 1 has

higher concentrations of quartz, K-feldspar, biotite and presence of pertites. The secondary mineralogy is dominated by alumina smectites. Alteration route with K-feldspar / biotite > Ilite> beidelite. It presented pedalities with b-factories and biological cavities. In point 2 the quartz domain and higher concentrations of placiocases in relation to alkalis-feldspar, domain of smectites with octahedral sites of negative charge in the secondary, possible route Plagioclase / sericite / biotite > kaolinite / montmorilonoite. It presented weak pedality.

C1.3.3 - Anthrosols - the human constructed soils

(7005 - 1629) Amazonian Dark Earth: proposal of modification of the pretic horizon criteria

Fernanda Reis Cordeiro[1]; Ademir Fontana[2]; Andressa Rosas de Menezes[1]; Wenceslau Geraldes Teixeira[2]; Lúcia Helena Cunha dos Anjos[1]

Federal Rural University of Rio de Janeiro[1]; Embrapa Solos[2]

The Amazonian Dark Earths (ADE) were formed by influence of pre-Columbian anthropic activities and have being reported mainly in the Amazon Basin. According to the World Reference Base for Soil Resources (WRB), among the diagnostic horizons for the Anthrosol class, the pretic horizon is a mineral surface horizon characterized by its dark colour, the presence of artefacts and high contents of organic carbon, phosphorus, calcium, magnesium and micronutrients, usually contrasting with natural soils in the surrounding area. It typically contains visible remnants of charcoal. It has as diagnostic criteria: dark color; organic carbon (C org) ≥ 10 g kg^{-1}, P (Melich I) ≥ 30 mg kg^{-1} and Ca^{2+} + Mg^{2+} ≥ 2.0 $cmol_c$ kg^{-1}. The objective of this work was to classify profiles identified in Brazil as ADE using the WRB system. The profiles were compiled through a bibliographical research of soil surveys, thesis and dissertations, and other publications. Thirty profiles with anthropic horizons were identified with data sufficient to classify the soils using WRB. These ADE are distributed in the Brazilian states of Amazonas (24 profiles), Roraima (1 profile), Rondônia (1 profile), and Pará (4 profiles). From the horizons identified as anthropic (Au), only 30% were classified as pretic horizon. Therefore, considering the low correspondence of the taxonomic classification in the WRB with the identification of the ADE by Brazilian standards, new quantitative criteria are proposed for the pretic horizon: (i) thickness ≥ 20 cm; (ii) color (wet) with value ≤ 4 and chroma ≤ 3; (iii) Ca^{2+} + Mg^{2+} weighted: Σ [(Ca^{2+} + Mg^{2+} x thickness of the Au sub-horizons) / total thickness of the Anthropic A horizon] ≥ 2.0 $cmol_c$ kg^{-1}; (v) P (Melich I) weighted: Σ [(P x thickness of the sub-horizons Au) / total thickness of the anthropic horizon A] ≥ 30 mg kg^{-1}; and (v) C org weighted: Σ [(C org x thickness of the sub-horizons Au) / total thickness of the anthropic horizon A] ≥ 6.0 g kg^{-1}. It is also proposed to reduce the thickness of the pretic horizon required to be included in the Anthrosols class from 50 to 30 cm. Using these criteria 50% of the profiles that had a pretic horizon were classified as Anthrosols. The current WRB criteria for classification of pretic horizon and Anthrosols exclude 70% of the profiles identified in the literature from Brazil as ADE. Therefore, a revision of the criteria is recommended, since this horizon was created to encompass the so called Amazonian Dark Earths.

(7561 - 2497) Amazonian dark earths located in the fertile floodplains in the central Amazon - Brazil

Wenceslau Geraldes Teixeira[1]; Rodrigo Santana Macedo[2]; Eduardo Góes Neves[3]

Embrapa Solos, Rua Jardim Botânico, 1024, 22460-000, Rio de Janeiro, Brazil; wenceslau.teixeira@embrapa.br[1]; Instituto Nacional do Semiárido - INSA, Campina Grande, Brazil; rodrigo.macedo@insa.gov.br[2]; Museum of Archaeology and Ethnology, University of São Paulo,vedgneves@usp.br[3]

Amazonian Dark Earths (ADEs) are highly fertile soils horizons created by pre-Columbian Amerindian societies of the Amazon basin. However, there is still not agreement on whether these Anthrosols were produced intentionally to improve the unfertile Amazonian upland soils or whether resulted from the accumulation of waste from sedentary settlements. This study brings a pedogeochemical characterization of ADE found in the naturally fertile alluvial floodplains of the Amazon river in the Central Brazilian Amazon. The analyzes quantify total, exchangeable and available contents of elements and organic carbon in soil profiles. The ADEs showed higher contents of available, and total P, Ca, Zn and Cu. High contents of total Cr, Ni, Co and V indicate contribution of mafic minerals in the soil genesis, while higher contents of P, Zn, Ba and Sr in the ADEs indicate anthropic enrichment. The occurrence of ADE in floodplains brings strong evidence of non-intentional anthropic fertilization of the alluvial soils, which, in natural conditions have contents of P, Ca, Zn, Cu above of the critical levels to cultivate the most common plants. The presence of archaeological sites in the floodplains shows also that pre-Columbian populations lived on the floodplains as well as on the bluffs overlooking the Amazon river.

(6704 - 2734) Anthropic soils in central Brazil archaeological sites

Jordana Batista Barbosa[1]; Marisa Coutinho Afonso[1]; Julio Cezar Rubin de Rubin[2]

Museu de Arqueologia e Etnologia da Universidade de São Paulo[1]; Pontifícia Universidade Católica de Goiás[2]

Everything that surrounds us involves physical and chemical transformations, so that the understanding of these phenomena is essential for human development in every aspect. Making use of geochemistry, archaeometry and micromorphology techniques is fundamental to study the soils in archaeological context and its indicators of human occupation. Amid the biomes in Central Brazil, the *Cerrado* stands out for its biodiversity and tropical climate with two well defined seasons, humid in the summer and dry in winter and with a higher thermal amplitude than in the equatorial climate and lower rainfall. In this sense, the environment is an extremely important variable when it comes to chemical phenomena. An example is phosphorus which is considered a nutrient of low mobility in tropical soils, a behavior attributed to its fixation by the clay minerals. This element has a relevant presence in archaeological sites located in tropical environments that also present high levels of iron and aluminum oxides - with which P has a great affinity. Considering this, we use the archaeological sites Cangas I and Lago Rico (Goiás, Central Brazil) to study and understand the behavior of the chemical composition of anthropogenic soils in tropical environments and their pedological features (features inherited from the parental rock or formed by processes of deposition of transported material). Carbon, organic matter and some minerals stand out in the analyzes including phosphorus, calcium, zinc, potassium, barium and strontium. Among

all the analyses carried out at the sites, the values of Carbon and organic matter have similar mean values, but the phosphorus contents ranged from 55.0 to 288 (ppm) and Carbon from 5.8 to 14.5 (ppm) in the areas with higher concentration of ceramic traces. Hence, geoarchaeological techniques associated with ethnohistorical and ethnographic information allow inferences on the existence or non-correlation between cultural vestiges and forms of occupation, regardless of whether they are dark Earth (terra preta), and may present information on the patterns of human occupation of the area.

(9299 - 901) Anthrosols constructed by the indigenous people of southern Brazil

Fabrício de Araújo Pedron[1]; Luis Antonio Coutrim dos Santos[1]; Catiusca Peretto[1]; Alice Prates Bisso Dambroz[2]
Universidade Federal de Santa Maria[1]; Unversidade de Cruz Alta[2]

The indigenous peoples of the Neolithic period who lived in the southern region of Rio Grande do Sul (RS), Brazil, were known as Charruas and Minuanos. They had nomadic habits, living in seasonal camps on the banks of ponds or rivers. In order to escape the constant flooding of these lowlands, they constructed their camps on landfills called "cerritos". Cerritos are human made mounds of earth and residues of anthropic activity with a few centimeters to several meters in height. These archaeological sites were dated from 500BC to 1750AC. The cerritos are important archaeological sites with a huge research demand. The objective of this research was to investigate the characteristics of the soils constructed in an archaeological site located on the Butui-Mirim river in the municipality of São Borja, RS, Brazil. Four cerritos were evaluated, samples of adjacent natural soils were also collected under annual cropping and native grass field for comparison. The soils in the cerritos were classified as Anthrosols, while the adjacent soils were classified as Leptosols and Gleysols. The evaluated cerritos presented depth ranging from 60 to 120 cm. The Leptosols presented a maximum depth of 10 cm over the parent rock (basalt). The Gleysols had a depth greater than 80 cm. Morphological evidence of anthropic alteration was observed in the profile of the soils in the cerritos, such as the erratic presence of coarse fragments, resulting from the transport of stony soils from the surrounding areas and the presence of chipped silicified sandstone. The average clay content of the Gleysols was 50% while in the Antrhosols it was 21%, very close to the value of the Leptosols (24%) suggesting that the cerritos were constructed by the accumulation of adjacent areas. The Anthrosols presented an average of sum of bases (14 cmolc kg^{-1}) higher than the adjacent Leptosols (7 cmolc kg^{-1}). The P values, which ranged from 37 to 486 mg kg^{-1} in the Anthrosols, from 8 to 19 mg kg^{-1} in Leptosols and from 2 to 5 mg kg^{-1} in the Gleysols, evidencing the increase of P in the soils constructed by the native indians. These archaeological sites have suffered frequent degradation by their leveling in areas of irrigated rice cultivation. Its preservation and study is fundamental for the understanding of important pedological processes for society.

(8870 - 1416) Chemical properties and Δ13 C of Amazonian Dark Earths under different land uses from Southern Amazon

Rafael de Souza Cavassani[1]; Lúcia Helena Cunha dos Anjos[1]; Marcos Gervasio Pereira[1]; Robson Altiellys Tosta Marcondes[1]
Universidade Federal Rural do Rio de Janeiro[1]

The Amazon Dark Earths (ADE), also known as "*Terra Preta de Índio*", are identified by the anthropic horizons, and result of ancient Pre-Colombian civilizations. Five sites of ADE where chosen in Rondônia, Southern Amazon. Profiles with (P1 to P6) and without (P7) anthropic horizons, and variation of land coverage (forest, pasture, and no-till system with soybean and maize) were selected. Soils were characterized according to Santos et al (2013) and EMBRAPA (1997). The total organic carbon (TOC) and isotopic variation of $^{13}C/^{12}C$ (δ13C) were analyzed. Charcoal samples were submitted to radiocarbon dating by Accelerator Mass Spectrometry technique. Contents of Ca^{2+} and Mg^{2+} were high (23.0 and 4.4 $cmol_c$ kg^{-1}) compared to the non-ADE soil (2.8 and 1.3 $cmol_c$ kg^{-1}). This is associated with presence of animal bones, and some authors relate it to increase of CEC due to high contents of stable organic matter. Contents of phosphorus were also very high, up to 451.9 mg kg^{-1}. The high P is associated to dietician habits of the Pre-Colombian civilizations. Sodium and potassium were low in all soils. The high precipitation rates of Amazon region leads to lixiviation of monovalent cations. The CEC of ADE were up to 27.7 $cmol_c$ kg^{-1}, while the non-ADE had values lower than 8.0 $cmol_c$ kg^{-1}. The low CEC is typical of weathered soils with low organic matter. The results of δ13C in the ADE under pasture had δ13C varying from -20.8 to -25.8 ‰. Despite the usage with grasses (*Brachiaria sp)* of cycle C4 for over 20 years, the results reveal dominance of C from plants with metabolic cycle C3, inherited from previous forest cover. It is not clear if these results are related to a higher capacity of ADE in maintaining the δ13C levels because of the biochar content, or simply due to time of usage with C4 plants. Values of δ13C were similar among P5 (ADE-under forest), P6 (ADE) and P7 (non-ADE), these last two under no-till system. The similarity is explained by implementation time of the system, only 7 years, as well as presence of soybean (C3 plant) in this succession. The horizons used for 14C carbon dating, P2 Au4, P4 AB and P5 Au4 had values δ13C of -24.4, -23.4 and -23.8 ‰, respectively, indicating the origin of the C from C3 plants. The main aspect in ADE soils is the high amounts of stabilized organic matter and pyrogenic carbon, up to 44.43 g kg^{-1}. Understanding formation of ADE can lead to development of agricultural sustainable models in tropical low fertility soils.

(3526 - 2097) ecosystem engineers and other macroinvertebrates in dark earths and non-anthropic soils in central amazonia

Wilian C. Demetrio[1]; David Stanton[2]; Ana Caroline Conrado[1]; Talita Ferreira[1]; Marie L. C. Bartz[3]; Alessandra Santos[1]; Peter Kille[2]; Luís Cunha[2]; George G. Brown[4]; TPI Network[5]
Federal University of Paraná[1]; Cardiff University[2]; Positivo University[3]; Embrapa Forestry[4]; [5]

Soil invertebrates drive many ecological functions in the environment. Due their sensitivity to anthropic disturbances, these animals can be used as a tool to evaluate environmental quality. Earthworms, ants and termites generally represent the majority of the soil macrofauna population at a given site, and are called "ecosystem engineers" for being able to alter the physical soil environment. However, little is known about soil animals in Terras Pretas de Índio (TPIs), also called Amazonian Dark Earths, soils formed after centuries of occupation the pre-Columbian civilizations, and the consequences of ancient and recent land use management on their populations. We evaluated soil macrofauna communities in TPIs and non-anthropic soils (ADJ) under

old and young forests and agricultural systems in three States of Central Amazonia (Brazil) using the Tropical Soil Biology and Fertility (TBSF) standard handsorting methodology. The Principal Component Analysis (PCA) separated TPIs from ADJ soil in the first axis considering the soil fertility, and the environments evaluated in the second one considering the level of human disturbance. The results showed that ecosystem engineers were the most representative macrofauna group in all systems studied and soils evaluated. Termites presented preference by ADJ soils, while earthworms were more abundant in TPIs. Other invertebrates, such as ants, beetles and myriapods showed no preference for TPIs or ADJ soils, however, land use systems strongly affected their populations, with lower densities observed with increasing environmental disturbance.

(5901 - 1828) Features and processes behind charcoal-kiln artefacts on volcanic lands

Mwampamba T.H.[1]; Olivares-Martínez L.D.[2]

Ecosystems and sustainability Research Institute, UNAM Campus Morelia, 8701 Antigua Carretera a Pátzcuaro Col. Ex Hacienda de Sán José de la Huerta, Morelia, Michoacán, Z.C. 58190 México[1]; [2]

Rural people living in forests uses wood for charcoal production, they cut some trees, then they pile them up in mounds used as in situ kilns which they pyrolysis after; at the end they take the useful charcoal from the kiln and leave a thin debris layer. This activity can produce not only charcoal garbage, but strong physical disturbances. We surveyed the features of 8 charcoal-kiln influenced soils in forest of the Trans-Mexican Volcanic Belt and we evaluated their physical and morphological effects on volcanic soils. We used preliminary classifications according to all the applicable WRB criteria for only field descriptions and inferred characteristics without lab analysis. Eighteen horizons with charcoal remnants with different abandonedages where identified, The normal length of a charcoal-kiln horizon was around 20 cm. It is very often that the place destined once to be a charcoal-kiln is used again as a charcoal-kiln. Very recent abandoned charcoal-kilns showed the superficial crust and a layer full of pieces of charcoal. In charcoal-kilns with more than 5 years of abandonment showed some fine earth between the charcoal pieces and some hydrophobicity in their underneath layer. In old rests there were just a couple of little pieces of charcoal, but a high soil penetrability. It resulted evident the more time of abandonment the less charcoal percentage in a layer. Moreover, the soils where classified as Technosols for the accumulated charcoal content of all the layers, the oldest charcoal soils returned back to Andosols –the dominant soil and the original soil on these cases– anyway they preserved enough remanent artifacts and Prototechnic was an applicable qualifier. The hydrophobic effects seem to be related with the heat reached during the pyrolysis of the kiln. It is possible than the hydrophobic materials were formed during the pyrolysis and during the decomposition and washing of the remanent charcoal by the rain. The rodent activity generated parts on specific layers with less amount of artefacts, which reduces the layer percentage of charcoal and promotes an illusion of older soils. Tilling generates a very similar effect. At the end, charcoal-kilns affect the hydrophobicity, the bulk density and the length of the original soil, in most cases Andosols. The more years an abandoned layer has the less charcoal percentage is observed.

Keywords: Anthropic soils, hydrophobicity, Technosol

(8807 - 934) Geochemical balance of Archaeological Dark Earth and adjacent soils in Western Amazonia, Brazil

Luís Antônio Coutrim dos Santos[1]; Fabrício de Araújo Pedron[1]; Bruno Campos Mantovanelli[1]; Mariana Coutrim dos sSntos[2]; Catiusca Peretto[1]; Uilson Franciscon[2]

Federal University of Santa Maria[1]; Federal University of Amazonas[2]

In the middle of the landscape of infertile soils of the Brazilian Amazon, there are patches of soils of high natural fertility, known as Archaeological Dark Earth (ADEs). The objective of this work was to study the geochemical balance in ADEs and adjacent soils in the Western Amazon. The areas of Archaeological Dark Earths (ADEs), Mulatto Earth (MEs) and Non-Antropical Soils (SNAs) are located in the Southern Amazonas mesoregion, more precisely in the municipality of Apuí. Two sites were selected in each environment to open trenchs, totaling six profiles. The semiquantification of total elements (Al, Si, Fe, K, Na, Mg, Ca, Mn, Zr, Zn, Ti and P) was performed in an X-ray fluorescence spectrometer. The elements were expressed in the form of oxides: Na_2O, MgO, Al_2O_3, SiO_2, P_2O_5, K_2O, CaO, TiO_2, MnO, Fe_2O_3, ZnO, ZrO_2. It was estimated the degree of weathering by chemical change index (CIA) and geochemical balance by means of the mass transport function in open system (Ʈ) by the relations between the most mobile elements (K, Ca, P, Fe, Si and Al) and less mobile (titanium). The dominance of SiO_2 and Al_2O_3 was observed for all studied soils. The similarity of the values of the less mobile elements in the soil (TiO_2 and ZrO_2) between the soil horizons and between the soils indicates the same source material for the soils. The highest CIA values were observed for the NASs, with values higher than 98%, evidencing a weathering stage above the other soils. The function Ʈ presented losses for the elements Al, K and Si in all the soils, showing the mobility and the loss of these elements during the weathering. The positive values of the function Ʈ (Fe), shows the enrichment of Fe, mainly in the B horizons, which is justified by the concentration of iron sesquioxides in these horizons. For the ADEs and the anthropogenic horizons of MEs, the values of Ʈ (Ca) show the gain of this element in the soil, mainly in the superficial horizons. The function Ʈ (P) was positive only for the Aup horizons of the ADEs. The highest positive values of Ʈ (Ca) and (P) are directly related to the higher incorporation of calcium and phosphorus rich residues during the antrophication process of the anthropic soils. In spite of the formation of the same source material, the enrichment of P and Ca in the ADEs and MEs shows the contrast between the anthropic soils and the NASs, thus showing that the anthropophic processes were responsible for the Ca and P enrichment of the anthropic soils.

(4584 - 1297) Magnetic signature of anthropogenic and non-anthropogenic soils from Western Amazonia, Brazil

Alice Prates Bisso Dambroz[1]; Luís Antônio Coutrim dos Santos[2]; Fabrício de Araújo Pedron[2]; Laércio Santos Silva[3]; Camila Viero Maia[2]

University of Cruz Alta[1]; Federal University of Santa Maria[2]; São Paulo State University, School of Agricultural and Veterinary Studies[3]

Amazon's anthropogenic soils are characterized by the presence of ceramic fragments, high natural fertility and high levels of organic matter, in contrast to adjacent soils. The determination of the presence of ferrimagnetic minerals in Archaeological Dark Earths (ADEs), through the magnetic susceptibility (MS) technique, allows the understanding of these soils attributes and formation processes. The aim of this study was to determine the magnetic susceptibility and the percentage of dependent frequency magnetic susceptibility (χdf) of Archaeological Dark Earths, Mulatto Earths (MEs) and non-anthropogenic soils. The soils are located in the municipality of Apuí, Southern region of the state of Amazonas. Six profiles were analyzed, two with ADEs, two with MEs and two non-anthropogenic soils. The MS of air-dried fine earth (ADFE) and of clay fraction samples were determined. To calculate the χdf, the values of low and high frequency

MS were used. In the ADFE samples, the highest low frequency MS (MSlf) value was observed in ADEs, while the lowest MSlf values were observed in non-anthropogenic soils and ME 02. In the ADEs and ME 01, the highest MSlf values are observed in the surface horizons, decreasing in depth (9,20 – 0,52 10^{-6} m^3 kg^{-1}), these results are probably due to the anthropogenic actions, such as the use of fire, which favor the formation of magnetic minerals, as maghemite, in the anthropogenic A horizons, by the process of burning organic matter. The MSlf of the clay fraction showed the same tendency from the values found in the ADFE, with the higher values being observed in ADEs. The relatively close values of the MSlf in the ADFE and clay fraction, indicate that the MS is mainly resulting from the maghemite. The χdf in the ADFE samples from ADEs surface horizons showed values from 7,53 to 9,69%, thus indicating a mixture of multi-domain and single-domain (SD) minerals, or probably, a predominance of superparamagnetic minerals (SP). The close to 10% χdf values observed in ADEs and ME 01 indicate the predominance of particles smaller than 0,03µm, with a SP behavior, common in the clay fraction (maghemite), to the detriment of SD and multiple (magnetite), common in sand and silt's coarse fractions. The higher MS in ADEs and ME 01 is due to the use of fire by pre-Columbian populations, consequently promoting maghemite formation in these soils.

(6879 - 1563) Magnetic susceptibility and its relation to human modification of soils in archaeological sites in brazilian central plateau.

Daniel V. Sousa[1]; Wenceslau G. Teixeira[2]; Maria J. Rodet[3]; André Prous[3]; João C. Ker[4]; Carlos E. R.G. Schaefer[4]

Universidade Federal do Vale do São Francisco[1]; Centro Nacional de Pesquisa em Solos[2]; Universidade Federal de Minas Gerais[3]; Universidade Federal de Viçosa[4]

The study of magnetic properties in archaeological soils has been very useful in detecting activities related to the use of fire. The warming produces a reorganization of the molecules and a neoformation of magnetic minerals. The present study aims to evaluate the variation of magnetic susceptibility in soils archaeological sites in San Francisco's depression. Ten archaeological sites and three control sites were studied. Volumetric magnetic susceptibility (VMS) were determined in 10 cm^3 aliquots of TFSA using a Bartington MS2 system and an MS2B sensor, Carbon-14 dating was also done. The control sites results show values of VMS in order of 40 to 62 x 10^{-3} m^3 kg^{-1}. Samples related to human burning features the VMS ranged from 2518 to 145 x 10^{-3} m^3 kg^{-1}. The site called Lapa Pintada seems to have the more intense anthropic fire activities, followed by Lapa do Boquete. Dating showed that an intense occupation was between 1000 and 8000 yrs BP but with indications of an occupation older than 12000 years BP. The Anthrosol of Santana do Riacho had a value of VMS 1293 X 10^{-3} m^3 kg^{-1} in the burials layer. Dating show an age between 8230+-150 to 9460±110 years BP, we have also found an indication of throwing ashes and coals inside the graves, as well as make campfires above them. The oldest level dated was 11960±250 yrs BP, and shows high MS values, although lower than the previous ones, 877 X 1010^{-3} m^3 kg^{-1}. The Bibocas II archaeological site, in its oldest level, 10470±80 BP, show intense fire activities. The VMS data suggest that the Lapa Grande, Lapa do Malhador, Cave da Passagem and Lapa do Sol, had incipient human activities. The Lapa Grande had its highest value in recent level. The Lapa of the Malhador, had high VMS value (2199 x 10^{-3} m^3 kg^{-1}) in its oldest level. The cave da Passagem, had its highest value in a representative level of bonfire. The Lapa do Sol, is an open-air site, had high VSM at the same level where many lithic artifacts were found. Our results indicated that VSM is a very useful parameter as diagnostic characteristic for anthropic soils horizons, or horizons were activities using fire were conducted.These activities that heat the soil and change the magnetic characteristics and may also change the mineralogical assemblage are related to fire to food and pigment preparation, thermal flaking, ceramic burning, lighting, or ritual bonfires.

(3849 - 3129) Micromorphology study of the soil of the archaeological site Sol de Campinas do Acre

Kelly Brandão[1]; Ximena Suarez Villagran[1]

Museu de Arqueologia e Etnologia da Universidade de São Paulo[1]

The southwest region of the Brazilian Amazon has gained visibility in the last decades due to the mapping of many earthworks build, currently counted in 450 sites and this number only increases. Two types of distinct structures are observed, geoglyphs are formed by ditches or embankments and appear in great quantity, whereas mound constructions normally are in elliptic shape, are scarce and are associated spatially with the geoglyphs. One of the main issues nowadays is the indigenous interference in the Amazonian landscape and these earth structures are inserted in this debate due to the movement of the necessary pedological material during their constructions. Recent research in the region conceives earth engineering as a dynamic and enduring cultural practice that has transformed the landscape and established regional communication networks. This research has a geoarchaeological approach and studies archaeosedimentary material from the archaeological site Sol de Campinas do Acre. The site consists of 15 mounts with an average height of 3 meters, which are arranged elliptically around a central square covering approximately 15.000 m². The dating radiocarbon on mound 11 revealed a succession of occupancy events between the 11th and 17th centuries, placing the period of its construction later than the geoglyphs of the region. Preliminary results of the micromorphological study of Mound 11 in SCA indicated an intentionality in the choice of building material. The lower layers of Mound 11 were designed using the A horizon of the surrounding soil, adding allochthonous material such as iron oxide and / or manganese nodules, possibly to provide more strength to the structure. Micromorphology has the potential to reveal hidden aspects in the formation of earthworks and to offer complementary data for the interpretation of the use and function of the site. To complement the micromorphological data particle size and X-ray Fluorescence analyzes are being performed.

(3357 - 2483) Spatial variability of soil erodibility in areas of indian dark earth under different uses in the south of the Amazon

Milton César Costa Campos[1]; Elilson Gomes de Brito Filho[1]; José Maurício da Cunha[1]; Wildson Benedito Mendes Brito[1]; Lucivânia Izidoro da Silva[1]; Eduardo Antonio Neves dos Santos[1]; Luana Celestino Calista[1]; Francisca Xavier Quintino Neta[1]; Fernando Gomes de Souza[1]

Federal University of Amazonas[1]

The erodibility represents the susceptibility of the soil when exposed to erosive agents, disintegration and transport of particles, and can

occur naturally or even accelerated by anthropic action due to inadequate management. The indirectly estimated erodibility is defined by the variables K, Ki, Kr and Tc, being respectively global erodibility, interrill and rill erosion and critical shear stress. In the case of Indian Dark Earth (IDE) few studies have been concerned about understanding the influence of management on the chemical and physical attributes. Therefore, the aim of this work was to investigate the spatial variability of soil erodibility in area of Indian Dark Earth under cultivation of pea beans and native forest in the region of Manicoré, AM. The sampling was done in the two IDE areas, containing meshes of 88 m x 64 m with regular spacing of 8 m between the points, making a total of 88 sampling points per mesh. These points were geo-referenced using GPS equipment in order to have the Digital Elevation Model (MDE) constructed. The samples were then collected at a depth of 0.00-0.20 m. The following procedures were performed: textural analysis, organic matter, sand fractionation and stability of the aggregates. After this step, indirect models of soil loss prediction were used to estimate the erodibility factors (K, Ki, Kr, and Tc), followed by descriptive and geostatistical analyzes for modeling spatial variability. The mean and median values in both areas were similar with tendency to a symmetrical distribution of the data, which can be confirmed with asymmetry values close to zero. However, the mean values of the factor K in the pea bean area were higher than those of the forest area, indicating that the management influenced to a greater loss of soil, considering that the uncovered soil was more susceptible to erosion. All the variables studied presented normality, except the silt in the forest area, although the normality of the data is not a requirement in geostatistics. Regarding geostatistics, the models that fit the most were exponential and spherical, showing a strong and moderate degree of spatial dependence (DSD) for all the attributes studied. The range varied between 11 and 20 m in the forest area and 13 to 29 m in the area of pea beans. Therefore, the lower vegetation covered of the pea bean cultivated area provided a higher K factor. The area of pea bean reported a higher DSD, showing a lower variability.

(2950 - 293) Spatial variability of soil respiration in Archaeological Dark Earth areas in Amazonas state, Brazil

José Maurício da Cunha[1]; Milton César Costa Campos[1]; Marcelo Dayron Rodrigues Soares[1]; Douglas Marcelo pinheiro da Silva[1]; Alan Ferreira Leite de Lima[1]; Bruno Campos Mantovanelli[2]; Uilson Franciscon[1]

Universidade Federal do Amazonas[1]; Universidade Federal de Santa Maria[2]

In natural ecosystems, soil respirationis one of the important components of carbon emission into the atmosphere – CO_2 efflux. Soil CO_2 efflux has both temporal (due to temperature and moisture changes) and spatial variability, which can be explained by different types of soil, soil use and management, as well as the influence of vegetation on CO_2 efflux. In this context, quantifying and understanding the spatial variability of soil CO_2 efflux may help elucidate the dynamics of abiotic and biotic effects on the main components of soil CO_2 efflux. Thus, in these environments few studies assess the spatial variability of soil CO_2 efflux, soil temperature and soil moisture content, which requires a more detailed understanding of the spatial variability patterns of these attributes in native forest and agricultural areas, thereby contributing to a better understanding of CO_2 efflux dynamics in atypical soils. As such, we aim to evaluate the spatial variability of soil CO_2 efflux, soil temperature and soil moisture content in archaeological dark earth environments in guandu bean and pasture areas, compared to the natural forest environment. To that end, regular meshes were marked out in areas of forest (6 x 6 m spacing), guandu bean (4 x 5 m spacing) and pasture (8 x 8 m spacing) measuring 2,500 m^2, 1,700 m^2 and 4,800 m^2, respectively, with 88 sample points georeferenced in each area. Soil CO_2 efflux and soil temperature were measured at the intersection points of the meshes, and soil samples were collected at a depth of 0.00-0.10 m to determine soil moisture in the laboratory. Soil CO_2 efflux and soil temperature measurements were taken using LI-6400 systems, and soil moisture using soil samples collected at 0.00-0.10 m. Spatial variability was observed for soil CO_2 efflux, soil temperature and soil moisture, with a high degree of spatial dependence. Higher spatial correlation ranges were recorded for soil CO_2 efflux and soil temperature in the pasture area, as well as soil moisture in the forest area. The spatial distribution maps indicate a trend towards concentration among the properties assessed, showing positive correlations between soil CO_2 efflux and soil moisture and negative correlations between soil CO_2 efflux with soil temperature, in the forest area.

Keywords: spatial variability; soil temperature; soil moisture.

(7577 - 2850) Terras Pretas Arqueológicas: comparing sites on the Solimões River and its tributaries

José Furtado de Miranda[1]; Carlos Ernesto Gonçalves R. Schaefer[1]; João Santiago Reis[1]; Hedinaldo Narciso Lima[2]; Ronaldo de Almeida[3]; Angélica de Cássia Ladeira[1]

Universidade Federal de Viçosa[1]; Universidade Federal do Amazonas[2]; Universidade Federal de Rondônia[3]

Research on Terra Preta Arqueológica, or Terra Preta de Índio (TPAs), is mostly concentrated along the Amazon River, with few studies being conducted at sites far from the main river, where are supposed to be chemically poor and less developed. Based on the finding that size, depth and chemical richness differ between TPAs, it was hypothesized that TPAs on the banks of the Solimões/Amazonas River provided a greater opportunity for sedentarization compared to the tributaries. This study compare sites of TPAs on the Solimões River and on their tributaries. The study area is located along almost the entire Solimões/Amazonas River. A database was constructed from the collection of papers that studied TPAs, in articles, theses and dissertations, totaling 125 soil profiles. The analyzed variables were: pH; available calcium (Ca^{2+}), magnesium, potassium, and phosphorus; exchangeable acidity; potential acidity (H^++Al); base sum (SB); base saturation (V); saturation by aluminum; total organic carbon (CO); cation exchange capacity (CTC); sand, silt and clay. The dataset was organized on anthropic A horizon and B horizon in banks of Solimões/Amazonas River and in tributary rivers. Principal Component Analysis (PCA) and Discriminant Analysis (DA) were performed in software R. A and B horizons of adjacent non-anthropic soils (ANS) were also included for DA. The averages of the characteristics of the A horizons of the Solimões TPAs are higher for most variables. This also occur in the B horizons. PCA has selected two main components, accounting for 80% of the variables. pH, Ca^{2+}, SB, CTC, H^++Al and V were selected as the most important to explain the variability of TPAs. DA generated two functions for the A horizons, with a hit of 73.91%. Similar results in B horizons show 83% of accuracy. For the A horizons of the ANS the classification was 100% correct, indicating that there is perfect differentiation of these compared to the TPAs. In the 139 observations in A horizons (tributaries), 96 remained in this group, 11 were relocated in the ANS and 32 in the Solimões TPAs. About the 150 observations of the A horizon of the Solimões, the function maintained the classification in 115 cases, only 2 were for the ANS,

and 33 for the TPAs of the tributaries. Similar results was observed in B horizons. Therefore, the TPAs of the tributary rivers show more similarities with characteristics of the ANS, evidencing less chemical enrichment, in contrast to the Solimões TPAs.

(1751 - 2816) Characterization and classification of soils with lamellae in the semiarid region of Pernambuco, Brazil

Francis Henrique Tenório Firmino[1]; Marcelo Metri Corrêa[2]; Alexandre Ferreira do Nascimento[3]; Valdomiro Severino de Souza-Junior[4]; Brivaldo Gomes de Almemida[4]; José Romualdo de Sousa Lima[2]
Universidade Federal de Viçosa/UFV; Viçosa, MG; francis-henrique@hotmail.com[1]; Universidade Federal Rural de Pernambuco/Unidade Acadêmica de Garanhuns-UFRPE/UAG; Garanhuns, PE[2]; Empresa Brasileira de Pesquisa Agropecuária (Embrapa Agrossilvipastoril), Sinop, MT[3]; Universidade Federal Rural de Pernambuco - UFRPE; Recife, PE[4]

The Brazilian Soil Classification System (SiBCS) is 20 years old, currently in its third edition. And to each of them the improvement is sought with alterations, corrections of the definitions and concepts, even with the restructuring of classes in all the categorical levels. In relation to the presence of lamellae in soils, the SiBCS makes a single mention, which defines that the occurrence, when demarcated by texture's summation and specificities, constitute a B textural (Bt) horizon . However, studies have shown the importance of these features when these specifications are not met. What makes emerge the need for studies that evaluate how the presence of lamellae with different patterns (thickness, depth and total sum) are contemplated by the taxonomic classification systems. For that, three sites were selected within a toposequence with an auger. In each site a trench (P1, P2 and P3) was opened for morphological description and sample collection for chemical, granulometric, physical-hydro, mineralogical and micromorphological analyzes. Each profile was classified according to Soil Taxonomy, World Reference Base (WRB) and SiBCS criteria. Morphologically the most significant differences between the profiles were in the horizons with presence of lamellae. The textural class is similar between the profiles, with quantity greater than 4% of primary minerals of easy weathering in the sand fraction. When the sum of the lamellae was greater than 0.15 m (P3), the horizon did not fit as Bt, because the lamella particle size did not present a sandy or finer sandy texture. Micromorphology indicates that the lamellae are of an e-iluvial constitution due to the clay movement (argilluviation). Despite the dystrophy in the horizons with lamellae, the lamellae are eutrophic in addition to favoring the increase in water retention capacity. For the SiBCS the profiles are classified as Neossolo Regolítico Distrófico espessarênico. By Soil Taxonomy, P1 and P2 are classified as Lamellic Ustipsamments and P3 as Lamellic Haplustalfs, while in WRB P1 and P2 are classified as Dystric Regossol (Arenic, Lamellic) and P3 as Totilamellic Acrisols (Arenic, Cutanic, Differentic, Hyperdystric, Proffondic). The non-imposition of the lamellae in the SiBCS does not emphasize the presence of extraordinary characteristics at the fourth categorical level. Thus, the need to include the lamelic character at the level of a subgroup is emphasized, for the importance of these features.

(4135 - 974) Characterization of the soil classes of the southeast region of the Mato Grosso State - Brazil, by the digital model of elevation in different reliefs and slopes

Kelly Cristina da Silva Freitas[1]; Jeferson Vieira José[1]; Edna Maria Bonfim-Silva[1]; Tonny José Araujo da Silva[1]; Helon Hebáno de Freitas Souza[1]; Ronaldo Aparecido de Oliveira[1]; Niclene Ponce Rodrigues de Oliveira[1]
UFMT[1]

Soil surveys are important tools for land use planning. However, there is a lack of mapping due to the limitations of soil data acquisition due to the great demand for time and cost. Thus, the objective was to characterize the soil classes of the southeast region of Mato Grosso in function of the relief and corresponding slopes based on the digital terrain model (DTM). The DTM SRTM (Shuttle Radar Topographic Mission) was obtained through the GIS for the characterization of the soil classes of the region, resulting in the elaboration of maps with the occurrence of the classes of soils and respective classes of slopes and altitudes. The study area covers an area of 16,438,600 ha. It was predominant in the region, the Entisols Quartzipsamments with 34.58% of the total area, located in regions of flat or smooth corrugated relief, being suitable for reforestation because they have sandy texture and reduced available water quantity. The highest elevations were found in flat and smooth undulating regions classified as Oxisols (13.9% of the total area), with an average altitude of 846 meters, these soils are characterized by being well drained and deep. In the distribution of slope, the highest average was observed in the class of Ultisols, with an average slope of 11.7% and the lowest average was observed in the Alfisols Albaqualfs (2.4%). lowlands, floodplains and depressions, this region was that of the Mato Grosso marshland and corresponding to about 1,184,109 ha totaling 7.20% of the total area.

(2109 - 1786) Classification of the soils of the area of influence of Santa María Asunción Codex and their pictorial representation

Ma. del Carmen Gutierrez Castorena[1]; Edgar Vladimir Gutierrez Castorena[2]
Programa de edafologia, Colegio de Postgraduados[1]; Facultad de Agronomía, Universidad Autónoma de Nuevo León[2]
Classification of the soils of the area of influence of Santa María Asunción Codex and their pictorial representation Ma. del Carmen Gutiérrez Castorena[1], Carlos Alberto Ortiz Solorio[1], Beatriz Stephanie Fernández Galán[1], Edgar Vladimir Gutiérrez Castorena[2] and Tania González Vargas[1] 1 Programa de Edafología, Colegio de Postgraduados. Km 36.5 Carretera México-Texcoco. 56230 Texcoco, Estado de México, México. castor@colpos.mx. 2 Facultad de Agronomía. Universidad Autónoma de Nuevo León. Escobedo, N. L., México.

Although the Santa Maria Asunción Codex (SMAC) has been extensively studied, the soil survey on which it was based to interpret the glyphs of different kinds of land was performed outside the area of influence of the codex. Reinterpreting the glyphs of different land classes through a study of soils, geomorphology and parent materials are the objective of this research. Five neighborhoods that appear in the SMAC were studied, and the frequency of the glyphs in each one of them was quantified. Subsequently, plot-by-plot field visits were carried out and samples of soil and tuffs (tepetates) were collected for laboratory analysis and taxonomic classification. The results indicate that the soils of area of influence of the SMAC are classified mainly of Terric Anthrosols (*Escalic*, *Technic*), Leptosols/Regosols (*tephric, technic*) formed from rhyolite, andesite and tuffs, and Fluvisols (*technic*). The frequency of glyphs in each neighborhood and type of soil indicated that Tepetatlalli (tepetates) can represent terraces (land

and stones), Xalallis granular peds (< 3 mm) and non-sandy soils; Tezoquilt represent the land with subangular blocky/granular peds with hard and soft consistency (< 2 cm); Tlalcoztli is a dusty yellow land of low agricultural quality; and Atoctlis and Tezoquitl/ Xalalli correspond to active and passive alluvial soils, respectively. In addition, with soil classification, local knowledge and geomorphology were possible to determine the localization of the different plots represented in the SMAC The conclusions are that the Nahua classified their lands based on aggregate size, soil consistency, and origin (natural and artificial), and not on texture or color; and the soils correspond to Anthrosols with abundant gment of ceramic (*technic*). Finally, the tepetates (*tepetatlallis*) do not correspond to indurated volcanic soils but to terraces. *Keywords: Ethnoedaphology, soil classification*, *land classes, aggregation*

(6475 - 1537) Genesis and classification of Gleissolos Belonging of the Meia Ponte River on the Granulitic Complex Anápolis-Itauçú, Goiás State, Brazil.

Djavan Pinheiro Santos[1]; Tiago Camilo Duarte[1]; José Arnaldo de Castro Netto[1]; Rafael Almeida Ferreira[1]; Lucas Pergentino Brandão[1]; Gustavo Cassiano da Silva[1]; Thiago Pereira de Souza[1]; Angélica Pires Batista Martins[1]; Otávio Silveira Gravina[1]; Glenio Guimarães Santos[1]
Universidade Federal de Goiás[1]

The Granulitic Complex Anápolis-Itauçú has predominance of igneous rocks of basic-ultrabasic affiliation. The aim of this study was to know the genesis and classification of two soil profiles adjacent to the Meia Ponte River on the Granulitic Complex Anápolis-Itauçú in the State of Goiás, Brazil. The geographic coordinates of profile 1 are: 16° 36' 03.3" S, 49° 17' 37.5" W, 711 m altitude and profile 2: 16° 35' 43.8" S, 49° 17' 24.9" W, 703 m altitude. The climate of the region is classified as type Aw, according to the Köppen classification, with a mean annual temperature of 22.5 ºC and precipitation of 1,571.4 mm. Two soil profiles were selected belonging to the watershed of Meia Ponte River in the municipality of Goiânia, State of Goiás, Brazil, between the months June and July 2016, which present poor drainage conditions, characterizing them in morphological, physical and chemical properties of the soil. The soils formed in this watershed are due to the factors and processes of soil formation and the performance of alluvial and colluvial materials due to the position of the relief. For reasons of the organic carbon content and the thickness, the surface horizons of the two soil profiles were identified as A moderate horizon. Profile 1, located in area saturated in the rainy season, influenced by the water table and aluvinares materials from Meia Ponte River allows accumulation of water for a long time, favoring the development of pedogenetic process of gleation, indicated by the colors with low chroma. The set of attributes observed this profile allowed to classify as Gleissolo Háplico at the suborder level, associated with high clay activity, with base saturation greater than 50% in large groups and have a vertic character in one or more horizons up until 100 cm of the surface of the soil, allowing to classify as Gleissolo Háplico Ta Eutrófico vertissólico. The profile 2 had a high contribution of coluvial materials, due to the position in the relief, presented with similar characteristics to the P1 profile in first and second categorical levels, with low clay activity and base saturation less than 50%. In this way, it was noticed as intermediate soils for Neossolo and presence of fluvic character, being determinant to characterize as Gleissolo Háplico Tb Distrófico neofluvissólico. It is concluded that the relief and alluvium-colluvial materials were the most active factors in the genesis and classification of these soils studied.

(5129 - 610) Great groups of soils of the Northeast of Brazil not yet cataloged in the Brazilian System of Soil Classification

José Coelho de Araújo Filho[1]; Flávio Adriano Marques[1]; Karolina Esther da Silva[2]
Embrapa Soils[1]; Universidade Federal Rural de Pernambuco[2]

The improvement of the Brazilian System of Soil Classification (SiBCS) depends on its effective use in soil surveys, soil classification and correlation meetings, and researches in soil science. The objective of this work is to present taxonomic information on soil great groups not yet cataloged in the SiBCS. The study area comprises the coastal parts (Coastal Tablelands, Coastal Lowlands and surrounding areas) of seven states, amounting to an extension of 224,000 km², of the Northeast region of Brazil. In order to accomplish the objective, it was reviewed morphological, analytical and taxonomic information of 650 soil profiles, comprising 300 soil profiles available from pedological studies published in the 70's and 80's of the past century, and 350 profiles of the reconnaissance soil survey (1:100,000 scale) under execution in Ceará State of Brazil. All these profiles were analyzed according to the methodology of Embrapa Soils, the National Soil Research Center of the Brazilian Agricultural Research Corporation (Embrapa). The analyses of the 650 soil profiles and of the current structure of the SiBCS showed the necessity of addition of five new great groups of soil to the system. They are: *Latossolos Vermelho-Amarelos Eutrocoesos* (Eutrudox), *Argissolos Vermelho-Amarelos Distrocoesos* (Kandiudults), *Luvissolos Crômicos Sódicos* (Natustalfs), *Vertissolos Ebânicos Sálicos* (Salusterts) and *Neossolos Flúvicos Ta Distróficos* (Ustifluvents).

Keywords: Taxonomy of soils; tropical soils; Coastal Tablelands; Northeast of Brazil.

(7389 - 1841) Identification and classification of the soils of Garhwal Himalayas in India using remote sensing and GIS techniques.

S.K. Mahapatra[1]; Ritu Nagdev[2]; R.P. Yadav[2]; S.K. Singh[3]
ICAR-National Bureau of Soil Survey and Land Use Planning, Regional Centre, IARI Campus, New Delhi 110012, India (sankarkmahapatra@yahoo.co.in)[1]; ICAR-National Bureau of Soil Survey and Land Use Planning, Regional Centre, IARI Campus, New Delhi 110012, India[2]; ICAR-National Bureau of Soil Survey and Land Use Planning, Amravati Road, Nagpur, 440033, Maharashtra, India[3]

A study was undertaken to identify and classify the soils of Tehri Garhwal district of Uttarakahnd state in India using remote sensing and GIS techniques. The area falls in warm humid Garhwal region of Lesser Himalayas. It lies between $32^0 00'$ to $31^0 10'$ N latitides and $77^0 55'$ to $79^0 05'$ E longitudes covering 3,33,000 ha area. About 70% area of the district is under forest and only 11% of the district is under agriculture which is main occupation of the inhabitants of this area. The elevation ranges from 350 to 6578 m above msl. Ont he basis of image data (IRS 1D LISS IV) interpretation, major physiographies viz., summits/ridge tops, side/reposed slopes, valleys and piedmonts were identified with varying degree of slopes. On the basis of field study and laboratory characterisation 17 soil series have been identified and mapped into 43 soil units as soil series association. The soils of summits/ridge tops occur on moderately steep to steep slopes and are mainly very shallow to moderately shallow, excessively drained, gravelly loam, sandy loam to laom in texture and suffer from severe to very severe erosion and stoniness. They are classified as loamy skeletal/coarse loamy Lithi/Typic Udorthents and patches of Typic Dystrudepts. Soils of side/reposed slopes occur on moderately steep to very steep slopes and are mostly very shallow to moderately deep, excessively drained, gravelly sandy loam, gravelly loam and gravelly clay loam in texture and prone to very severe erosion. They are

classified as loamy skeletal Lithic/Typic udorthents and coarse loamy Typic Dystrudepts. Soils of valleys occur on gentle to moderate slopes and are moderately shallow to deep, sandy loam to loam in texture and prone to moderate to severe erosion and stoniness. They are classified as loamy skeletal Typic Udorthents and coarse loamy Typic Dystrudsepts. Soil of piedmonts occur on gentle slopes and are moderately deep to very deep, well drained, sandy loam to loam in texture and prone to moderate erosion. They are classified as loamy skeletal Typic Udorthents, coarse loamy Typic Dystrudepts and fine loamy Dystric Eutrudepts. Thematic maps viz., soil erosion, drainage, texture, reaction, soil depth, slope and organic carbon have been generated in GIS mode.

(2097 - 1187) Optimal simultaneous classification of salt-affected soils into USDA ST, WRB and Hungarian Soil Classification soil types

Tibor Tóth[1]; Gábor Szatmári[1]

1Institute for Soil Science and Agricultural Chemistry, Centre for Agricultural Research, Hungarian Academy of Sciences, H–1022 Budapest Herman Ottó út 15., Hungary[1]

Long before the future Universal Soil Classification will be widely accepted, more and more pieces of land will be classified into more than one classification system because of legal etc issues. The European Community is an exemplary region, where often national and WRB classifications are used parallel. Soil classification, as a rule, is carried out with the proper designated field and laboratory methods of the respective classification systems. When more than one taxonomic systems are used for many soil profiles, there are several options. a) Each soil profile might be classified by the proper methods in each soil classification system. This is the lengthiest and most costly procedure. b) Another option is to limit the field/laboratory analysis by using cross-correlative functions between the designated methods in order to facilitate faster and less costly analysis. The dataset on which the functions are based is ideally the same as that being classified. The only requirement of the cross-correlative functions is to provide precise decision on reaching the threshold values. c) Classifying algorithms can be used to convert one soil classification system into another. We shall compare these options for classifying 200 salt-affected soils by USDA ST, WRB and Hungarian Soil Classification systems. Our presentation shows the conceptual framework for selecting the best option in terms of cost, time and precision for the simultaneous classification of salt-affected soils in three classification systems.

Keywords: cross-correlative function, classifying algorithm, optimal classification

(9127 - 909) Physical, chemical, mineralogical and spectroscopic constitution of the soils of a microbasin representative of the extreme stream basin, Federal District

Otávio Junio de Oliveira Souza[1]; Marilusa Pinto Coelho Lacerda[1]; Caio Isaias Cardoso[1]; Letícia dos Santos Ferreira[1]; Manoel Pereira de Oliveira Junior[1]

Universidade de Brasília[1]

Soil surveys are becoming increasingly necessary and detailed so that the best agricultural yields can be obtained from them without causing so many environmental changes in the present ecosystem. The objective of this work was to determine the physical, chemical, mineralogical and spectroscopic composition of the soils class of occurrence in the Barbatimão stream microbasin, considered representative of the Extrema river basin, to generate data for surveys and pedological mapping of greater detail of the field. With primary level curve data, quoted points and hydrography a terrain model was generated in ArcGis 10.3. obtaining a map of hypsometry and slope. With this one was selected a topossequence in the region of the barbatimão stream. The position of the soil profiles to be studied was orientated according to the change of slope, and four representative profiles were selected. In the soil profiles the physical, chemical, mineralogical and spectroscopic characterization of the soil diagnostic horizons. The physical, chemical, mineralogical and spectroscopic analyzes allowed to individualize the following classes of soils. The first profile was classified with typical Red Latossol Distrophic in flat relief in typical cerrado vegetation. It presented a clayey and very porous texture with good drainage. The second profile was classified as a dystrophic petroplinthic red-yellow Latosol with a clayey texture, with a thick and dense A horizon. This profile was found in change of slope between smooth wavy to wavy. The third profile was established when the slope was uniform in smooth corrugation being classified with typical dystrophic Red Latosol. Featuring clayey texture, very porous and good drainage. The fourth profile studied was classified as Plintossolo Háplico was found wavy relief already near the drainage. It presented clay texture, with horizon A compact. Physical, chemical, mineralogical and spectroscopic analyzes were essential in the characterization and classification of soils studied in the Barbatimão stream microbasin, representative of the stream Extrema basin, DF. The data generated can support information for more detailed pedological mappings in relation to those in the region.

(4603 - 3105) Preliminary characterization study of a Cenozoic-Mesozoic transition layer to improve parameter information for numerical groundwater flux model

Jaqueline Vígolo Coutinho[1]; Edson Wendland[1]

Universidade de São Paulo[1]

Water flux in saturated zone depends on several factors related to hydrological data, land use and soil characteristics such as soil particle size distribution and porosity. These soil features, as well as chemical characteristics, vary with the soil depth which may aid to characterize geologic layers with different ages. On a transition geologic zone, hydrogeological parameters (e.g. hydraulic conductivity) may suffer an abrupt change which highly modifies groundwater flow nets. Usually, numerical models have been used to simulate groundwater fluxes, however there is a lack of substantial soil information to feed the models. This study aims to identify a transition layer from Cenozoic to Mesozoic sediments to improve a conceptual hydrogeological model applied to an outcrop zone of the Guarani Aquifer System, in Brotas, São Paulo, Brazil. Preliminary physical and chemical soil characterization through field observation, soil particle size distribution by the gamma-ray attenuation method, and determination of iron (III) in sulfuric acid analysis were realized on six disturbed soil samples. The samples were collect from 6 depths: i) 0-1, ii) 1-2, iii) 2-3.45, iv) 3.45-4, v) 4-5 and vi) 5-5.45 m. Predominantly sandy soil (mean of 90.57%) was identified at the first meters (i, ii and iii samples). A line of pebbles was identified at depth of 3 m which is common at the bottom of Cenozoic layer. In sequence, there was a thin sheet of mostly sandy soil (96.2%) (iv sample) following by v and vi soil samples with higher iron (III) content (increase of 91.25%) and more clay fraction (21.8%). The latter layers correspond to Mesozoic sediments. Also, it was detected that the water level was above the Cenozoic sediments. Therefore, it was possible to identify soil morphology changes in depth which characterized a transition layer from Cenozoic to Mesozoic sediments, located below groundwater level, which may contribute to improve a conceptual hydrogeological model.

(5322 - 1580) Progress in making fundamental changes to Soil Taxonomy

David Lindbo[1]; Mark Stolt[2]; Joey Shaw[3]; John Galbraith[4]; Marty Rabenhorst[5]; Curtis Monger[1]
USDA-NRCS[1]; URI[2]; Auburn University[3]; VPI[4]; UMd[5]

Soil Taxonomy is the dominant soil classification system in the United States and is recognized by the IUSS as one of the two international classification systems. As the system has developed and grown, it has become increasingly complex, resulting in a document that is difficult for non-trained soil scientists to apply. Thus, few other disciplines use the system to communicate soils information. In 2015 the Soil Science Society of America established the Fundamental Changes to Soil Taxonomy Task Force to address the growing number of issues with using and teaching Soil Taxonomy. The objective of the task force is to facilitate an open and transparent process to develop a suite of fundamental changes to Soil Taxonomy leading to a more user-friendly product that can and will be used by more than just trained soil scientists. The task force has identified and discussed many fundamental changes. Proposals to redefine organic soil materials and reducing the complexity of the oxic and kandic diagnostic horizons have been vetted to the larger soil science community (over 70 soil scientists world-wide have agreed to comment on proposed changes). In addition, there has been significant progress towards developing proposals for a new wet soil order, removing the complexity from the mollic epipedon criteria, and including all climate related components of the classification system at the family level. This poster will highlight these proposals, reasons supporting the changes, and the associated discussion.

(9219 - 2331) Soil potential in agricultural areas of Cerrado in southern Tocantins

Gilberto Coutinho Machado Filho[1]; Weslany Silva Rocha[1]; Marcelo Almeida Mota[1]; Fabiano Rocha da Silva[1]; Osvaldo Jose Ferreira Junior[1]; Tania Rodrigues Peixoto Sakai[1]; Samara Ferreira de Azevedo[1]; Edson Santos Castro[1]; Manoel Mota dos Santos[1]
Universidade Federal do Tocantins[1]

The misuse of land leads to a shortage of resources, enabling destruction, increasing poverty, and do not preventing the permanence of man in countryside, and other social damages. In view of this reality, the study aimed the realization of a soil survey in area of livestock exploration, located in the state of Tocantins. At first, the area was separated according to the soil patches. Trenches were opened to study the physical and morphological characteristics of soil profile. After exposing each soil profile, the horizons were identified, delimiting them using a millimeter grid and determining the thicknesses of each horizon and depth of the soil profile. Also, occurred verification of presence of impediments to roots, structure, drainage, color, consistency, slope and other attributes that helped in the classifications. After which the classification according to the Brazilian Soil Classification System (*Sistema Brasileiro de Classificação de Solos* - SiBCS) and their possible uses, according to agricultural aptitude. The studied area showed four classes of soils, which were classified as *PLINTOSSOLO ARGILÚVICO Distrófico petroplíntico, LATOSSOLO VERMELHO-AMARELO Distrófico típico* and *GLEISSOLO MELÂNICO Ta Eutrófico* with agricultural suitability in subgroups 1(a)bC; 4P; 1aBC and 3(bc), in order. The studied area showed that it could be used for other types of agricultural crops besides livestock.

(3260 - 1981) Soil Series Survey and Research of Zhejiang Province Based on Chinese Soil Taxonomy

Wanzhu MA[1]; Mingkui ZHANG[2]; Xiaonan LV[1]; Zhouqiao REN[1]
Insitute of Digital Agriculture, Zhejiang Academy of Agricultural Sciences.[1]; Zhejiang University[2]

Soil classification is a summary of human understanding of soil. It is not only an important way to further understand the soil, but also the basis for suitable comprehensive utilization of the soils. Therefore, it has always been a great concern of relevant researchers. Currently, there were three major factions in the international soil classification system, namely the soil diagnostic classification of the Unite State (Soil Taxonomy), the soil genetic classification of the Soviet Union and the soil morphogenetic classification of the Western Europe. The quantitative and standardized classification of Soil Taxonomy is now the mainstream of international soil classification. Chinese Soil Taxonomy is based on diagnostic horizons and characteristicses, and guided by the principle of genesis. The project of 'Soil Series Survey and Research of China' is the study of primary soil classification led by Nanjing Institute of Soil Research, CAS, and participated by several soil research institutes and colleges, that was supported by the Chinese National Science and Technology Basic Reaearch Project(2008FY110600). The soil series survey and research project of Zhejiang Province, China was started in 2009 and lasted for 5 years. There were 145 soil profiles investigated, 205 soil profiles observed, 588 soil layers sampled and more than 3500 survey photos shot. Through comprehensive analysis and classification of field observations and laboratory test data and the history of Zhejiang province soil classification data retrieval, the 145 sections respectively belong to 8 soil orders as Anthrosols, Halosols, Gleyosols, Isohumosols, Ferrosols, Argosols, Cambosols and Primosols, 13 suborders, 28 soil groups and 52 subgroups. With the establishment of soil families and soil series classification principles and standards, all these profiles were divided into 106 families, and 144 series were established. For each soil series, details of distributional environment, characteristic amplitude, representative pedon and utilization performance were described. Soil series survey scope covers most of the soils that with large distribute area, high importance of agricultural use and regional characteristics in Zhejiang province, China.

(1575 - 2727) Soil subgroups of the Northeast of Brazil not yet cataloged in the Brazilian System of Soil Classification

Karolina Esther da Silva[1]; Antônio Diomescio da Silva Filho[1]; Estevão Lucas Ramos da Silva[2]; Melissa Correia Lacerda[2]; Arthur Felipe Ferreira de Lima[2]; Joaquim Pedro de Santana Xavier[2]; José Coelho de Araújo Filho[3]; Daniel Chaves Webber[3]; Flávio Adriano Marques[3]
Universidade Federal Rural de Pernambuco[1]; Universidade Federal de Pernambuco[2]; Embrapa Solos UEP Recife[3]

The Brazilian System of Soil Classification (SiBCS) is under continuous improvement since its first edition published in 1999. Advancements in the System have been accomplished with its use in soil surveys, classification and correlation meetings and researches in Soil Science. The objective of this work is to suggest the addition of new subgroups into the SiBCS as a result of studies in the Northeast Region of Brazil. The Coastal Tablelands and surrounding areas of the

Northeast Region of Brazil comprises the study area. The proposal of the new subgroups are based on the morphological, analitical and taxonomic review of 750 soil profiles, comprising 400 soil profiles available from pedological studies published in the 70s and 80s of the past century, and 350 soil profiles of the reconaissance soil survey (1:100,000 scale) under execution in the State of Ceará. The physical and chemical analyses of all soil profiles were made according to the methodology developed and used by Embrapa Soils. The detailed analysis of the 750 soil profiles and the current SiBCS structure showed the necessity of addition of 45 new subgroups to the system. These new subgroups will be distributed as follows: 13 in the order of the *Argissolos* (Ultisols); 3 in the order of the *Cambissolos* (Inceptisolos); 2 in the order of the *Chernossolos* (Molisols); 3 in the order of the *Espodosolos* (Spodosols); 2 in the order of the *Gleissolos* (Aqualfs); 7 in the order of the *Latossolos* (Oxisols); 3 in the order of the *Luvissolos* (Alfisols); 3 in the order of the *Neossolos* (Entisols); 1 in the order of the *Organossolos* (Histosols); 2 in the order of the Planossolos (Alfisols); 4 in the order of the *Plintossolos* (Plinthudults); and 2 in the order of the *Vertissolos* (Vertisols).

(8673 - 2925) *Soils and soil organic carbon stocks in the Restinga de Cabedelo National Forest, in Cabedelo and João Pessoa Municipalities, Paraíba State, Brazil*

Aline Pacobahyba de Oliveira[1]; Maurício Rizzato Coelho[1]; Alexandre Fonseca D' Andrea[2]; Orione Álvares da Silva[3]; Gustavo de Mattos Vasques[1]
Embrapa[1]; IFPB - Campus João Pessoa[2]; ICMBio[3]

National Forests are conservation units of the nature that objective the sustainable multiple use of forest resources and the scientific research. This work aims to provide soil information for part of the Restinga de Cabedelo National Forest (Flona Cabedelo), specifically on taxonomic soil classes and soil organic carbon stocks (CS). The Flona Cabedelo is located in the municipalities of Cabedelo and João Pessoa (PB) and encompasses an area of 114.34 ha. Conventional methods were used to soil survey of the all area under coastal sandy plain vegetation (*restinga* vegetation) and a small area of mangrove. The carbon stock (CS) was to assess only under *restinga* vegetation at 0-20 cm and 0-100 cm depths using kriging. The results showed a close soil-sediment-vegetation relationship in the area: *Neossolos Quartzarênicos* are the unique soil classes under *restinga* vegetation. They occupy about 58 ha (91 % of the area) and are related to the sandy sediments of holocene marine terraces. The rest of the area is strongly influenced by riverine and marine tides, which can cause sulfidic, saline, sodic, gleyzic and lithologic discontinuity features in soils. The presence and intensity of one or more of these features in the soil are related to the current and past hydrological dynamics, which shaped the local relief, causing subtle differences in elevation at short distances, often defining the soil class, drainage regime and vegetation. At the lower elevations under permanently flooded salt marsh, the *Gleissolos Tiomórficos* predominate. As the landscape rises subtly, the soils are progressively less poorly drained, predominantly non-sulfidic, but still salic or solodic, and saline, and still present lithological discontinuities within 100 cm depth. In these areas, halophilic grass vegetation with a low density of individuals occur on *Gleissolos Sálicos* and *Neossolos Flúvicos*. The CS up to 100 cm depth in the *restinga* vegetation area ranged from 4.89 to 43.79 Mg ha^{-1} (mean of 23.20 Mg ha^{-1}), with approximately 50 % of this stock concentrated in the upper 20 cm. There was no clear relationship between soil classes and EC. Higher CS values for both depths were observed in the eastern part of the study area, possibly due to the stronger edge effect relative to the other parts of the remnant *restinga* vegetation.

Keywords: Soil-landscape relationship; coastal sandy plain; mangrove soils, *restinga* vegetation

(2229 - 2675) Soils of the Brazilian *Quadrilátero Ferrífero*, Minas Gerais state, under different native vegetation and parent materials

Maurício R Coelho[1]; Gustavo M Vasques[1]; Diego Tassinari[1]; Zélio Resende de Souza[2]; Aline P de Oliveira[1]; Fátima M S Moreira[2]
Embrapa Solos[1]; Universidade Federal de Lavras[2]

The *Quadrilátero Ferrífero (QF)*, in the Brazilian state of Minas Gerais, is a region of great environmental diversity with strong potential for mining. Consequently, mining-related studies have been carried out, whereas soil-related studies are less common. This study aims to characterize the soils and evaluate their relation to the relief, geology and native vegetation in three representative sites of the *QF* region in Minas Gerais state: Córrego do Meio mine, municipality of Sabará; Miguelão mine, municipality of Nova Lima; and Córrego do Feijão mine, municipality of Brumadinho. The 28 soil profiles are allocated in five toposequences, encompassing all local physiographic variations. In most toposequences, *Cambissolos Háplicos Distróficos latossólicos* (Cambisols) were the dominant soils in Sabará, occurring on metasedimentary rocks, hilly relief with concave curvature, and under semi-deciduous forest and savanna vegetation. They are soils with low fertility, usually aluminic, stony at the surface when occurring under savanna, with high silt content, often superior to clay, and have medium (savanna) or clay (forest) texture. *Latossolos Vermelhos Distróficos cambissólicos* or *húmicos* (Ferralsols) are also present in Sabará on the same parent materials, both under semi-deciduous forest and savanna, and always located at the footslopes on hilly relief. In Brumadinho, *Latossolos Vermelhos* or *Vermelho-Amarelos* (Ferralsols) occur under semi-deciduous forest on granite parent material on gently undulated relief with concave curvature. These are the most evolved non-ferric soils observed in this study, and are located at the upper third of the only toposequence visited in Brumadinho. Below this portion of the slope, *Cambissolos Háplicos* or *Húmicos* (Cambisols) vary in classification and attributes as a function of the local relief ranging from gently undulated with convex curvature to undulated with concave curvature. In Nova Lima, *Plintossolos Pétricos* (Petroplinthic Plinthosols) are the only soils present in the *canga* fields in the visited toposequence, and are originated from the weathering of the ferruginous rocky outcrop. They have more than 70 % in volume of petroplinthite beginning at different depths in their profiles, and their physical and chemical attributes vary much across the landscape. Soil and relief vary at short distances in Nova Lima originating different physiographic, vegetation types and microhabitats for the local fauna and flora.

(7884 - 452) Soils of the hydrographic bowl of the Uberaba river

Joao Chrisostomo Pedroso Neto[1]
EPAMIG[1]

The catchment area of the Uberaba river includes tropical soils, highly weathered and with great agricultural potential, which makes the Uberaba municipality the largest state producer of corn and soybean. However, much information about the limitations and potentials of these soils remains beyond the reach of farmers. Thus, the work was conducted in the years of 2009 and 2010, with the objectives of geological characterization of the area; detailed survey of soils of the basin and classification of these soils, using the Brazilian Soil Classification System. Fieldwork consisted of the identification and characterization of the areas, as well as the collection of materials for analysis. According to the results obtained, it can be concluded that:

near the river banks, basaltic rocks with gray to black coloration were found, giving rise to clayey soils, low acidity and medium to high natural fertility; The upper edges of the basin consist of volcanic sandstones, with medium granulation and small pebbles, besides debris from the erosion of pre-existing volcanic rocks. They originate soils with frank to sandy texture, with medium acidity and medium to low natural fertility; It was observed predominance of soils of the order LATOSSOLO, in the RED and RED-YELLOW suborders and dystrophic, eutroferric and dystroferric classes. To a lesser extent, soils of the orders CAMBISSOLO, GLEISSOLOS, NEOSSOLOS and ARGISSOLOS were observed.

(5738 - 577) Carbon stock of a Red-Yellow Latosol under different plant coverages

Victor Barros Damacena[1]; Giovana Fornaciari Moreira[1]; Thalia Inês Aleixo Barbosa[1]; Jeferson da Silva Muniz[1]

Instituto Federal de Mato Grosso - Campus Profº Olegário Baldo[1]

Understanding ecological dynamics in ecosystems, especially soil and carbon, is extremely important for their maintenance and restoration, as well as to promote management strategies. In this context, this work aimed to quantify and evaluate the carbon stock of a dystrophic red-yellow latosol under different vegetation cover. The study was conducted at the Federal Institute of Mato Grosso - Prof. Olegário Baldo Campus (Cáceres-MT, Brazil), whose geographical coordinates are latitude 16º07'43.9 ", longitude 57º41'09.5" and elevation of 117 m. The climate is of tropical savannas with wet summer and dry winter (Awi), according to the classification of Köppen, with average annual temperature varying between 23 ° C and 25 ° C. Four treatments were evaluated: T1- remaining forest savanna; T2- native forested savanna; T3- continuous pasture of Brachiaria brizantha and T4- silvipastoril integrated system. Soil sampling was done by collecting four samples in each treatment, at depths of 0-10, 10-20, 20-40 and 40-60 cm, totaling 64 samples (undeformed). The total soil carbon content was defined by the oxidation of organic matter with $K_2Cr_2O_7$ in sulfuric medium. The carbon stock in each layer of soil was determined by the expression: C content (g kg^{-1}) × ds × e, where ds = soil density (kg dm^{-3}) and e = soil layer thickness cm). The experimental design was a randomized complete block design, in a 4x4x4 factorial scheme, with 4 treatments, 4 depths and 4 replications. The data were presented to the analysis of variance and their means were compared by the Tukey test at 5% of probability, using the R software. The divergence of the sampling depths shows that the highest values are found in the first layer 0-10 cm. When the treatments at the different sampling depths were analyzed, there is a reduction in carbon stock with depth addition. The highest values were obtained for depth 0-10 cm in the soil under the native forested savanna.

(9445 - 2393) Estimation of carbon stock and nitrogen in the semiarid region

Isnara Regina Assunção Medeiros[1]; Adilson Alves Costa[1]; Bruno de Oliveira Dias[1]; Luiz Fernando Carvalho Leite[2]; Henrique Antunes de Souza[2]

Federal University of Paraíba[1]; Embrapa Meio Norte[2]

The management and use of the soil in semi-arid areas, over time have caused significant decreases of carbon (C) and nitrogen (N) in these soils, due to the fact that it is a region where normally enough conditions are found favorable to the different decomposition processes of MOS, with man being the main agent responsible for these phenomena. The use of mathematical models can be a useful tool to improve understanding and to assist in more compatible practices of land use and management of the characteristics of this ecosystem. The Century model has been used in several ecosystems, but the model has not been adapted yet to simulate ecosystems of dry tropical forests, such as the caatinga in northeastern Brazil. With this, the objective of the present work was to validate the Century model for simulations of C and N stocks in caatinga areas under different cropping systems. The data used for the calibration of the model were obtained in field plots with preserved vegetation, in the municipality of São João do Piauí, located in the semiarid region of Piauí, Brazil, under the dominance of the Caatinga biome. For the validation, we used data from the municipality of Santa Teresinha-PB, with a distance between them of 740 km and similar soil-climatic conditions, but different soil types. Thus, it was possible to analyze the behavior of the C and N stocks of the soil. In the native vegetation areas, simulated values of C and N stocks (23.76 and 5.27 Mg ha^{-1}) were similar to the values observed in the field (25.72 and 5.77 Mg ha^{-1}) , where the differences between simulated and found values are well below the maximum allowed which is 20%. Therefore, the Century model can be used to simulate the C and N cycling in the soil system, in addition to being able to present future scenarios for improvements in caatinga areas of the Brazilian semiarid region.

(9032 - 704) Multivariate analysis of CO_2 emissions in surface horizons under different types of soil cover.

Cássia Barreto Brandão[1]

Universidade do Estado do Rio de Janeiro-UERJ[1]

The analysis of CO_2 emissions from soil in recent years has become an object of study, especially in tropical forests, in an attempt to understand the participation of these ecosystems in the global carbon cycle. Thus, this study proposes to estimate the CO_2 efflux in surface horizons in different areas under the domain of the Atlantic forest in the city of Santo Antonio de Padua-RJ. For this, the closed chamber with infrared sensor technique was used for three days of summer (13/01-15/01) and winter (28/07-30/07) of 2015 in four different types of areas (A1- area reforested ; A2- deforested areas ,A3- area in recovery, A4- control area) in simultaneous analysis in the morning (08:00) and afternoon (15:00) periods. Associated with the analyses of CO_2 were collected meteorological and pedological information from selected areas, in order to establish correlations statistics through Multivariate analysis of main components. A seasonal variation of CO_2 efflux was observed in the results obtained, with the highest effluxes in the summer and the lowest in the winter, as well as the highest values at 3 p.m. and the lowest values at 8 a.m. The results of the main components analysis showed an opposite behavior between the deforested area and the control area, and as the chemical parameters were more adequate, the lower the CO_2 emissions and vice versa. In the ACP, the first three components together explained 85.4% of the total variance of the data set, and of the fifteen variables selected, only five were more important, especially the role of phosphorus, base saturation, organic matter, CTC and clay, the latter in positive association with the emissions and the others in inverse relation. The reforested and recovering areas were more influenced by the atmospheric and physical parameters of the soil, and the deforested area was more induced by air and soil temperature and by the clay content. Thus, this study highlights the importance of preserving

native forests as well as the recovery of degraded areas, since deforested areas contributed more to emissions than to carbon sequestration, and the most preserved ones, such as the control area of this study contributed more to the sequestration than to the CO_2 emissions to the atmosphere.

Keywords: Emissions; CO_2, soil; multivariate; surface horizons.

(4985 - 2080) Multivariate approach of soil carbon flow in sugarcane areas in Brazil

Paulo Alexandre Silva[1]; Bruno Horschut de Lima[2]; Alan Rodrigo Panosso[2]; Newton La Scala Junior[1]; Nelson José Peruzzi[1]; Fabio Roberto Chavarette([2]

Paulista State University/UNESP, s/n Path of Access Prof. Paulo Donato Castellane, Jaboticabal-SP, Zip: 14884-900[1]; Paulista State University /UNESP, 56 South Brazil Av., Single Island – SP, Zip: 15385-000, Brazil[2]

In the year of 2015 the CO_2 concentrations in the atmosphere reached record levels of 400 parts per million (ppm) that contributed to the formation of the El Niño phenomenon, causing the devastation of several areas in the world in 2015 and 2016. Therefore, the process of CO_2 emission soil (FCO_2) it comes from the interactions of the physical, chemical and biological attributes of the soil. The amount of organic carbon, nitrogen content, C/N ratio, temperature and moisture influence the stability of carbon in agricultural areas, expressed by the soil carbon decay constant (k). Aim: The objective of this work was to determine the multivariate structure of the spatial variability of the carbon stability and its relationship with the soil attributes in the areas of sugarcane. Material and Methods – The data were collected in sugarcane cultivation areas in the green management system, located in the cities of Guariba and Pradópolis (São Paulo, Brazil) (2008, 2010 and 2012) and city of Aparecida do Taboado (Mato Grosso do Sul, Brazil) in the year of 2014. Soil samples were collected at depth of 0 to 0.10 m to determine soil attributes: Moisture (Us), air-filled pore space (PLA), macroporosity (Macro), available Phosphorus content (P) and cation exchange capacity. (CTC). The carbon stock was calculated at a depth of 0.10 m and the decay constant (k) was calculated based on the ratio between the C-CO_2 emissions and the soil carbon stock. Results and Discussion - Principal component analysis (ACP) indicated that the first two major components (CPs), CP1 and CP2 explained 55% and 68% of the total variability in the dataset, respectively. In 2008 the values of the factor k ranged from 1.4 to 3.9 × 10^{-3} times^{-1}, with carbon stock (EstC) ranging from 7.2 to 8.7 Mg ha^{-1}. In the year of 2010 the values of factor k ranged from 0.65 to 1.65 × 10^{-3} time^{-1}, with carbon stock (EstC) varying from 10 to 16 Mg ha^{-1}. Already in the observed values of the factor k were between 1 and 2.40 × 10^{-3} time^{-1}, with carbon stock (EstC) ranging from 6.2 to 10.2 Mg ha^{-1}. For 2014, in Aparecida do Taboado (MS) the values of factor k were between 2 and 3,15 × 10^{-3} times^{-1}, with carbon stock (EstC) varying from 5.8 to 7.05 Mg ha^{-1}. In the same area, there were changes in the spatial patterns of the factor k, there are regions with potential for accumulation or carbon emission in areas of sugarcane, defining thus, specific management regions within the same area.

(1965 - 558) Prediction and mapping of soil carbon using Vis-NIR spectroscopy and magnetic susceptibility

Angélica Santos Rabelo de Souza Bahia[1]; José Marques Júnior[1]; Newton La Scala Júnior[1]; Carlos Eduardo Pellegrino Cerri[2]

State University of São Paulo (FCAV/UNESP)[1]; São Paulo University (ESALQ/USP)[2]

The development of prediction models to represent the spatial variability of soil carbon is essential for strategic planning from agricultural emissions. For this it's necessary the use of fast, accurate and low cost tools for soil carbon prediction, allowing the detailed mapping of large areas, since with conventional methods this task becomes difficult due to the large number of samples required. Thus, this study aimed to evaluate the capacity for predicting soil carbon and their spatial variability using visible and infrared (Vis-NIR) spectroscopy and magnetic susceptibility (MS). Soil samples (0-25 cm depth) were collected at 446 sites in the sandstone-basaltic transition, in the geomorphological unit of the Western Paulista Plateau, São Paulo, Brazil. The Vis–NIR spectra of each soil sample were measured in laboratory using a Lambda 950 UV/Vis/NIR PerkinElmer spectrophotometer. The MS of the soil samples was measured on the Bartington MS2 sensor, coupled to the Bartington MS2B magnetic sensitivity sensor. To develop models based on soil spectra and laboratory data, the partial least squares regression (PLSR) was used. Already, the MS-based models were calibrated by linear regression between magnetic and laboratory data. Good prediction accuracy parameters were obtained with Vis-NIR (R^2 = 0.88, RRMSE = 0.25), VIS (R^2 = 0.82, RRMSE = 0.33) and MS (R^2 = 0.79, RRMSE = 0.15). However, the more accurate results between the observed and predicted values (R^2 = 0.83, RRMSE = 1.18) were found for soil carbon estimated by MS. These results revealing that these tools are good predictors of key attributes of studied soils, even with wide chemical and mineralogical variation. Soil carbon maps predicted by Vis-NIR spectroscopy and MS shows similarity to the interpolated maps with the field observations. These are promising results once that Vis-NIR spectroscopy and MS are fast, cheap and non-destructive tools, allowing the prediction of a large number of samples. Therefore, both tools are very attractive for the strategic planning of land use and occupation, environmental monitoring and detailed mapping of large areas.

(7213 - 2282) Prediction models development for organic carbon and total nitrogen in Mexican forest soils through VIS-NIR spectroscopy

Esquivel-Valenzuela Berenice[1]; Cueto-Wong José Antonio[2]; Cruz-Gaistardo Carlos O.[3]; Guerrero-Peña Armando[4]; Jarquín-Sánchez Aaron[5]; Burgos-Cordova David A.[6]

Universidad Autónoma Chapingo[1]; Instituto Nacional de Investigaciones Forestales, Agrícolas y Pecuarias[2]; Instituto Nacional de Geografía y Estadística[3]; Colegio de Postgraduados[4]; Colegio de la Frontera Sur[5]; Insituto Nacional de Investigaciones Forestales, Agrícolas y Pecuarias[6]

The knowledge of the soil physical and chemical characteristics, allows us to make better decisions about its management and conservation. Commonly, soil properties are determined by laborious and costly methods that generate chemical residues that can cause environmental pollution. NIR spectroscopy is a non-destructive, low cost, and minimum sample management that has the potential to predict various soil properties with the reading of a single spectrum. The objective of this research was to create a prediction model for the organic carbon and total nitrogen content in soil samples from different regions of Mexico using VIS-NIR spectroscopy. A total of 599

samples of forest soils were analyzed. Total carbon (TC) and total nitrogen (TN) were obtained by the dry combustion method in a Flash 2000 Total Elemental Analyzer (Thermo Scientific). Inorganic carbon (IC) was calculated from the total carbonates content determined by the Bernard calciminer method. Organic carbon (OC) content was then calculated by substracting IC from TC. The development of the NIR model was carried out in a NIR Feed and Forage 6500 (FOSS) equipment. The spectral data was obtained with the software ISIscan v3.1 in a wavelength range of 400 to 2500 nm. The calibration equation was obtained by MPLS regression (Modified partial least squares) with the software winISI v4.20. The validation of the model was carried out with 46 samples independent of those used for the calibration. The accuracy of the model was evaluated based on the coefficient of determination (R^2) and the relationship between the standard error of prediction and the standard deviation (RPD). The values of R^2 in the calibration were 0.93 for OC and 0.88 for TN, respectively. In the case of the RPD, the values were 2.69 for OC and 2.05 for TN. According with several references, the models were classified with a good prediction capacity. In the case of validation, the values of R^2 were greater than 0.9 and RPD values greater than 2. Our results support that the use of NIR spectroscopy to determine soil TN and OC fast and accurate, reducing the time and cost necessary to process the sample, and with minimum waste generation.

(7363 - 1444) Scaling impacts on soil organic carbon stocks and its environmental controllers

Kabindra Adhikari[1]; Umakant Mishra[2]; Phillip R. Owens[3]; Skye Wills[4]; Zamir Libohova[4]
University of Arkansas, Department of Crop, Soil, and Environmental Sciences/USDA-ARS, Dale Bumpers Small Farms Research Center[1]; Argonne National Laboratory, Environmental Sciences Division[2]; USDA-ARS, Dale Bumpers Small Farms Research Center[3]; USDA-NRCS, National Soil Survey Center[4]

Achieving an accurate representation of the spatial heterogeneity of existing soil organic carbon (SOC) stocks in Earth system models (ESMs) is a prerequisite for reducing the existing uncertainty in predicting future carbon–climate feedbacks. Scaling properties of SOC stocks and its environmental controllers can help in appropriate representation of SOC spatial heterogeneity in ESMs. We quantified scaling impacts on SOC stocks and its environmental controllers at a regional scale in continental US. We selected Temperate Prairies Ecological Region (522,333 km^2 area) for this study, and compiled 428 pedon data of topsoil (0-30 cm) SOC stocks (Mg ha^{-1}) from Rapid Carbon Assessment (RaCA) project of the USDA-NRCS. Environmental variables of SOC predictors included terrain parameters derived from a digital elevation model (DEM), precipitation, temperature, incoming solar radiation, potential evapotranspiration, land use/land cover, satellite vegetation indices, soil types, soil temperature and moisture regime, parent material, geological age and bedrock types, and the geographical coordinates of the pedons. Terrain attributes were derived from a 10 m national DEM, and were subsequently aggregated to 30m, 90m, 200m, 500m, 1km, 2km, 5km, and 10km, grid size/scale. All the remaining variables were resampled to the similar spatial scale. Significant environmental controllers were identified at each scale using best subset regressions and SOC stocks at each scale were predicted using geographically weighted regression (GWR) model. The scaling impacts on environmental controllers were identified by plotting the median GWR coefficients (βs) of significant environmental controllers with scale. The predicted variance of SOC stocks at each scale was plotted with scale to determine the scaling property of SOC stocks. We expect that the strength of environmental controllers on SOC stocks changes with scale, and beyond certain scale, there is no significant influence. This study will determine the scaling properties of SOC stocks and its environmental controllers which inform the land surface models.

Brasil, Ilha Solteira,SP, 15385-000, Brazil.[3]; FCAV/UNESP – College of Agricultural and Veterinarian Sciences, São Paulo State University[4]

The identification of agricultural areas with the same characteristics is essential for studies related to soil carbon dioxide emissions (FCO_2) and soil carbon stock. To identify areas with the same characteristics the study of spatial variability of soil attributes has been adopted. This study aimed to describe the spatial variability of soil carbon dioxide emission and soil carbon stock in a silvopastoral system (consortium of *Myracrodruon urundeuva* and signalgrass with more than 30 years of implantation) in the Cerrado region located in the state of Mato Grosso do Sul. The spatial variability of FCO_2, carbon stock, temperature, moisture and chemical attributes was evaluated in a DYSTROPHIC HAPLUSTOX typical clayed. To study the relationship between FCO_2 and soil carbon stock the chemical and physical attributes were determined in the layer of 0-0,10 m. The spatial dependence of the variables was taken by experimental variogram analyses, the maps of the study area were made by sequential Gaussian simulation (sGs) and ordinary Kriging, the accuracy and goodness of reproduction of the probability density of the interpolation methods were evaluated by the G statistic. The FCO_2 average in the rain period was 4,62 µmol m^{-2} s^{-1} meanwhile in the dry period it was 2,96 µmol m^{-2} s^{-1}. The exponential semi-variograms model was fitted to FCO_2, for carbon stock and moisture the Spherical model was fitted. The range for FCO_2 was 74,50 m in the rainy period and 86,90 m for dry period, for carbon stock the range was 24,89 m. The FCO_2 showed a strong degree of spatial dependence justifying the use of geostatistic thecniques on this study. There wasn't correlation between the FCO_2, temperature and moisture maps. The higher values showed in the G statistics in the accuracy graphics for sequential Gaussian simulation indicate a good proximity of the simulates values and real values, like that this method is more reliable and accurate in the creation of maps.

Keywords: Keywords: soil respiration, geostatistic, sequential Gaussian simulation, semi-variogram.

(2941 - 2298) Spatial variability of soil carbon pools in the andean grassland (páramo ecosytem)

Pablo Armando Alvarez Figueroa[1]; Gabriela Moreno[1]
National University of Loja[1]

The paramo has great potential of carbon storage, due to the low rates of mineralization and high recycling of nutrients, as a consequence of its low temperatures. The present research was carried out with the purpose of quantifying the total carbon (soil, necromass and soil) contents of the PNP paramo ecosystem and its spatial distribution, for which 80 temporary plots of 1m2 were installed, where the content was quantified of carbon in biomass and necromass by the destructive method. To determine the carbon content in the soil, two samples of soil were taken, one disturbed to determine the carbon content in the soil by the modified method of Walkley and Black (1947) and the second sample in a Kopecky cylinder to determine the bulk density and hydrophysical soil constants. To determine its spatial distribution, the IDW interpolation method was used in the ArcGis 10.4 software. The average carbon content was 163.11 t ha^{-1}, where the soil contributed 90% of total carbon with positive correlation (r = 0.99), whereas that the vegetation did not significantly influence in its content. Spatially the highest total carbon contents were found in the lake systems named "Lagunas del Compadre", and the lowest contained in the north and south ends of the paramo ecosystem. The external variables that influenced its carbon content were: altitude (rs = 0.45), temperature (rs = -0.47), soil humidity at field capacity (rs = 0.64) and saturation (rs = 0.79).

(2914 - 2346) Spatial variability of soil CO_2 emission by Sequential Gaussian Simulation in the Cerrado of Mato Grosso do Sul, Brazil

Ludhanna Marinho Veras[1]; Vivian Aparecida Brancaglioni[2]; Maira Caroline Terçariol[1]; Carla Regina Pinotti[3]; Rafael Montanari[3]; Newton La Scala Junior[1]; Alan Rodrigo Panosso[3]

FCAV/UNESP – College of Agricultural and Veterinarian Sciences[1]; ESALq USP - Luiz de Queiroz College of Agriculture, University of São Paulo[2]; FEIS/UNESP – College of Engineering of Ilha Solteira, Sao Paulo State University[3]

The soil CO_2 emission (FCO2) shows high spatial variability which is strongly influenced by soil attributes. The characterization of this spatial variability is important because it is a main component of the terrestrial carbon cycle. The objective of this study was to identify and characterize the heterogeneity of CO_2, physical and chemical attributes of the soil in an area under cultivation of sugarcane and soybean in the east state of Mato Grosso do Sul, Brazil. Two experinments were conducted for this study, the first one with the soybean (*Glycine max* - L. Merril) in the experimental area of the College of Engineering of Ilha Solteira, city of Selviria in the state of Mato Grosso do Sul. The second study was conducted in the commercial planting area of sugarcane (*Saccharum* spp.) in the city of Aparecida do Taboado in the state of Mato Grosso do Sul. The soil of the areas were classified as dystrophic haplustox typical clayed, being the natural vegetation of the Cerrado. For the sampling to the initial characterization of physical and chemical attributes of the soils were conducted in the 0-0,20 m and 0,2-0,40 m depth. The CO_2 emission and soil temperature were verified by LI-COR (LI-8100), also the soil moisture was determined by TDR (Time Domain Reflectometry). The spatial dependence of the variables were made through the geostatistical analysis from the adjustment of theoretical mathematical models to the experimental variograms and the construction of maps of spatial patterns by the ordinary kriging technique (OK) and Sequential Gaussian Simulation (SGS), accuracy and goodness of reproduction of the probability density of the interpolation methods were evaluated by the G statistic. Higher emissions were found in the soybean area for temperature (27,38 ^{O}C) and soil moisture (17.6%), this result may be linked due to the values being higher when compared to the same variables in the sugarcane area, soil temperature (21,79 ^{O}C), and soil moisture (9,46%). The spatial variability structure of soil CO^2 emissions varied between the study days for the two areas evaluated. The sequential Gaussian simulation showed better performance in the soybean area with variation between 0,80 and 0,91, being superior and more homogeneous values of G statistic, when compared to the area of sugarcane with values between 0,51 and 0,88.

(3093 - 2621) Spatial variability of soil organic carbon from different management systems in the Cerrado - Sete Lagoas, MG

Matheus Paula Fialho de Carvalho[1]; Raphael Hosken[1]; André Thomazini[1]; Cláudio Manoel Teixeira Vitor[1]; José Carlos Moraes Rufini[1]

Universidade Federal de São João del-Rei[1]

Soil organic matter is highly sensitive to changes through management or land use, being widely used as an indicator of sustainability. The conversion from natural to agricultural systems has largely contributed to the degradation of Brazilian Cerrado. In this case, the impact of land management can be assessed by applying an efficient soil quality indicator coupled with digital mapping techniques. Thus, the objective of the study was to determine spatial variability of soil organic carbon from different management systems in the Cerrado region. The study was carried out in the experimental area of the Federal University of São João Del-Rei, Sete Lagoas, MG. In November 2017, a regular 60-point grid, with a minimum and maximum separation distance of 5 and 100 m was installed. In each grid-point, one single soil sample was taken at 0-10 cm depth. The entire area comprises plots with: Cerrado trees, pasture and fruits. Total soil organic carbon was determined according to Walkley–Black method. The spatial variability was assessed by producing an experimental semivariograma in order to verify the occurrence of spatial dependence. Maps of spatial distribution were generated using ordinary kriging interpolation method. Spatial variability pattern was best established using isotropic model (exponential model), with a range of 12 m, with low spatial dependence index (>75%). Results suggest that higher soil organic carbon contents were observed in the pasture area 60 g kg^{-1}. On the other hand, the most intensive land (fruits) used has been contributing to decreasing soil organic matter. By using the geostatistical technique, the spatial distribution of soil organic carbon can be easily observable, indicating where soil quality is rapidly decreasing. In this case, besides contributing with erosive processes, the depletion of the soil organic matter also contributes to the CO_2 emissions, directly linked with climate issues. In this study, pasture system provides a more efficient incorporation/preservation of organic matter in the soil. The lack of vegetation residues on the soil surface in the fruit cultivation accelerated mineralization, impairing the maintenance of soil quality.

(2456 - 2398) Spatial variability of soil organic carbon in anthropized areas of the Cerrado in Sete Lagoas, MG

Paulo Antonio Coura[1]; André Hirsch[1]; André Thomazini[1]; Samuel Petraccone Caixeta[1]

Universidade Federal de São João del Rei - Campi Sete Lagoas[1]

Surface soils (0–30 cm depth) store almost half of soil organic carbon

and up to three times of the above-ground carbon stored on vegetation. This soil layer is strongly vulnerable to carbon losses, mainly due to oxidation processes and erosion, as a consequence of climatic changes and land management practices. However, carbon distribution on landscapes is highly heterogeneous. With this, through the application of spatial statistical analysis (geostatistical techniques), factors leading to current carbon dynamic can be properly determined and assessed, helping the correct use and management of ecosystems, especially in tropical zones. The objective of the present study was to map and to determine spatial variability of soil organic carbon of the UFSJ boundary (*campi* Sete Lagoas, MG, Brazil). In August 2017, a regular 29-point grid, with a minimum and maximum separation distance of 100 and 1000 m (one point per hectare) was generated in the *QGIS 2.14 Essen* software. In each grid-point, one single soil sample was taken at 0-5 cm depth. Total soil organic carbon was determined according to Walkley–Black method. The spatial variability was assessed by producing an experimental semivariograma in order to verify the occurrence of spatial dependence. Maps of spatial distribution were generated using ordinary kriging interpolation method. Spatial variability pattern was best established using isotropic model (spherical model), with a range of 120 m, with low spatial dependence index (>75%). Greater organic carbon contents were observed in areas with Cerrado fragments, ranging from 50 to 70 g kg^{-1}. In this area, the A horizon is preserved, storing more carbon than experimental areas of the University, as well as where vegetation was removed due to the human activities. We observed organic carbon contents varying from 20 to 40 g kg^{-1} at anthropized areas, suggesting a degradation of the A horizon. Results evidence that human activity has been contributing to the degradation of soil organic matter in Cerrado areas. Thus, it's important to point out the importance of soil organic carbon preservation at this Brazilian biome, in order to improve soil quality and reduce greenhouse gas emissions.

(8125 - 392) Spectral range (FRX-VIS-NIR-SWIR-MIR) interaction on the organic matter prediction

Diego Fernando Urbina Salazar[1]; José A. M. Demattê*[2]; Luiz E. Vicente[3]; Clecia C. Guimaraes[1]; Arnaldo Barros de Souza[1]; Leonardo Inforsato[4]; Hudson Wallace Pereira de Carvalho[4]
Department of Soil Science, College of Agriculture Luiz de Queiroz, University of São Paulo[1]; Department of Soil Science, College of Agriculture Luiz de Queiroz, University of São Paulo*[2]; Satellite Monitoring Unit, Brazilian Corporation of Agricultural Research-EMBRAPA[3]; Center of Nuclear Energy in Agriculture, University of São Paulo[4]

Organic matter (OM) is an important indicator of soil quality and, therefore, must be quantified quickly and efficiently. Besides traditional methods, and countless studies with sensors have been advanced, but few integratively. This work aimed to develop models for OM content prediction using the FRX-VIS-NIR-SWIR-MIR regions separately and together. A total of 22 soil samples were collected in the state of São Paulo, Brazil (80-100 cm). Each sample was oven dried at 45 ° C for 48 hours, milled and sieved to a diameter of 0.150 mm and had a series of 8 treatments, considering the addition of humified organic material (MOH) in different amounts (0, 5, 10, 15, 20, 30, 40, 50 g). Afterwards, the treated samples were read in the sensors FIELDSPEC-PRO (VISNIRSWIR), ALPHA FTIR (MIR), and portable FRX for the extraction of the spectral responses. For the creation of the best model by Partial least squares regression (PLSR), 70% of the samples were used for calibration and 30% for validation and different preprocessing techniques were used: transformation of the reflectance data for absorbance, smoothing, first derivative Savitzky-Golay (SGD), standard normal variation (SNV) and multiplicative signal correction (MSC). The spectral data were tested separately and together using the absorbance transformation as a fixed preprocessing to which other was added. The calibration results for all models presented R^2 greater than 0.8 for the best preprocessing, which varies according to the spectral region analyzed. The best validation occurred for the preprocessed model with only absorbance and smoothing using the VIS-NIR-SIWIR-MIR spectral regions and presented values of R^2, RMSE and RPIQ equal to 0.8, 6.8 and 4.55, respectively. When using all the regions (RX-VIS-NIR-SWIR-MIR) simultaneously, validation values similar to those cited above (R^2 = 0.8, RMSE = 6.96 and RPIQ = 4.45)were obtained, indicating that the X-ray region does not influence the improvement of the prediction of OM. Models created only with a the spectral x-ray region presented the worst validation values. OM considerably influences on the spectral response from visible to medium infrared regions and, in this manner, they can be used for more accurate prediction of its values.

(4103 - 2573) Total soil organic carbon in integrated systems in the Brazilian Amazon

Rodrigo da Silva Ribeiro[1]; Marilia Locatelli[1]; Pedro Gomes da Cruz[1]; Alaerto Luiz Marcolan[1]; Henrique Nery Cipriani[1]; Alexandre Martins Abdão dos Passos[2]
EMBRAPA RONDÔNIA[1]; EMBRAPA MILHO E SORGO[2]

Amazon The Integrated Crop-Livestock (ICL) or Crop - Livestock-Forestry (ICLF) systems are alternatives for soil quality recovery in degraded areas of the Amazon, and also help the development of agriculture without incorporating new forest areas into the production. The objective of this work was to evaluate total soil organic carbon content (TSOC) in ICL and ICLF systems in Amazonia. The experiment was conducted at Embrapa Rondônia, in Porto Velho - RO at 8º 47 '42''south latitude and 63º 50' 45 '' west longitude, since 2008/2009 agricultural period. The soil of the experimental area is a plinthic dystrophic Red-Yellow Oxisol of clay texture. The ICLFS has two eucalyptus clones (VM01 and GG100) in various spatial arrangements between plants and tiers. Tiers are composed of four planting lines, spaced at 3.5 m. The soil was managed with succession of soybean (*Glycine max* cv. BRS Valiosa), maize (*Zea mays* cv. LG6038), intercropped with Xaraes grass (*Urochloa brizantha* cv Xaraés). Soil sampling took place in 2014 in May (dry period) and November (rainy season). The sampling points were determined in a regular grid of 30 x 30 m, in the depths of 0 to 10 and of 10 to 20 cm. The organic matter data for TSOC calculation were obtained according to the method proposed by Walkley & Black. The ICL and ICLF systems were compared using the t-test (ICL n = 56 and ICLF n = 64). TSOC was higher in the ICL system when compared to the ICLF system ($p \leq 0.05$). The ICL system in the rainy season presented TSOC values of 21.71 and 30.16 g kg^{-1} and the ICLF values of 16.41 and 16.84 g kg-1, at depths of 0 to 10 and 10 a 20 cm, respectively. There were differences in the ICL and ICLF systems ($p \leq 0.05$), in both depths evaluated. The ICL system presented a TSOC increase of 8.7 and 64.2% at depths of 0-10 and 10-20 cm. For the ICLF system, there was a reduction of TSOC of 1.5 and 2.6% in the depths of 0-10 and 10-20 cm. The ICL system promoted increase of TSOC in the topsoil from 0 to 20 cm.

(8771 - 2280) Unraveling the fate of organic carbon in plinthic horizons upon flooding

Benini, Natalia Silva[1]; De-Campos, Alfredo Borges[1]
Institute of Geosciences, University of Campinas (UNICAMP)[1]

Flood irrigation projects for agricultural purpose have been implemented in Plinthosols in Central Brazil. Little is known about the geochemical transformations that can occur in these soils during flooding, especially those related to the fate of organic carbon compounds which can potentially solubilize and migrate in the soil profile. Plinthosols' diagnostic Fe and Al-rich plinthic horizons may control the mobilization of organic carbon but this hypothesis has not been tested. The objective of this study was to determine the changes in concentration of dissolved organic carbon (DOC) related to plinthic horizons when these horizons undergo prolonged flooding. Samples of plinthic horizons were collected at 60cm depth (Bf1) and 100cm depth (Bf2) from an area under flood irrigation for 18yr located in the district of Luis Alves do Araguaia, state of Goias, Brazil. The soil organic matter content was 2 g/dm^3 for both horizons. After sieving (<2mm), soil samples were incubated in triplicate under anoxic and reducing conditions in the laboratory for 1,7,15,30,60,120 days, then filtered (0.22µm) and analyzed for DOC by TOC analyzer. Between 1 and 15 days the mean value of DOC concentrations (mg/L) was 23.6 for Bf1 and 14.5 for Bf2 whereas between 30 and 120 days was 5.6 for Bf1 and 5.0 for Bf2. Results showed flooding favored the solubilization of organic carbon between 1 and 15 days for both horizons, but after this period DOC did not remain in solution and was possibly resorbed by the solid phase. This indicates the period of greatest mobility of organic carbon in plinthic horizons is at the beginning of flooding. Results also showed DOC solubilization was higher for Bf1 in comparison to Bf2. This indicates that in Plinthosols subjected to prolonged flood irrigation organic carbon is more easily solubilized in plinthic horizons close to the surface, regardless of the organic matter content. In conclusion, organic carbon from plinthic horizons only migrates in the soil profile or is exported to adjacent water bodies at the beginning of flooding. The mobilization of organic compounds in plinthic horizons depends on soil depth. Soil mineralogy might contribute to enhance or decrease organic carbon mobilization however this was not investigated in this study.

(6923 - 914) Using of regression tree for soil organic carbon prediction in the caatinga biome

Valéria Ramos Lourenço[1]; Carlos Alberto Kenji Taniguchi[2]; Carlos Alexandre Gomes Costa[3]; Raul Shiso Toma[3]; Pedro Henrique Lima Alencar[3]

Universidade Federal de Viçosa[1]; Embrapa Agroindústria Tropical[2]; Universidade Federal do Ceará[3]

The selection of variables related to soil organic carbon content and its distribution on the ecosystem is essential for the parameterization of prediction models. In the Caatinga biome is indispensable the selection of parameter able to represent its dynamics in different space-temporal compounds observed in the local vegetation. Accordingly, this work aimed to evaluate the viability of the use of climatic and topographic parameters on carbon prediction through regression trees in a Caatinga biome watershed. The experiment was carried in the Bengue Representative Basin (BRB), which has an area of approximately 1,000 km², located in the Brazilian northeastern region, in the state of Ceará. In order to proceed analysis of organic carbon (g.kg-1), forty deformed soil samples on the depth of 0 – 0.2 m were collected in the BRB. Climatic and topographic parameters were obtained using digital elevation models (SRTM data), geoprocessing tools and climatic database FUNCEME (Company of Meteorology and Water Resources of Ceará). The methods of classification were developed in R language and the package "rpart" was used for the prediction using regression tree. For the performance analysis of the prediction model, the following indicators were used: Mean absolute error (MAE = 0.43 g.kg-1), the root mean squared error of prediction (RMSE = 3.02 g.kg-1) and the coefficient of determination (R^2 = 0.65). Those values indicate a small difference between observed and modelled data, nonetheless with a certain sensibility to outliers that may be attributed to collect issues. The value of R^2 argues that the model has a fair skill on predicting soil organic carbon content. Thus, we may conclude that models of prediction using regression tree receiving inputs of climatic and topographic data showed to be promising on the prediction soil carbon content in the Caatinga Biome.

C1.5.2 - Crucial techniques for the critical zone: Soil morphometrics, monitoring & modeling

(4020 - 2414) Contribution of different environmental covariates in digital soil mapping

Ebrahim Majmoudabadi[1]; Gholam Hosain Haghnia[1]; Alireza Karimi[1]; Adel Sepehr[2]

Department of Soil Science, Ferdowsi University of Mashhad[1]; Department of Desert Arid Zones Management, Natural Resources and Environment[2]

Soil covariates are the available and cost-effective data over large areas which can be applied as inputs of digital soil mapping procedures. Environmental factors have been recognized as governing the soil formation (e.g. parent material, relief, vegetation, and climate) and the spatial soil information that can be retrieved from remote sensing images or small scale soil maps of the region of interest. Therefore, a great variety of environmental covariates are now used as input for estimating soil properties. The purpose of this paper was to find the contribution of different auxiliary data to the prediction of different soil properties. The study area with an area of 1225 ha was located in Bajgiran rangelands, Khorasan Razavi province, Iran. In order to investigate vegetation cover and soil, 137 sampling sites were investigated in which 3-5 plots were selected with a distance of 10 meters apart along a transect. In each plot, plant species names and numbers as well as vegetation cover percentage (VCP) were recorded. Next, one soil sample was taken from each transect (Totally 137 soil sample). Train attributes were derived from digital elevation model; different bands and spectral indices were obtained from the Landsat7 ETM+ images, and vegetation features were calculated in the plots. These obtained parameters were used as covariate in estimating calcium carbonate equivalent (CCE), clay, bulk density (BD), total nitrogen (TN), soil organic carbon (SOC), sand, silt and soil moisture capacity (SMC) using artificial neural network. The significance of input variables on different outputs was investigated based on performance of ANN models in estimating output variable. The results indicated that vegetation features and indices were more effective than remotely sensed data and terrain attributes in the prediction of SOC, TN, silt, SMC CCE, BD, and sand. However, Terrain attributes data were the most important auxiliary data for the prediction of clay contents. It is also found that vegetation spectral indices, including NDVI, SAVI, MSAVI, SARVI, RDVI, and DVI, showed greater effectiveness in the estimation of soil properties relative to the separate bands and even soil spectral indices. It is concluded that vegetation features data especially vegetation percentage cover (a component of o in scorpan model) can be used as an effective covariate to enhance the accuracy of soil properties prediction models.

(3232 - 1866) Evaluation of spectral analysis models for determination of soil attibutes

Patrícia Morais da Matta Campbell[1]; Márcio Rocha Francelino[2]; Elpídio Inácio Fernandes Filho[2]; José Alexandre Melo Demattê[3]; Clécia Cristina Barbosa Guimarães[3]; Carlos E R G. Schaefer[4]

Universidade Federal Rural do Rio de Janeiro, Rodovia BR 465, Km 07, s/n - Zona Rural, Seropédica - RJ, 23890-000 , Brasil[1]; Universidade Federal de Viçosa, Avenida Peter Henry Rolfs, s/n - Campus Universitário, Viçosa - MG, 36570-900, Brasil[2]; Escola Superior de Agricultura "Luiz de Queiroz", Avenida Pádua Dias, 11 - Agronomia, Piracicaba - SP, 13418-900, Brasil[3]; 2Universidade Federal de Viçosa, Avenida Peter Henry Rolfs, s/n - Campus Universitário, Viçosa - MG, 36570-900, Brasil[4]

The quantification of soil attributes is essential for a better knowledge on environmental aspects and improved soil management. However, traditional laboratory methods are time consuming and expensive, besides harmful in many aspects. Hence, the development of new techniques, such as spectroscopy, is needed to have a feasible and economic way of rapidly estimating a wide range of soil properties. The objective of this work was to predict organic carbon (CO), clay and extractable P contents from the MIR, Vis-NIR and Vis-NIR-MIR spectra using different methods of pre-processing (Continuum removal-CR; Absorbance-ABS (SNP) and the Multiplicative Scatter Correction (MSC), combined with five predictive models (Partial Least Squares Regression-PLSR, Artificial Neural Network-ANN, Random Forest-RF, Guassian Process Regression-GPR and Support Vector Machine-SVM). The work was carried out in Iconha/ES (Brazil), in the Ribeirão Inhaúma catchment. We used 184 samples, collected in 92 points at two depths (0-10 and 10-30 cm). Physical, chemical and spectral analyzes were performed according to the method used in the routine soil laboratory. Of the samples, 70% were randomly selected for training and 30% for validation (external set of samples) of the models, cross-validation was used. By combining the pre-processing methods and the multivariate regression algorithms, we obtained 30 tests. For the performance analysis, the coefficient of determination R^2, RMSE, prediction error standardization indexes, RPD (Ratio of performance/prediction to deviation) and RPIQ (Ratio of performance/prediction to interquatile) were calculated. For clay and OC the best R^2 was found in the MIR spectrum, 0.69 and 0.65, respectively; whereas for P (0.57) using Vis-NIR. This study found satisfactory models (RPIQ superior to 2.0) to predict clay, OC and P. The MSC, CR and SNV preprocessing were the most efficient for prediction of clay, OC and P, respectively, while the PLSR (OC and P) and SVM (clay) methods stood out as the best predictions and are therefore recommended for modeling these attributes in similar areas. The models found can be tested to discriminate soils according to a critical test value for clay, OC and P, as for example, separating sandy and clayey soils. It is believed that the addition of more samples in the training and validation set can improve the models with RPIQ and RPD between 1.4 and 2.0, improving their accuravy and attaining excellent prediction performance.

(6151 - 654) Evaluation of the spatial distribution of selected soil attributes in the El Oro Province, Ecuador.

Rayner Sversut Barbieri[1]; Eduarda Lossavaro de Almeida[1]; Douglas Henrique Bandeira[2]; Salomón Alejandro Barrezueta-Unda[3]; Julio Enrique Chabla-Carrillo[3]; Rafael Montanari[1]; Antonio Paz González[2] Universidade Estadual Paulista "Júlio de Mesquita Filho", Faculdade de Engenharia de Ilha Solteira.[1]; Centro de Investigaciones Científicas Avanzadas (CICA), grupo AQUASOL-Facultad de Ciencias, Universidad de La Coruña, Campus A Zapateira s/n 15008 A Coruña, Spain.[2]; Facultad de Ciencias Agropecuarias, Universidad Técnica de Machala. Km 51/2 Via Machala-Pasaje, Ecuador.[3]

The mathematical modeling of the semivariogram, and the kriging technique, which allows interpolation of values at any unsampled position within a study field, without trend and with minimum variance through geostatistical analysis are tools increasingly used for agricultural and environmental research. This study was motivated by the need of soil studies in the province of El Oro, Ecuador, and the objectives were to obtain information through the analysis of spatial variability and to assess the structure of the spatial dependence of selected soil attributes, for assisting in the planning of agricultural activities. We used data from soils sampled at six municipalities in the province, namely: Huaquillas, Machala, Chilla, Atahualpa, Portovelo and Las Lajas. Samples were collected every two kilometers following a regular grid and georeferenced using a GPS. The grid consisted of 368 points and sampling depth was 0-20 cm. The studied attributes were: pH, exchangeable sodium, potassium, calcium, and magnesium, sum of bases and available concentrations of of zinc, copper, iron and manganese. Adjustment of semivariogam models and interpolation by ordinary kriging were performed by the R Core Team program. Most semivariograms were best fitted by spherical models; the greater range was for magnesium (41.500 m) and the lowest for copper (7.740 m).Extractable zinc concentrations showed the best fit to a theorethical semivariogram with the highest coefficient of determination (r2 = 0,959). Mappings were carried out by means of kriging. Kriging allowed to verify that only for of the studied attributes, namely pH, iron and sodium concentrations and base sum showed higher estimation reliability in the non-sampled area, while the rest of the attributes presented very high variation. The maps of soil pH, magnesium and calcium concentrations and sum of bases have been demonstrated to show high similarities and were important to determine specific areas of soil management in each municipality.This was mainly true when considering acidity. In this sense, the pH is accredited in this research as an influencer of other soil attributes studied and their specific areas of management.Despite the absence of sampling points between the 6 municipalities studied and the high variability of the attributes induced by soil use our results indicated that geostatistical analysis can be used as a /source of planning in the future management of soils in the region of El Oro, Ecuador.

The factors of soil formation, due to the complexity of interactions of their processes in nature, are responsible for the different patterns of spatial distribution of soil properties, varying in intensity in different directions and spatial scales. The study aimed to: i. quantify the spatial variability of organic carbon of the surface layer of a Gleysol mapping unit in reconnaissance scale in the Coastal Plain of Rio Grande do Sul

(RS) state, Brazil, through Geostatistics with the use of isotropic and anisotropic models, and ii. compare the results taking into account the existence at least one mapping unit in semi-detailed scale within the reconnaissance scale mapping unit. The study was carried out in a 403 ha area, located within the "Formiga" mapping unit according to the Reconnaissance Survey in the RS state. An experimental grid of 403 points, spaced 100 m from each other, was established in the area. At each experimental point, soil no-preserved samples were collected to determine the organic carbon (C) in the 0-0.20 m layer. The data set was submitted to an exploratory analysis through a descriptive statistical and the Kolmogorov-Smirnov test to check its normality. The proportional effect and spatial continuity, by applying the Monte Carlo simulation envelopes, were also evaluated. Directional semivariograms were built to identify the anisotropy type. Anistropic and isotropic models were built for the organic carbon data set in the reconnaissance and semi-detailed mapping units. Ordinary kriging was used to build contour maps of C at each scale. C data showed moderate variability, tended a normal distribution and no proportional effect was observed at both scales. Spatial continuity was verified for the distribution of C considering both soil map units. Results show that the organic carbon spatial variability structure was best modeled by an anisotropic model and by an isotropic one in the reconnaissance and semi-detailed scales, respectively. The use of an isotropy or an anisotropy semivariogram to model the organic carbon spatial variability structure depends on the study scale.

(9305 - 1632) Pedoclimatic monitoring in high andean intertropical mountains (Bolivia and Peru)

Eduardo Osório Senra[1]; Carlos Ernesto Schaefer[1]; André Thomazini[2]; Marcio Rocha Francelino[1]
Universidade Federal de Viçosa[1]; Universidade Federal de São João Del Rei[2]

Pedoclimatic regimes in high mountain environments at snow line are differently affected by latitudinal efects. The objective of this work was to compare two pedoclimatic sites in different latitudes, in the central portion of high Andean mountain. The physiographic conditions are similar, same altitude (4800m), slope and face of exposure. Monitoring was conducted in the Cordillera Blanca (P1, 9^0 South), Peru, and another profile in the Cordillera Real (P2, 16^0 South), Bolivia. Time data for soil temperature (5, 10, 30, 50, 80 cm), humidity (10, 30, 50, 80 cm) and air temperature (100 cm above the soil surface) were continuously collected over 4 years at P1 and 9 months at P2. The two soils were classified as Entisols, with a cryic temperature regime up to 80 cm deep and without evidence of current permafrost, despite the evidence of cryoturbian and periglacial features. The thermal and water behavior of the soils were affected by the local climate, situation and morphology. Soils with contribution of coarse material (> 2mm) show higher thermal conductivity, while organic matter and higher percentage of clay have a buffer effect on temperature variation. The Peruvian site (P1) has higher average and maximum temperatures, with a strong isothermal, consistent with its lower latitude. In Bolivia (P2) the mean and minimum temperature values are smaller, with a more pronounced thermal seasonality over the time series. In P2 there is a more evident water drought between the months of May and September, but P1 has greater daily variations. P2, at the bottom of the slope, has a greater depth of solum, higher clay content and higher organic matter input while P1, at the top, with sparse vegetation, is shallow and has a higher contribution of coarse material (> 2mm). Therefore local terrain differences, such as hillside situation and vegetation cover, affect soil and climate regimes and consequently weathering. In both sites the analysis of the periglacial thermal pattern is very different from that observed in regions of high latitudes.

(5531 - 2903) Proximal sensors on soil profiles evaluation with morphometrics purposes at field conditions

Arnaldo B. Souza[1]; José A. M. Demattê[1]; Fellipe Alcântara[1]; Vinicio Lima[1]
ESALQ/USP[1]

Field measurements are a big challenge on soil science. The sensors are greatly affected by humidity and other natural uncontrolled conditions. We studied soil profiles using three sensors with different working spectra range to find out potentials and limitations on morphometrics purposes. Seven soil profiles from Southeast of São Paulo Brazil (Lixisols and Ferralsols, WRB/FAO) were measured up to 1.7 m deep every 10 cm by VIS-NIR-SWIR Diffuse Reflectance (DR) (350-2500 nm), and Elemental Distribution by XRF (X-Ray Fluorescence – 0-40 keV) and Gamma Spectrometry (GS) (0-3,000 keV). VIS-NIR-SWIR DR gives a multi soil properties perspective due to be affected by Humidity, Organic Matter, Clay content and its quality (i.e., 2:1 or 1:1). This properties assessment allows inferring about biotic and abiotic process on soil profiles, which are essential on soil evolution and behavior. XRF technic is based on a primary method that gives information about chemical composition and relative abundance of the elements on soil profiles. This method can be helpful on element's dynamics studies allowing to identify imported material or translocation processes at field conditions. It's necessary to consider matrix effect in using this technic due to constructive and destructive energy interactions. Soil's natural gamma radiation is mainly due to Uranium (U), Thorium (Th) and Potassium (K) decay series. The distribution dynamics of these elements differs one to another and allows differentiating soil bodies and the originating materials. Along with this, nutrient's stocks can be modeled and used on Soil Quality Indexes development. Ultimately, proximal sensors use enables the study of soil at natural conditions. This approach allows to reconstruct soil's evolution history and associate it with natural phenomena, like climate changes. Soil's vertical organization can be accessed by sensors. It gives support on soil vertical evolution identification and elements dynamics in real time. It's possible to identify elements concentration through profiles and to make inferences about soil genesis at field conditions.

(8982 - 1555) Quantifying the soil hydromorphism in riparian zone by magnetic induction

R.J.Heck[1]; K.Prapagar[1]; N.V.Thevathasan[1]
University of Guelph[1]

This research study is part of the multidisciplinary project, "Riparian buffer plantings: An Agroforestry land-use for greenhouse gas mitigation including multiple benefits to Canadian agricultural systems" funded by Agriculture and Agri- food Canada. The goal on this research to explore the potential to use electromagnetic induction techniques to help delineate hydromorphic conditions within riparian zones .Riparian forest buffers play a significant role in improving soil and water quality. The presence and distribution of gleying and mottling is typically used, at the field level, to determine natural soil drainage classes, which is one of the principal considerations for soil mapping in the province of Ontario. Soil redox behavior, key to the question of the sequestration of organic

compounds and generation of greenhouse gases, is also fundamental in the development of hydromorphic features, including iron oxides (zones of depletion/accumulation, oxidation state). The measurement of magnetic susceptibility can be useful to help understand the state of iron oxide behaviour in the soil. Detailed analysis of magnetic susceptibility by electromagnetic induction survey combined with laboratory-based measurements will provide the reference basis for soil hydromorphism, which in turn help to delineate soil drainage classes. The findings will also help to evaluate greenhouse gas emission reduction potentials in agroforestry ecosystems. In this context, this research is designed with the following specific objective; to characterize the magnetic susceptibility of soil along hydromorphic gradients in relation to the nature of secondary iron oxide. The following methodology is applied to test the objective; Soil samples are collected by hand auger, from 4 depths (0-25, 25-50, 50-75 and 75-100 cm) along the upstream and downstream transacts, to represent 5 soil drainage classes; detailed laboratory analysis is conducted to characterization soil material for i) magnetic susceptibility (MS), using a Bartington MS-2B system; ii) iron oxide characterization by acid ammonium oxalate and by citrate bicarbonate-dithionite (CBD) extraction; and iii) effect of heating on magnetic susceptibility by progressive heating soil samples in a furnace. Key words: Bartington MS-2B system, iron oxide, magnetic susceptibility, upstream-downstream Financial support: Agriculture and Agri- food Canada (AAFC)

Soil hydro-physical and topographic attributes are key factors to understand and model hydrological process at the watershed scale. The objective of this study was to evaluate the relationship between soil physical and hydraulic attributes and topographic attributes along a 25 km spatial transect using cluster cluster analysis. The spatial transect was set up in the Pelotas river watershed (PRW), Pelotas, Rio Grande do Sul State, Brazil. Upstream of the outlet named as “Ponte” Cordeiro de Farias, 100 points spaced 250 m from each other were demarcated along a 25 km transect. At each experimental point, samples of preserved and non-preserved soil were collected in the 0.0-0.20 m layer to determine the following attributes: soil bulk density, soil total porosity, macroporosity and microporosity, sand, silt and clay percentages, organic carbon content, saturated soil hydraulic conductivity, soil water content at field capacity (-10 kPa-matric potential) and soil water content at permanent wilting point (-1,500 kPa-matric potential). Some topographical attributes, such as elevation, slope, profile curve, aspect, curvature, plan curvature, upslope contributing area and contour area, were derived from the Hydrologically Consistent Digital Elevation Model (HCDEM). The HCDEM was elaborated based on the cartographic database of Rio Grande do Sul (scale 1: 50,000). To measure the similarity between the soil and topographic attributes, the Euclidian distance and the Ward methods were used to form the clusters. All the statistical procedures were performed in the software R, version 3.4.2. Five clusters were formed according to the attributes as follows: 1 – elevation, saturated soil hydraulic conductivity, soil total porosity, macroporosity and sand percentage; 2 –slope, profile curve, aspect, soil bulk density; 3 – curvature e plan curve; 4 – upslope contributing area, specific upslope contributing area and width of contour; and 5 – organic carbon content, clay and silt percentages, soil water contents at field capacity and at permanent wilting point, and microporosity. It was concluded that some clusters were theoretically and consistently formed among soil hydro-physical and topographic attributes, while some of them had not meaning from the practical point of view.

(6306 - 2054) Soil cation exchange capacity and sum of bases prediction from pXRF and laboratory analysis in Brazil

Michele Duarte de Menezes[1]; Sérgio Henrique Godinho Silva[1]; Wilson Missina Faria[1]; Gabriela Costa Lima da Silva[1]; Marcelo Mancini[1]; Thaís Santos Branco Dijair[1]; Laís Rodarte Barros[1]; Luis Roberto Guimarães Guilherme[1]; Nilton Curi[1]
Universidade Federal de Lavras[1]

Cation exchange capacity (CEC) and sum of bases (SB) are important fertility parameters, which are routinely measured to guide fertilizer application rate. Their prediction by means of a cheaper, faster, less polluting, non-destructive sensor, as portable X-ray fluorescence (pXRF), would be strategic to decrease costs of agricultural practices. Since pXRF provides several elemental data, there is a great potential of such information to predict CEC and SB from machine-learning techniques, as Artificial Neural Networks (ANN) and Support Vector Machine (SVM). The methods are promising, since no assumption concerning data distribution are necessary, and they have outperformed other predictive algorithms in different environmental studies. This work aimed to test the potential of pXRF for soil CEC and SB prediction by evaluating 594 soil samples widespread in several Brazilian regions (totaling seven Brazilian states). ANN and SVM were applied to the CEC and SB determined by tradition laboratory techniques, establishing relationship between them and pXRF (Bruker model S1 Titan LE; samples were air-dried and passed through a 2-mm sieve) results, with or without additional traditional laboratory determined soil properties (organic matter, clay, silt and sandy content). In addition, different dataset input models were also tested: samples from A or B horizon. The models accuracy was assessed by an independent dataset, composed by 30% of total soil samples. Thus, mean square of error (MAE), root mean square of error (RMSE) and R^2adjusted calculated from adjustment of predicted and estimated values were calculated. ANN presented highest accuracy of prediction. The methods performed differently when A or B horizon were used as input information. The use of lab-determined soil properties did not promoted an increase in accuracy for all of models. The best CEC model performance was found for ANN, pXRF+lab determined from B horizon input dataset (MAE = 1.70 $cmol_c\ kg^{-1}$; RMSE=2.24 $cmol_c\ kg^{-1}$;

R^2adjusted= 0.70). Considering that the use of only pXRF would be faster and cheaper option, the ANN model from A horizon (MAE = 2.98 $cmol_c$ kg^{-1}; RMSE=4.15; $cmol_c$ kg^{-1}; R^2adjusted= 0.62) could be considered as an alternative for CEC prediction. The best model performance for SB was obtained from ANN, pXRF from A horizon (MAE = 1.26 $cmol_c$ kg^{-1}; RMSE=1.77; $cmol_c$ kg^{-1}; R^2adjusted= 0.86). Considering the accuracy indexes, the prediction of CEC and SB by means of pXRF is feasible.

Soil saturated hydraulic conductivity (K_S) is a hydro-physical key property to understand and to simulate hydrological processes in a watershed. It is well known that K_S is highly variable on space and time. Autocorrelation function has been used in the quantification of the spatial variability structure of hydro-physical soil properties, indicating the range of spatial dependence amongst observations of a variable. However, the Power Spectrum Density (PSD) can also be used to define the range of spatial correlation of a soil property, since it is obtained by the Fourier transform of the autocorrelation function of a process, that is, it describes the distribution of the variance of a process in the frequency domain. The objective of the present study was to quantify the range of spatial dependence of the soil saturated hydraulic conductivity measured along a spatial transect of 25 km via PSD. The spatial transect was set up at the Pelotas River Watershed, Pelotas, Rio Grande do Sul state, Brazil. Upstream of the Ponte Cordeiro de Farias control section, 100 points, 250 m far from each other, were demarcated along the spatial transect. At each experimental point, preserved soil samples were collected, in the 0.0-0.20 m soil layer, to determine the soil saturated hydraulic conductivity through the method of constant head permeameter. From a log-log graph between PSD ("y" axis) and frequency ("x" axis) values, a linear regression model was adjusted and the β value was obtained, which indicates the range of spatial dependence of K_S values. All statistical procedures were performed in the MATLAB® R2017b software. The obtained β value was -0.01861, indicating a low range of spatial dependence amongst K_S adjacent observations, since the closer to zero the β value is, the lower is the range of spatial dependence of the variable. Therefore, we can conclude that PSD is a useful tool to quantify the range of spatial dependence of a property based on frequency-domain tools.

(5468 - 1163) Using soil spatial data for crop yield estimation and optimisation: A machine learning approach

Mr Stirling Roberton[1]; A/Prof John Bennett[1]; A/Prof Yan Li[1]; Dr Craig Lobsey[1]
University of Southern Queensland[1]

Advancements in Precision Agriculture (PA) over the past decade has led to the development and adoption of Variable Rate Agriculture (VRA), which aims to optimize production by making site-specific recommendations based on soil variability. Such recommendations are currently being made on limited soil information that is not available at the required resolution, and often does not capture the extent of the variability. Whilst there is limited data in the x-y plane, the greatest limitation to date is the severe lack of soil depth information (z plane) and knowledge on its interaction with crop performance. Even if such data was available, traditional statistical approaches may not provide the level of insight required, purely due to the highly complex patterns that may exist. We therefore propose a machine learning (ML) approach that incorporates spatial soil data in an effort for site-specific yield estimation and optimisation. The ML model will be learnt from data collected at a 100ha trial site that has been grid sampled (60m grids) at 4 depth increments to 80cm and analysed for an array of soil parameters. Using this dataset along with historical yield and weather information, the model will be trained to predict site-specific yield in an attempt to later perform yield optimisation. This body of work aims to 1) Model the complex relationship between soil-depth information and yield in order to optimize production, and 2) Showcase the potential for machine learning to be used as a powerful tool in modelling the complexities within the soil system.

C1.5.3 - Reconciling pedometrics and pedology

(5995 - 565) A detailed soil weathering evaluation of profiles from parent material to soil by proximal sensing (gama ray, X ray, hyperspectral vis-nir-swir-mir)

Clécia Cristina Barbosa Guimarães[1]; José Alexandre Melo Demattê[1]; Antônio Carlos de Azevedo[1]; Marcos Rafael Nanni[2]; Rafael Cipriano Silva[1]
Department of Soil Science, College of Agriculture Luiz de Queiroz, University of São Paulo[1]; Agronomy Department, Agricultural Science Center, State University of Maringá[2]

The study of weathering has primary importance since the chemical breakdown of thermodynamically unstable minerals on the surface of the earth by weathering agents is a fundamental part of the global element cycling. This process is responsible soil formation on which all terrestrial life depends, playing a central role in soil fertility control by providing many nutrients that enable plant growth. At the present time, the analysis of weathering is performed through mathematical indexes related to the presence or absence of certain minerals and observation of the behavior of the chemical elements along the soil profile. There is, therefore, a necessity for faster and more effective techniques. The objectives of the present work were to characterize

and evaluate the potential of several proximal sensor instruments in the identification of weathering processes in vertical sections of soils. Two soil profiles with contrasting source materials were used to evaluate spectroscopy as a tool capable of identifying changes in profile during weathering. Soil samples were collected and sent for chemical, physical, mineralogical and spectroscopic analyzes. For the latter, three sensors were used, each one contemplating a region of the electromagnetic spectrum (x-ray, visible and infrared). In the field, the gamma ray sensor and the multispectral AISA fênix camera were used to read the entire soil profile. The physical, chemical and mineralogical data were used to understand the behavior of the spectra and were made the elementary, mineralogical and other attributes descriptions present in the collected soil samples. The oxides were spatialized in the images of the Fenix AISA sensor for the visual observation of the behavior of the elements and minerals along the profiles. It was possible to identify, from the spectral behavior, the difference in texture of the horizons, the presence of structural and soil water, the influence of the organic matter and the main minerals that are results of the intensity of weathering. The data of the GAMA and FRX sensors presented high values of correlation with the oxides used in the quantification of the intensity of weathering, indicating the viability of the sensors for the calculation of the indices. The application of multivariate models to the AISA images allowed the quantification of these oxides pixel by pixel along the profile and to observe the differentiation of the horizons.

(5443 - 2237) Characterization of the magnetic susceptibility and its correlation with the chemical attributes in the Cerrado region

Maysa Danielly de Souza Ferreira[1]; Sammy Sidney Rocha Matias[1]; Maria Iolanda Leal Lustosa[1]; Cinthya Herley Kochhann Ribeiro[1]; Ronny Sobreira Barbosa[2]; Rafael Felippe Ratke[2]; Júlio César Azevedo Nóbrega[3]; Tarcisa Fé da Silva[1]; Inária Vogado Borges[1]

Universidade Estadual do Piauí[1]; Universidade Federal do Piauí[2]; Universidade Federal do Recôncavo da Bahia[3]

The correlation between variables indicates when one attribute is being influenced by another, or when, the management may be affecting that parameter. The present work aimed to characterize the magnetic susceptibility and its correlation with the chemical attributes in the Cerrado. The work was conducted in the municipality of Barreiras do Piauí, whose geographic coordinates are 10º03 'south latitude and 45º68' longitude west, with an average elevation of 400 m, with a slope variation of 1 and 10%. The climate of the region is type AW ', characterized by being semi-humid and with an average temperature of 27°C. The average annual precipitation is around 1200 mm, with concentrated rainfall from November to April. The soil was classified as ENTISOLS. The area under study was delimited and georeferenced, being selected an area of 1 (one) hectare with dimensions of 100 x 100 m. In this area a regular mesh of 10 x 10 m was assembled, totaling 121 sample points, being collected soil samples in the depth of 0.0-0.20 m. Soil characterization was performed by means of a soil profile. The parameters evaluated in the work were chemical attributes, pH in H_2O, phosphorus, potassium, calcium, magnesium and soil magnetic susceptibility (MS), being analyzed by means of an analytical balance. The data were evaluated through geostatistics and Pearson's linear correlation in the soil attributes studied. The correlations between the analyzed variables were determined using the Pearson's correlation (p and ≤ 0.3), moderate (0.4> and ≤ 0.6) and strong (0.7> and 1.0), with a good correlation above or equal to 0.60 (positive correlation), or below -0.60 (negative correlation). Through the geostatistic tool it was possible to establish and identify the variation of this attribute in the soil.When analyzing the data, it was not possible to establish a significant correlation of any of the chemical attributes with the magnetic susceptibility. This result may be related to the management of the area and intense burnings occurring in the place, disorganizing the contents present in the soil through volatilization of the nutrient or change of the state of availability for the plants. The magnetic susceptibility identified the spatial variability in the area. The magnetic susceptibility did not identify correlation with the attributes pH, potassium, calcium and magnesium in the Cerrado region of Piauí.

(1789 - 2232) Chemical attributes characterization in soil of Barreiras of Piauí city, Brazil

Tarcisa Fé da Silva[1]; Sammy Sidney Rocha Matias[1]; Maria Iolanda Leal Lustosa[1]; Cinthya Herley Kochhann Ribeiro[1]; Ronny Sobreira Barbosa[2]; Rafael Felippe Ratke[2]; Júlio César Azevedo Nóbrega[3]; Maysa Danielly de Sousa Ferreira[1]; Inária Vogado Borges[1]

Universidade Estadual do Piauí[1]; Universidade Federal do Piauí[2]; Universidade Federal do Recôncavo da Bahia[3]

Soil management interferes with the evaluation of soil chemical attributes, causing errors in its interpretations. The present work had as objective to evaluate the chemical attributes in the municipality of Barreiras do Piauí. The work was conducted in the Barreiras of Piauí city, whose geographic coordinates are 10º03 'south latitude and 45º68' longitude west, with an average elevation of 400 m. The climate of the region is type AW, average temperature of 27°C. The average annual precipitation is around 1200 mm. The soil was classified as ENTISOLS. The area under study was delimited and georeferenced, being selected an area of 1 (one) hectare with dimensions of 100 x 100 m. In this area, a sample mesh of 10 x 10 m was assembled, and soil samples were collected at depths of 0.0-0.20 and 0.20-0.40 m. Soil characterization was performed by means of a soil profile. The parameters evaluated in the work were pH in H_2O, phosphorus, potassium, calcium and magnesium. Data were evaluated through descriptive statistics, initially an exploratory data study was carried out using Minitab software, calculating location (mean and median), variability (coefficient of variation) and central tendency measurements (asymmetry and kurtosis), to verify the normality of the evaluated attributes. For the analysis of the coefficient of variation, the following classification was used, low variability for values lower than 12%, average between 12 and 60%, and high values higher than 60%. The descriptive analysis of the data showed that the distribution of data follows a trend of normality for the attributes pH, potassium and magnesium, according to the asymmetry and kurtosis, not being observed the same result for calcium and phosphorus in the two depths. In this situation, the result should be confirmed by the mean and median, to identify a normal log distribution. By verifying the data, we can see that all attributes analyzed can be represented by the mean and median values, with the exception of calcium at both depths. The coefficient of variation values were classified as low for pH and high for phosphorus, potassium, calcium and magnesium at both depths. The variation of the coefficient is a reflection of the interactions of the processes of its formation and of the management adopted in the place. Descriptive analysis confirmed the normality of the data. Variations of the chemical attributes were identified by the coefficient of variation.

(9144 - 1250) Distribution of the soils in the watershed of the São Francisco Verdadeiro river, watershed of the Paraná III - state Paraná – Brazil

Bruno Aparecido da Silva[1]; Marcia Regina Calegari[1]
West State University of Paraná[1]

Digital Soil Mapping (DSM) are important tools that help in the pedological mapping, because they allow to predict the distribution of soils from the soil-landscape model. In the West of the state of Paraná, the MDS have allowed understanding the distribution of soil covers about landforms flat to wavy. However, the absence of soil mapping in detail scale (1:50,000) has become a methodological barrier to environmental research. Therefore, the objective of this work was to systematize information regarding distribution of soils through the DSM in the watershed of the São Francisco Verdadeiro river. Thematic maps of Slope and Curvature were elaborated from SRTM (Shuttle Radar Topography Mission) and Topodata Project, respectively, both in the Geographic Information System (GIS) Qgis 2.18.0. The Sediment Transport Capacity (CTS) map was elaborated in SAGA 2.2.6. Finally, we proceeded with the map algebra in Arcgis 10.4 to generate the MDS and identify the mapping units in the field. Finally, map algebra was realized in Arcgis 10.4 to generate the DSM and identify the field mapping units. Ferrasols, Nitisols, Regosol + Leptosol + Cambisol and Gleysols were the identified units. The Ferrasols are in the top sectors with slope 0-3%, rectilinear and convex forms, and in stable areas (low CTS). The Nitisols dominate the high-medium and low slope with gradient between 6 and 20% and concave and convex shapes. This unit occupies segments with low to medium CTS, stable sectors of the slope. The association Regosol + Leptosol + Cambisol is distributed in sectors with gradient between 20 and > 45%; in segments with rectilinear, convex and concave forms and unstable sectors of the slope (high CTS). Gleysols are found in the flat valley bottom. The MDS, complemented with the field works, allowed the identification of 4 mapping units. The distribution of soils is related to the morphological characteristics of the slope, reflecting in sectors of progressive and/or regressive pedogenesis. The results corroborated the influence of landform on the distribution of soil.

(4641 - 2186) Environmental covariates selection by mathematical algorithm for digital soils mapping of mountainous relief area

Martin Meier[1]; Márcio Rocha Francelino[1]; Elpídio Inácio Fernandes Filho[1]; Adriano Luis Schünnemann[2]
UFV[1]; Unipampa[2]

Digital Soil Mapping (MDS) seeks to create a soil spatial distribution system by numerical models, from the spatial distribution of environmental variables used in MDS to establish which properties are grouped in homogeneous patterns that characterize the soil units. It's believed that the variation of the morphometric characteristics has a cause and effect connection with the formation and distribution of soils. The objective of this work was to infer about the selection of covariates for the prediction of soil classes using hierarchical classifications in mathematical algorithms for the production of detailed maps of a mountainous area of the Zona da Mata region of Minas Gerais state. Data describing variables related to soil formation factors obtained from: Orbital images; Euclidean distance between the drainage network; Digital elevation model (MDE) with resolution of 12.5 meters of Alos-Palsar; Conventional map of soils of the state of Minas Gerais in scale 1: 650,000 in vector format; Map of lithology in scale 1: 100,000: in the vector format of the area of Juiz de For a municipality; WorldClim average precipitation and temperature database; Images of LANDSAT-8. The RSaga library was used in the R program to generate 40 morphometric covariates from the MDE. With a function of the "Hmisc" R package, from the values of nonlinear correlation and similarity, the redundant variables of the model were removed, as well as those that best described the dispersion of the soil classes. Classification accuracy values were measured by the Kappa index. A total of 10 covariables were selected in order of importance with best performance in the MDS: 4 Morphometric (Elevation of Slope, Standardized Elevation, TWI and MRVBF), Landsat-8 Bands 7 and 11; Euclidian distance of the drainage network; and two climatic covariables: precipitation of the coldest quarter (BIO19) and annual temperature variation (BIO07). The results of the variables being related to the predominance of the relief factor in the soil formation of the region, agrees that the contribution of the morphometric covariates derived from the MDE is more important that other covariates and variables, in the description, through mathematical perspective, of the relief importance as a soils formation factor.

(7575 - 967) Estimation of sediment moisture with terrestrial laser scanner data

Felipe Carvalho Santana[1]; Guilherme de Castro Oliveira[1]; Márcio Rocha Francelino[1]; Elpídio Inácio Fernandes Filho[1]
Universidade Federal de Viçosa[1]

In the spectral range of the infrared, water and soil have a lot different spectral behavior. While water absorbs practically all incident energy, dry soil reflects more than a third of it, so the gradual increase in soil water content can be inferred by remote sensing. Based on this fact, the present study sought to verify the correlation between the moisture of sediment and the reflectance measured with the use of the Riegl VZ-1000 Terrestrial Laser Scanner. The scanning was carried out in the floor surface of a dam that had only the watercourse, comprising a good part of the dry area, located on the campus of the Federal University of Viçosa, in the state of Minas Gerais, Brazil. A scanning frequency of 300 KHz was used. Three transects were delimited perpendicular to the dam spillway, being traced from the dry sediment to where it was saturated with water. In each of them, immediately after the scanning, five superficial samples (0.05 m) of the sediment were collected for moisture verification, spaced approximately 1.50 m apart. The collection of the reflectance intensity data (dB) of the sediment was done in the RiscanPRO software, in which five samples (points) were extracted from the place where the surface samples were taken. The sediment samples were dried in a forced air oven at 65 ºC for 48 hours and then weighed in an analytical balance. The moisture content of the sediment samples varied from 0.05 to 2.15 g g^{-1}, while the reflectance intensity ranged from -2.46 to -9.06 dB. The correlation between the sediment moisture and the reflectance intensity (dB) of the laser was 0.90. The linear regression y = -2.4337x - 3.3401 was adjusted with the coefficient of linear determination (R^2) of 0.81. The reflectance data in dB were converted to reflectance coefficient, and new correlation and regression were adjusted, with the values correlation coefficient and the R^2 remaining the same. The reflectance data obtained by laser scanner have the potential of use in estimating the moisture of sediments, provided that they are calibrated to the type of sediment or soil to be studied, reducing time and costs with the sampling and analysis.

(3640 - 2986) Mapping of iron oxides using indirect techniques in soils of the Western Paulista Plateau, Brazil.

JOSÉ MARQUES JÚNIOR[1]; LAÉRCIO SANTOS SILVA[1]
UNESP Jaboticabal[1]

The characterization of the spatial behavior of soil attributes in large areas becomes unfeasible using traditional methodologies. An alternative is the use of indirect methods such as diffuse reflectance

spectroscopy (DRS) and magnetic susceptibility variation (χFD). They are methods that can aid in soil survey and classification, especially in tropical environments, where color and spontaneous magnetism are reliable pedoindicators of the presence of iron oxides and their covariate attributes. Among of many advantages of these methods is the low cost of analysis and rapid results, which can be carried out in the field. Therefore, the purpose is to present the application of DRS and χFD in the mapping of hematite (Hm) and goethite (Gt) in soils of the Western Plateau. For this, 300 soil samples were selected in the depth 0.0 - 0.20 m, spaced 10 km apart. Soils are representative of the Serra Geral (basalt) and Vale do Rio do Peixe (sandstone) geological formations, corresponding to 13 million hectares (~ 50% of the State of São Paulo). The iron oxides Hm and Gt were characterized by X-ray diffraction (XRD), diffuse reflectance spectroscopy (DRS) and the variation of magnetic susceptibility (χFD). The real content estimated and the values of the χFD were submitted to geostatistical analysis, being the points that ware not sampled, estimated by ordinary kriging. It was observed the predominance of Hm on the edges of the Western Paulista Plateau in the lithological domain of basalt, while in the center, where the substrate is essentially sandstone, the goethite was predominant. By both techniques, the semivariogram parameters indicated that the Gt /(Gt+Hm) relation fitted to the spherical model, presenting moderate spatial dependence [$(C_0/(C_0+C_1)\times100]$ =35 and 50%). The range values (a) of the χFD maps (117 km)> ERD (101 km)> XRD (94 km) show the XRD with greater spatial variability for Hm and Gt, since it provides microstructural information dependent on the pedoenvironmental conditions. The well-distant and defined isolines of the ERD map defined the sandstone-basalt lithologic control, while the χFD presented a hybrid behavior between the XRD and the DRS, since the pedoenvironmental and lithological differences affect the χFD. It is concluded that the ERD and χFD are promising in the mapping of soil attributes also in large areas, delimiting bodies of soils with potential to assist in the elaboration of mapping and soil survey units on a regional scale.

(1798 - 2907) Multifractal and joint multifractal analysis of soil water content measured at successive depths and during three periods along a transect

Antonio Paz-González[1]; Glécio M. Siqueira[2]; Enio F. F. Silva[3]
University of A Coruña (UDC)[1]; Federal University of Maranhao (UFMA)[2]; Federal Rural University of Pernambuco (UFRPE)[3]

Soils are highly variable and heterogeneous over several spatial scales. The spatial variability of soils might be characterized through concepts of scale invariance, fractals and multifractals. Spatiotemporal behavior of soil water content has important applications in soil physics and hydrodynamics. The objective of this study was to analyse and to compare the scaling patterns and structural heterogeneity of soil water contents measured at successive depths along a longitudinal transect, and during three different periods, using the multifractal formalism. The data set analyzed was obtained at an experimental farm in Pernambuco state, Brazil. The studied transect was 185 m long, and along this transect 128 point measurements of soil water content were carried out at the 0-20 and 20-40 cm depth during three different periods using time domain reflectometry (TDR). The spatial distributions of soil water content at all the depths and periods studied exhibited various degrees of scaling heterogeneity or multifractality, which were characterized though three functions: generalized dimension, mass exponent function and singularity spectra functions. In general increasing depth resulted in the reduction of the degree of multifractality. Moreover, joint multifractal analysis showed that the relationships of soil water content measured at successive depths were scale dependent across the spatial domain studied, and that their respective scaling indices had a high degree of association during the three periods studied. The multifractal nature of the spatial distributions of soil water content indicated that multiple scaling indices are needed for assessing soil water variability information over various scales. The strong similarity between the scaling properties at the surface and subsurface layer allowed inference about the soil water dynamics at successive soil depths using the scaling properties of the soil water content measured at the uppermost layer. Also, the multifractal approach provided considerable detailed information on the hidden structure of the spatial data sets of water content studied. It was shown that soil water content variability was driven by natural causes, mainly topography, but also by other soil forming factors such as parent material. Moreover, at the soil surface layers, scale heterogeneity in the spatial distribution of soil water content was enhanced by the interaction of various natural or anthropogenic sources of variability.

(3906 - 3074) Spatial correlation between terrain attributes and soil depth in small-extent rugged terrain

Taciara Zborowski Horst[1]; Alessandro Samuel-Rosa[1]; Ricardo Simão Diniz Dalmolin[1]; Jean Michel Moura-Bueno[1]
Universidade Federal de Santa Maria[1]

Soil deepening generally occurs in response to water flows over the landscape and through the soil profile. Terrain attributes can provide an accurate picture of water distribution across the landscape. If the underlying geology is homogeneous, then a strong correlation between terrain attributes and soil depth can be expected to exist. The objective of this study was to investigate the presence and strength of this correlation in a small-extent rugged terrain (109 ha) in southern Brazil, used for timber production over the last 30 years, as a means to make spatial soil depth predictions. Soil depth (up to 10 dm) was recorded at 102 point locations (0.9 points per ha) purposively selected using conditioned Latin Hypercube Sampling as to reproduce the correlation and marginal distribution of the 10-m spatial resolution covariates elevation, slope, topographic wetness index, valley depth, and channel network base level. Ten neighbourhood sizes, ranging from 10 to 100 m, were considered for mean-sampling covariates at the observation locations. The largest neighbourhood size (100 m) was selected for yielding the strongest correlation between covariates and soil depth. A linear mixed effects model with the exponential covariance function was fitted to the data (assuming Gaussian-distributed errors) using restricted maximum likelihood. Spatial predictions were made using the empirical best linear unbiased predictor. Prediction performance was evaluated using the amount of variance explained (AVE), root mean square error (RMSE), and mean error (ME) computed using leave-one-out cross-validation. The latter showed that predictions are unbiased (ME = -0.04 dm), but have low accuracy (AVE = 14%, RMSE = 3.28 dm), mostly due to the weak correlation of soil depth with terrain attributes. The strongest correlation was with slope (r = -0.16), the reason why smaller depths were predicted in steeper slopes. The estimated nugget variance was high, about 50% of the total variance (11 dm^2). When the nugget (measurement error) variance was fixed at 0.25 dm^2, the estimated range dropped from 97 to 47 m, which is shorter than the mean sampling distance (61 m). This result suggests that the spatial autocorrelation of soil depth in the area is structured over distances of a few tens of meters, indicating the occurrence of a strong local control of soil development, e.g. litology. For this reason, predictions can likely be improved by using more intensive sampling.

(5396 - 2365) Spatial prediction of weathering-related soil properties obtained from portable X-ray fluorescence

Fabio Arnaldo Pomar Avalos[1]; Bárbara Pereira Christofaro Silva[1]; Michele Duarte de Menezes[1]; Marx Leandro Naves Silva[1]; Nilton Curi[1]

Universidade Federal de Lavras[1]

Portable X-ray Fluorescence (pXRF) stands as an efficient equipment for the characterization of soil geochemical features. Spatial distribution of such features is an important resource for soil characterization, as investigation of pedogenesis processes. This work aimed to model the spatial distribution of weathering-related soil geochemical variables. For this, aluminum oxide (Al_2O_3), iron (Fe) and silicon dioxide (SiO_2) parts-per-million (ppm) contents from 72 B-horizon samples in the Posses watershed, southeast Brazil, were retrieved by means of pXRF (Bruker model S1 Titan LE). For the analysis, soil samples were previously air-dried and passed through a 2-mm sieve. Then, a regression-kriging approach was applied for the geochemical variables, where a random forest regression model (RF), with 24 digital terrain attributes as covariates and Al_2O_3, Fe and SiO_2, as dependent variables. Accuracy assessment was based on RF out-of-bag error. Kriging interpolation for RF residual values was intended, however, residuals from each RF model showed pure nugget effect of variograms, putting away the necessity of this procedure and emphasizing the association between terrain landscape and soil geochemical properties. The most important terrain attributes for spatial prediction were channel network base level for Fe, with accuracy indexes of RMSE = 8281.4 and R^2 = 0.89. The stream power index was the most important for Al_2O_3, with RMSE = 10984.4 and R^2= 0.87. Multiresolution index of valley bottom flatness and topographic wetness index were the most important variables for SiO_2, with RMSE = 21703.98 and R^2 = 0.88. These results indicate that the association between terrain landscape and weathering-related soil properties could be mapped out by means of regression trees only.

(4626 - 3088) Spatial variability and multivariate analysis in the determination of the sample density of the Western Paulista Plateau, Brazil

Laércio Santos Silva[1]; José Marques Júnior[1]; Romário Pimenta Gomes[1]; Diego Silva Siqueira[1]; Jeferson dos Santos da Silva[1]; Thiago de Andrade Águas[1]

Unesp Jaboticabal[1]

In large areas, the prediction and knowledge of the spatial variability of the attributes can delimit homogeneous areas and assist the planning of agricultural practices. However, one of the difficulties and know the minimum of sampled points representative of the lithological, pedological and geomorphological diversity. Thus, mathematical tools such as multivariate analysis and geostatistics have been one of the alternatives, so we evaluated the potential of combining these techniques in the selection of pedoindicator attributes of environments and determination of sample density. In the Western Paulista Plateau with 13 000000 hectares, 200 soil samples were selected in depth 0.0 - 0.20 m, distanced at 10 km from each other, from arenitic and basaltic rocks. A granulometric analysis was carried out and the oxides of iron hematite and goethite were characterized by x-ray diffraction and magnetic susceptibility (SM). The analytical results were submitted to multivariate and geostatistical statistics. The semivariograms (simple and scaled) and the map of mineralogical and textural attributes were performed from the scores of the variables retained in CP1. Sample density was calculated from the ranges. The analysis of factors indicated hematite, SMbf, sand and clay attributes with high discriminatory power of the soils, contributing with 89.25% of explanation of the total variance of the data (73.01% and 16.24%). This behavior allowed the main component analysis (PCA) to better evaluate soil attributes correlated with lithological characteristics. The semivariogram performed from the variables retained in CP1 presented a spatial dependence structure, described by the spherical model. The degree of spatial dependence [(C0 / (C0 + C1))> 25%] for the semivariogram of CP1 and the graded one was classified as moderate spatial dependence. The proximity of the range values of CP1 (a = 88.70 km) and the scaled semivariogram (a = 70 km) reveals the similar sensitivity of the techniques in capturing the heterogeneity of the attributes. It is concluded that hematite, SMbf, clay and sand present high discriminatory power of soils of different geological types, requiring a minimum number of 17 (CP1) or 27 (scaled semivariograms) samples to represent the diversity of attributes evaluated in the Western Paulista Plateau.
Keywords: Hematite, goethite, magnetic susceptibility, scaled semivariogram, pedometrics

(9504 - 2248) Spatial variability of attributes with different sample densities in the savanna

Inária Vogado Borges[1]; Sammy Sidney Rocha Matias[1]; Maria Iolanda Leal Lustosa[1]; Cinthya Herley Kochhann Ribeiro[1]; Ronny Sobreira Barbosa[2]; Rafael Felippe Ratke[2]; Júlio César Azevedo Nóbrega[3]; Tarcisa Fé da Silva[1]; Maysa Danielly de Sousa Ferreira[1]

Universidade Estadual do Piauí[1]; Universidade Federal do Piauí[2]; Universidade Federal do Recôncavo da Bahia[3]

The behavior of soil attributes can be verified in several ways. The present work had as objective to verify the spatial variability of the attributes with different sample densities in the Cerrado of Piauí. The work was conducted in the municipality of Barreiras do Piauí, whose geographic coordinates are 10º03 'south latitude and 45º68' longitude west, with an average elevation of 400 m. The average annual precipitation is around 1200 mm. The soil was classified as ENTISOLS. The area under study was delimited and georeferenced, being selected an area of 1 (one) hectare with dimensions of 100 x 100 m. In this area, two sample densities were set apart between the central points in 10 x 10 and 20 x 20 m, and soil samples were collected at a depth of 0.0-0.20 m. Soil characterization was performed by means of a soil profile. The parameters evaluated in the work were pH in H_2O, phosphorus and potassium. Data were evaluated through semivariograms, and the models were adjusted in spherical, exponential and gaussian. By means of these models, we predicted each attribute in areas not sampled by kriging, represented in contour maps. The choice of the theoretical models was performed observing the sum of the square of the residues, the coefficient of determination and, later, the correlation coefficient obtained by the cross-validation technique. The classification of the degree of spatial dependence was made based on the ratio between the nugget effect and the level, being considered strong, superior of 75%, moderate between 25% and 75%, and weakness when smaller of than 25%. The adjusted models in the two sample densities were the same for phosphorus and potassium, gaussian and spherical respectively. For pH, in both cases (densities) the adjusted models were, gaussian and exponential, spacing of 10 x 10m and 20 x 20 m, respectively. In relation to the degree of spatial dependence, all presented moderate dependence.

The range varied from 34 to 48 m, with the highest range obtained for pH at the sample density of 10 x 10 m. The coefficients of spatial determination (R2) for pH and potassium obtained values above 0.71 at both depths. This result was also evidenced by cross validation. The geostatistical technique identified the spatial variability of the pH, phosphorus and potassium attributes through the kriging maps. The 20 x 20m spacing can be used for soil sampling and identification of the variability of chemical attributes pH, phosphorus and potassium.
Keywords: Soil management soil sampling, spatial variability.

(9658 - 1480) Usage of pedometrics for data evaluation and harmonization in soil profiles from Cerrado region, Mato Grosso do Sul

Pedro Armentano Mudado Xavier[1]; Lúcia Helena Cunha dos Anjos[1]; Helena Saraiva Koenow Pinheiro[1]; César da Silva Chagas[2]; Waldir de Carvalho Junior[2]
UFRRJ[1]; EMBRAPA Solos[2]

Usage of pedometric tools to analyze information on soil properties relevant to classification and interpretation of potential is increasing. Harmonization of key soil properties, such as granulometry, organic carbon, pH, cation exchange capacity, allows comparison between soils, facilitates transfer of information among scientists and users, and contributes to modeling of soil horizons spatial distribution. The global consortium for soil mapping suggests harmonization of data in depths at predefined intervals, to compile the global database and to generate maps for different properties. The objective of this study is to point out similarities between soils from a collection of 19 profiles, sampled in the state of Mato Grosso do Sul, latitude 20º26'34 "South and longitude 54 ° 38'47" West. The total surface is of 8,096,051 km². The climate is tropical with dry season, average annual rainfall of 1534 mm and temperature of 25 °C. It belongs to domains of the phytogeographic region of savanna with deciduous trees, Cerrado Biome. It has a dominantly flat topography, and geology is of Serra Geral Formation that has a sequence of basalt from Jurassic to Cretaceous periods in Mesozoic Era. These effusive rocks covered sandstones of the Botucatu Formation. The elevation ranges from 490 to 701 meters, with 532 meters average. The most important cause of soil variability in the study area is parent material, composed of basic eruptive rocks (basalt), sandstones and colluvial sediments derived from them. The most representative soil classes, according to Brazilian Soil Classification System, are *Latossolos, Neossolos* and *Planossolos,* but also occur *Gleissolos, Cambissolos* and *Organossolo*s. The motivation for the research is that with the data harmonization a more detailed analysis of the soil classes and their spatial distribution will be possible. The quantitative pedology algorithms, known as the AQP package (Beaudette et al., 2013), were applied in the R software. The application of the slice-wise algorithm of the AQP package allowed to define values for soil properties in each one centimeter layer of the soil profiles. After that, the data in different layer thicknesses were grouped, allowing analysis of the similarity between the profiles, using a dissimilarity matrix for each depth slice. The results are presented in the form of graphics and tables that simplify the comparisons and interpretation of dominant classes and soil properties in the area.
Keywords: Quantitative pedology; algorithms for quantitative pedology- AQP; harmonization of soil data.

(5151 - 3045) Use of magnetic susceptibility for the Identification of Pedogenetic Environments in Archaeological Black Earth in southern Amazonas, Brazil

Ivanildo Amorim de Oliveira[1]; José Marques Júnior[2]; Milton César Costa Campos[3]; Ludmila de Freitas[1]; Renato Eleotério de Aquino[2]; Diego Silva Siqueira[2]; Laércio Santos Silva[2]; Ana Beatriz Coelho França[2]
IFPA Campus Breves[1]; Unesp Campus Jaboticabal[2]; UFAM Campus Humaitá[3]

In the Brazilian Amazon region, it is common the existence of archaeological sites in which there are significant changes in the physical, morphological and chemical aspects of the soils, promoted by the human action known as Archaeological Black Earth (ABE). Although many studies have been conducted in order to understand the magnitude of these modifications and their reflexes in soil genesis, many questions need to be clarified, especially those related to the mineralogy of these soils. The objective of this study was to use the magnetic susceptibility (MS) to identify different pedogenetics environments in ABE in the southern region of the Amazonas. Thirteen profiles of ABE and one (1) a forest profile (non-anthropogenic) were analyzed, being collected samples by horizon in each profile. Mineralogical analysis was performed, and certain minerals of the clay fraction hematite (Hm_012), goethite (Gt_110) and maghemita (Mh_220 and Mh_400) being characterized by x-ray Diffraction (XRD) at blades made with powdered material. Were determined the iron contents extracted with dithionite–citrate–bicarbonate of sodium (FeDBC (in %)), iron contents extracted with ammonium oxalate (FeOAA (in %)) and total iron (in %). The MS was evaluated in soils (earth thin air-dried), in the ashes of plants and in ceramic fragments found in ABE areas, being determined to SM in low frequency (MSlf) and the percentage of frequency-dependent magnetic susceptibility (χ_{fd}). The ceramic fragments have greater magnetic susceptibility compared to soils with archeological black earth (earth thin air-dried), and can be one of the reasons of the highest values of magnetic susceptibility in relation to non-anthropogenic soil. On the other hand, it is possible to observe through the diffractograms the characterization of clay fraction oxides Hm and Gt, including discreet expression of Mh in ABE. The ashes of the plants showed low values of magnetic susceptibility, indicating the phytogenetic influence in the values of MS of ABE can occur as a result of the cumulative process of burning of the plants over the years. The χ_{fd} has greater variation in subsurface in the archeological black earth, due to the mixture and accumulation of minerals formed in normal conditions (hypothesis pedogenetic and/or lithogenetic), in addition to the influence of fire (pedogenic hypothesis) and ashes of the plants (hypothesis phytogenetic).

(8513 - 957) Using the Toposhape algorithm as a tool to automatic generation of terrain variables applied to digital soil mapping in a watershed

Mara de Andrade Marinho[1]; Estevão Conceição Gomes Junior[2]
State University of Campinas[1]; State University of Londrina[2]

Terrain inclination and surface shape are the elements of the relief that largely control the dynamics of the surface water. Additionally, the slope orientation affects the amount of solar radiation that reaches the soil surface. These elements influence deeply the development of a given soil, reason for what their use is quite common as auxiliary variables in digital soil mapping (DSM). The present work aimed to generate terrain auxiliary variables for DSM in a watershed by applying a computational algorithm for automatic classification of the surface shapes. The study area encompass the Ceveiro watershed (SP, Brazil) and the employed algorithm was the Toposhape, developed by Pellegrini in 1995 (*apud* Herrington and Pellegrini, 2000). This algorithm works from a digital elevation model (DEM), runs in a geographical information system environment and

performs a continuous classification by taking into account the changes in the slope and curvature of the terrain. Eleven possible classes of surface shapes are distinguished: peak, ridge, saddle, flat, ravine, pit, convex hillside, saddle hillside, slope hillside, concave hillside and inflection hillside. To validate the automatic terrain classification and to observe the soils associated to the surface shapes, a field survey was performed in six sequences of soils distributed along the watershed. The algorithm has identified all the eleven classes of surface shapes in the Ceveiro watershed. However, saddle hillsides, convex hillsides and ridges were the most frequent. The field work, adopted as the terrain truth, has demonstrated the occurrence of a high rate of correspondence (85%) between the automated classification and the field segmentation; such results demonstrate the validity of the classification performed by the algorithm in the watershed. Other results have showed that the largest inclinations (higher slopes) were associated with convex hillsides in the majority (more than 90%) of the cases. The cross between the surface shape map and the detailed soil map has allowed associating the occurrence of *Tropoaquents* in the low flat areas and of *Entisols* in the convex hillsides. From the results we concluded that the algorithm is a promising tool to generate auxiliary variables applicable in DSM.

(1148 - 1166) Archaeopedological analyses of Bronze Age land use practices and landscape evolution in Southwest Germany

Sascha Scherer[1]; Benjamin Höpfer[2]; Eva Lehndorff[3]; Markus Fuchs[4]; Thomas Scholten[1]; Thomas Knopf[2]; Peter Kühn[1]

Department of Geosciences, Chair of Soil Science and Geomorphology, Eberhard Karls University Tübingen, Germany[1]; Institute of Pre- and Protohistory and Medieval Archaeology, Eberhard Karls University Tübingen, Germany[2]; Institute of Crop Science and Resource Conservation (INRES), Soil Sciences and Soil Ecology, Bonn University, Germany[3]; Department of Geography, Justus-Liebig-University Giessen, Germany[4]

What data do colluvial deposits provide to portray land use practices in Bronze Age (~2200-800 BCE)? Can small-scale movements and local impact on landscape be identified for the Bronze Age agricultural society? Are differences and shifts between allegedly favorable and unfavorable regions ascertainable? To examine these questions, the authors combine archaeopedological and archaeological approaches in a project of the Collaborative Research Center 1070 ResourceCultures. Distinctions in Bronze Age assessment and utilization of particular landscape are investigated by the sudy of three physio-geographically differing regions in Southwestern Germany: the Baar and Western Allgäu (unfavorable) and the Hegau (favorable). In this respect, evolution and distribution of colluvial deposits in the landscape generally indicate patterns of human activity at various spatial and temporal scales. We study on- and offsite colluvial deposits located in the surrounding of Bronze Age settlements. A high resolution sampling strategy (5 cm depth increments within diagnostic horizons) and variety of (paleo-)pedological methods are applied. Besides the typological classification of archaeological finds, chronostratigraphic analysis is conducted using AMS ^{14}C and luminescence dating techniques to identify phases of soil erosion. Phases of pedogenesis are differentiated by pedochemical (calcium carbonate, pedogenic oxides, pH, SOC) and soil micromorphological indices (soil microstructure, small-scale soil formation processes). Further, we use heavy metals (Cd, Cu, Cr, Ni, Pb, Zn, Hg, As) and geobiochemical markers (black carbon, phosphorus, steroids, gallic acids) as anthropogenic tracers for land use practices such as metal processing, fertilization and livestock farming within and in the surrounding of Bronze Age settlement areas. The archaeological approach comprises a source-critical evaluation and GIS-analysis of known sites as well as own prospections or smaller sondages. Among others, a yet unpublished Middle Bronze Age settlement in the Hegau, excavated on several hectares by the Cultural Heritage authorities of Baden-Württemberg during the last decade, serves as reference site and as initial point for the archaeopedological investigations. The poster presentation comprises first pedological and archaeological mappings, their incorporation into the theoretical project framework and a reflection of research status concerning the formulated questions.

(1535 - 2044) Fire dynamics of a mid mountain range – analytical evidence versus fire modelling

Luisa Wöstehoff[1]; Arne Kappenberg[1]; Frank Sirocko[2]; Yaping Shao[3]; Wulf Amelung[1]; Eva Lehndorff[1]

Bonn University, INRES Soil Sciences & Soil Ecology, Nussallee 13, 53115 Bonn, Germany[1]; University of Mainz, Institute for Geosciences, J.-J.-Becher-Weg 21, 55128 Mainz, Germany[2]; University of Cologne, Institute for Geophysics and Meteorology, Pohligstraße 3, 50937 Cologne, Germany[3]

Fire impacts on the environment, shaping past landscapes and likely altering habitability by humans. Many studies show evidence of fire events for specific periods of time at one site. However, information about the spatial variation of fires on e.g. regional scales is yet unknown. To investigate the spatial properties of past fires, sediment cores from two maar lakes, situated at different elevation in the Eifel region, a Central European mid mountain range, were sampled. These sediments cover a continuous fire record of about 120,000 years before present (BP). They were analysed for black carbon (BC), polycyclic aromatic hydrocarbons (PAH) and lignin as geochemical markers for fire and vegetation composition and compared to modelling of paleo-temperatures, vegetation and fire aerosol dispersal using ChemWRF. We hypothesized that in the Eifel region significant variation in fire activity existed, due to the establishment of forests at lower elevation (37 to 28 ka BP). Further, we investigate whether change in annual mean temperature and vegetation cover (=fuel of fire) could have been responsible for this variation in fire activity. Within the period from 37 to 28 ka BP, we found significantly different lignin, BC and PAH inputs reaching between the two lakes. At lower elevation (450 m asl and 35 km east of the other maar lake), lignin and BC were at highest concentration, while at higher elevation (565 m asl) a decrease in concentration was observed. We interpret this as an indication for a local formation of steppe vegetation at high elevation (as supported by pollen data, Sirocko et al., 2016). However, in this steppe environment we found peaking PAH concentrations from fine material (<500 µm) which likely stemmed from long-distance transported fire aerosols. In accordance with peaking lignin and BC concentrations at the maar lake at lower elevation, this supports the hypothesis that some regions in Central Europe have been forested during this period of time, which is currently under debate. Such forests might have affected human mobility in Central Europe around 37 to 28 ka BP.

(5309 - 2307) Interface between soils, morphogenetic processes, records of past human occupation and environmental changes in the

low terraces of the Jacaré-Guaçu river (Boa Esperança do Sul, State of São Paulo, Brazil)

Pedro Michelutti Cheliz[1]; Francisco Sergio Bernardes Ladeira[1]
UNICAMP[1]

This work discuss about interface between soils and human occupation, referring to the low terraces of Jacaré-Guaçu river near to the hunter-gattherer site Boa Esperança II (BES II, Santos 2011), (SP-Brazil). Were done 2 new trenchs, micromorphological descriptions, recordings of archaeological pieces (together to Araújo, Rodrigues and Santos), and colect samples for chemical, OSL, C-14, petrographic and granulometric analyzes. Has registered the presence of gley soils marked by ausence of B horizon and with sand-clayey granulometry. They cover nivels with well roundeds gravels (sandstones), of a medium particle size (20 cm) until 4 times higher than the current river pebbles of Jacaré-Guaçu, with coarse-sand matrix (that also register gleying). Archaeological materials (mostly chipped sandstones) were distributed along the profiles, with higher concentration next to the limit between the gravel units and the C horizons that cover them. Chemical analyzes indicate discontinuities in the concentration of phosphorus (P) between the mentioned limit, with deeper gravel nivels with values of phosporus (7mg/dm3) until two times higher than that (3mg/dm3) of C horizon that cover them. It has appointed that the profiles involve the presence of two sets of soils. The former being connected to pedogenesis on the gravels-matrix nível (deposits of ephemeral channels). The second linked to the alteration of the sand-clayey covers (at least partially deposits of flood plains relied on a new and higher (5-8 m) base level that in a second moment would cover the gravel). OSL and C-14 data sugest that the first soil cycle starts at least on the Pleistocene-Holocene transition, and the second could extend at least to the Medium Holocene. It has apointed that the exposure of the gravel (source of suitable raw material for making lithic tools) for the time required to form the first soil would be attractive for human occupation, and could contribute to the concentration of archaeological pieces registered on gravel´s top. The intense gleying recorded in the whole would be related to the flood plains linked to the deposits that orignes the second soil, and to humidity increases in relation to the predominant environments when depositing the basal gravel. Interfaces between local soils, morphogenesis and human registers of these low terraces merge with a set of environmental changes, including passage from semi-arid to more umids patterns and multiple base level variations.

(4658 - 772) The coastal soil of the Atacama Desert, properties, and implications in the conservation of mummified bodies, in the validity of the postmortem chemical result and the inference regarding the health of the ancient human populations

Leonardo Figueroa[1]; Bernardo Arriaza[1]
Universidad de Tarapacá[1]

The coastal soil of the Atacama Desert, northern Chile, Aridisol class, devoid of rain and vegetation, of geological age in the Jurassic period and at least since the Quaternary, is an extremely arid desert. Considering the desert's geochemical composition, two aspects are discussed: 1) Its implication in the preservation of bioarchaeological remains and 2) the validity of the concentration result of the chemical analyte in the mummified body and the inference regarding the health of the old human populations. The sedimentary formation of these coastal soils, with absence of rainfall, warm environmental temperature, high solar radiation, moderate intensity winds in the photoperiod, high relative humidity, mild condensation of marine water vapor, constant reception of marine aerosol, absence of Edaphon , absence of runoff water, the prevalence of Na (1 to 5%), Ca (0.2 to 1%) and Cl (2 to 5%) as the most abundant ions, make these soils a medium capable of adsorbing water favoring the inactivity of bacteria in the human body and mummification. Less than 0.5% organic matter in these soils, determines that there are simple aggregates, with weathering limited by time, a thick texture, with macropores and favorable airspace for air flow and therefore the favorable preservation of bioarchaeological remains. On the other hand, the high concentration of natural As and Li in the water and soils used in life, affect the quality of life of the associated populations, producing pathologies that include cancer. The set of soil qualities and burial techniques have generated an unwritten legacy through the excellent preservation of human remains in the soil without contamination by diagenesis, ranging from the first populations called Chinchorro (ca. 7000 BC). Until the remains of the Inca Period (ca. 1400-1500 AD). Chemical studies carried out on mummies, particularly the Inca Period (Cam 9 site), reveal that these populations were significantly affected by overconsumption of Li and As. The mummified bodies show skin lesions and high concentrations of these elements in different organs. In short, this type of study allows us to visualize and reconstruct the living conditions faced by the ancient populations in the desert environment with water and soil that provide bioavailable substances naturally.

C1.6.2 - Soil memory: proxies for deciphering records of past environmental conditions in soils and palaeosols

(2642 - 1133) Biological memory of soils and occupation layers of archaeological sites.

Elena Chernysheva[1]; Alexandr Borisov[2]
Institute of Physicochemical and Biological Problems in Soil Science Russian Academy of Sciences, Institutskaya 2, Pushchino, Moscow region, 142290, Russia (chernysheva1988@gmail.com)[1]; Institute of Physicochemical and Biological Problems in Soil Science Russian Academy of Sciences, Institutskaya 2, Pushchino, Moscow region, 142290, Russia[2]

Applied to archaeological sites, the essence of biological memory consists in the following. Human activity is accompanied by the input of specific organic materials into the soil. These organic materials are subsequently lost due to their complete mineralization by soil microorganisms. Despite the fact that organic substances had been decomposed, the information about their income may store in changes of soil microbial communities and enzyme activity and these changes can be preserved up to now. Unique objects, allowing study dynamics of microbial communities in soils through hundreds and thousands years after cessation of anthropogenic activity, are the soils of archaeological sites. Soils and occupation layers of settlements, in this case, represent a natural experiment with well-known place, time, and nature of anthropogenic activity. Their study allows evaluating the peculiarities of transformation of soil microbial community. The aim of this work was to study the effect of residential land-use and farming practice on soil properties and evaluate the peculiarities of changes of microbiological and biochemical soil properties of archaeological sites. Objects of studies were: (i) occupation layers of settlements (AD 200-400); (ii) soils around archaeological sites (AD 200-800); and (iii) ancient stone corrals (1400-1200 BC). All sites investigated are situated in the Kislovodsk basin (North Caucasus, Russia), and were under only one step of occupation in ancient time presently out of exploitation. Farming practice with long-term manuring in AD 200-800 had led to significant changes in soil microbiological properties. Application of cattle manure had led to a change in microbial biomass and enzyme activity. It was shown that in the soils of ancient agricultural lands viable spores of thermophilic bacteria were preserved and their high level indicates the long-term

manuring in the past. At the settlements high urease activity and abundance of thermophilic microorganisms allow to reveal places of cattle keeping. The study of soils from corrals also showed a significant increasing of these microbiological parameters in buried anthropogenically transformed layers. Thus, our work shows that the information about entering into the soil organic substrate can be stored in soil biological memory for about 3000 years. However, the time of keeping the information about human activity is seem to be much longer.

(9451 - 785) Climate and environmental changes in central-eastern Brazil during the Last Glacial Maximum

Ingrid Horák-Terra[1]; Antonio Martínez Cortizas[2]; Cynthia Fernandes Pinto da Luz[3]; Alexandre Christófaro Silva[4]; Pablo Vidal-Torrado[5]
Federal University of Jequitinhonha and Mucuri Valleys (UFVJM), Av. Vereador João Narciso, 1380, Unaí (MG), 38610000, Brazil (ingrid.horak@ufvjm.edu.br)[1]; University of Santiago de Compostela (USC), Santiago de Compostela, Spain[2]; Institute of Botany - Secretary of São Paulo State for Environment, São Paulo, Brazil[3]; Federal University of Jequitinhonha and Mucuri Valleys, Diamantina, Brazil[4]; University of São Paulo, Piracicaba, Brazil[5]

It is consensus that landscape and climate have undergone several changes over time and at several spatio-temporal scales. However, there is an intense debate about the actual conditions prevailing in different phase, as for example the Last Glacial Maximum (LGM) in tropical regions. Recent studies have provided new insights and confronted with hypotheses already established (Amazonian refugia and Pleistocenic arc), these asserting aridity was prevalent. Tropical peatlands have a large potential for the reconstitution of Pleistocene climate changes, and records of a large variety of proxies (biotic and abiotic) have already been used. Here, we present data on stable isotopes, ^{14}C dating, geochemical, and pollen records of a peat core (PI, 324 cm deep, spanning the last ~60 kyr) sampled in a tropical mountain mire (Pinheiro) from central-eastern Brazil. Isotopic ($\delta^{13}C$, $\delta^{15}N$) and elemental composition were determined in continuous 2 cm peat slices using an elemental analyzer coupled to a mass spectrometer and a X-ray fluorescence analyzer, respectively; whereas pollen was counted on mounted slides after physico-chemical treatment every 10 cm. Thirteen peat samples (2 cm thick) were radiocarbon dated by AMS, and an age-depth model was obtained. Statistical analysis was applied only to elemental composition using PCA. At the onset of the LGM, by ~27.8 kyr BP, a new pattern of climate conditions was established after the MIS 3 phase (Marine Isotope Stage 3; ~60-27.8 kyr BP). This pattern remained more or less constant beyond the end LGM (~18.9 kyr BP) and until the mid-Holocene (~6.6 kyr BP). Predominant wet conditions are supported by constant low $\delta^{13}C$ values (between -23.3 and -21.4‰) and by cold and humid forest as indicated by pollen data (Drimys, Podocarpus, Myrsine and others). Erosion in the catchment increased with increasing humidity (as attested by increases in concentrations of lithogenic elements in the peat), but it was relatively lower than during MIS 3, most probably due to denser tree-shrub vegetation cover. Increasing trend of $\delta^{15}N$ values (between 2.7-4.5‰) suggest a greater accumulation of organic material. Growing oceanic-atmospheric activity inferred by the increasing of Br/C ratios (between 12.99-78.35 µmol mol^{-1}) strengthens the evidence of the LGM as a likely wetter period. Pinheiro mire certainly contains a sensitive record that suggests the LGM was wetter than previously reported, besides being cold.

(9331 - 1785) Environmental setting of the early irrigation in Oasisamerica: paleopedological evidences from the alluvial paleosols in la Playa/Sonoran Desert

Georgina Ibarra[1]; Elizabeth Solleiro[2]; Guadalupe Sánchez[3]; Sergey Sedov[2]; Carmen Ortega[4]
Posgrado Ciencias de la Tierra, UNAM[1]; Instituto de Geología, UNAM[2]; Instituto de Geología, ERNO, UNAM[3]; UES, México[4]

Environmental conditions and human-landscape interaction during the onset of the irrigated agriculture in Oasisamerica are not clear yet. In la Playa site (Sonora, NW Mexico) the evidences of sedentary population, land cultivation and water management developed after the end of Altithermal period since ~ 4.3 kyr BP: more than 550 archaeological features including hundreds of human cremations and a net of buried artificial channels. These findings are closely associated with several paleosol levels alternating with the sediments within a large alluvial fan. We studied micromorphological features, physical characteristics (texture, rock magnetic properties), composition of organic matter to reconstruct pedogenesis and sedimentary environment of the paleosol sequence. Additional paleoenvironmental information was extracted from pollen assemblages, extracted from paleosols. The results point to a long period of geomorphic and climatic stability in the early-middle Holocene marked by well developed red Cambisol. It was followed by an unstable interval round 4.5 kyr BP marked by severe erosion of earlier soil profiles and sedimentation of different kind: channel, floodplain, eolian. Later synsedimentary Fluvisols were formed showing signs of predominantly arid pedogenesis, interrupted by occasional flooding; indicators of human impact are also encountered. We conclude that the shift to irrigated agriculture as the main subsistence activity occurred during the period of major climatic and geomorphic fluctuation and then irrigation developed further under dry environment with limited water resources during the Late Holocene.

(8576 - 1284) Geochemical signals of pedogenic processes in the profiles of surface and buried soils at the Nozha-Var archaeological site, European Russia

Elena Aseeva[1]; Alexander Makeev[1]; Alexey Rusakov[2]; Ksenia Sorokina[1]; Fatima Kurbanova[1]
M.V. Lomonosov Moscow State University, Moscow, Russia[1]; Institute of Earth Sciences, Saint-Petersburg State University, Saint-Petersburg, Russia[2]

Many soil properties that are preserved in buried soils of archaeological sites are associated with particular type of environmental conditions and thus carry paleoenvironmental signatures. Visual observation of pedofeatures, however, provides insufficient information on the soil processes and therefore the integrated analysis including application of analytical methods is needed for their better interpretation. This study presents the results of a geochemical study of two nearly 2m deep morphologically similar soils which were formed on the same surface and in close proximity to each other at the Nozha-Var archaeological site, located at the

northern boundary of the forest-steppe zone in European Russia. The study objects included a paleosol buried 2000-1400 cal yr BP (Early Iron Age) under a fortification earth wall of an ancient settlement and the off-site surface soil. Concentrations of major and trace elements were determined in the bulk soil samples (n=29) and also in the soil clay-particle fraction (n=15) by XRS method after loss on ignition determination (1000ºC). Data on the ratios of relatively immobile elements (Ti/Al, Ti/Zr, Zr/Y, Zr/Nb) were used to evaluate the geochemical uniformity of the parent materials in which the soils were formed. The similarity between the soils according to the parameters' values and also the absence of abrupt changes in their depth functions were found. This allows for relating the possible differences in the soil geochemistry to either environmental changes or duration of pedogenesis. Both morphological and analytical features confirmed that the studied soils meet diagnostic criteria for Retisols and have a similar textural contrast between the upper (Ah, E) and middle (Argic) horizons. However, the surface soil showed better expressed retic properties which were in line with higher molar SiO_2/Al_2O_3 ratio both in the bulk samples and also in the clay-sized fraction. The distribution of element concentrations in the clay-particle fraction across soil horizons indicated better development of eluvial and leaching processes in the surface soil: in its upper horizons (Ah, E, E/Bt) the clay was clearly depleted in Fe_2O_3, Al_2O_3, CaO. In the Argic horizons of both soils the clay-sized fractions showed similar geochemical patterns. Thus, geochemical characteristics of the studied soils proved that they experienced one-way evolution and the geochemical differences between them seem to be related to the duration of pedogenesis.

(6271 - 357) Late Pleistocene Paleosols of Serra da Mantiqueira, southeastern Brazil: pedological processes and genesis conditions

Sheila A. C. Furquim[1]; Silvio T. Hiruma[2]

Environmental Sciences Department, Universidade Federal de São Paulo (UNIFESP), Diadema, SP (sacfurquim@gmail.com)[1]; Instituto Geológico (IG), Secretaria do Meio Ambiente/SP, São Paulo, SP (sthiruma@gmail.com)[2]

A vertical succession of 3 paleosols located in the summits of Serra da Mantiqueira, specifically in the Cambuí/Monte Verde (MV) plateau, was studied in order to understand their pedological processes and conditions of formation. Morphological descriptions, physical and chemical analysis and radiocarbon dating were perfomed in the soils. Each paleosol is formed by a black (10YR 2/1), thick (25 to 40 cm) and mostly massive organic horizon, which overlies brown (10YR 3/2), shallower (8 to 23 cm) and massive C horizons. The organic horizons are sapric, with variable texture, organic carbon (OC) from 290 to 430 g kg^{-1} and cation exchange capacity (CEC) between 380 and 470 mmolc kg^{-1}. The underlying C horizons have sandy clay loam texture and significantly lower OC (6 to 18 g kg^{-1}) and CEC (49.9 to 88.5 mmolc kg^{-1}). The age of the three generations of organic horizons, from the shallowest (92-117 cm) to the deepest (240-270 cm), is 14180±50, 25410±110 and 28990±170 BP. Thus, these soils likely developed over colluvium deposited in discontinuous periods of more active erosional processes during the late Pleistocene. Higher stability periods between intense colluviation allowed a more significant action of the pedological processes, especially the addition and accumulation of organic material in the surface and their transformation into organic matter. The parallelism between the topography boundaries of the horizons and the current surface topography suggests a concave paleosurface. Hence, the organic matter accumulation likely occurred in a geomorphological condition subjected to local water saturation, typical of H horizon formation. Because of this past concave position, which prevents intensive leaching, and the high presence of colloids in the organic horizons, the high CEC of these horizons is probably an ancient property that is still currently preserved. The age gap between the shallowest and intermediate organic horizons is 11230 years, and between the intermediate and bottom organic horizons is 3580 years. Thus, the deposition of colluvium and the intense accumulation of organic matter occurred in these short periods, generating a total thickness of 58 cm and 90 cm in the shallowest and intermediate paleosol, respectively. These data show the high velocity of the geomorphological and pedological processes in the area.

(5211 - 707) Paleoenvironmental reconstitution by stable C and N isotopes in a mountain tropical peatland, Minas Gerais State - Brazil

Camila Rodrigues Costa[1]; Alexandre Christófaro Silva[1]; Cynthia Fernandes Pinto da Luz[2]; Plínio Barbosa de Camargo[3]; Ingrid Horák-Terra[1]; Uidemar Morais Barral[1]; Aparecido de Penafort Abreu Filho[1]; Geisla Mendes Macedo[1]

Universidade Federal dos Vales do Jequitinhonha e Mucuri[1]; Núcleo de Pesquisa em Palinologia - Instituto de Botânica, São Paulo[2]; Universidade de São Paulo[3]

Peatlands are humid ecosystems formed by organosols, from the successive accumulation of decaying organic matter. Using the ^{13}C and ^{15}N stable isotopes, can know the origin of the soil organic matter recognizing the photosynthetic pattern (C3, C4 and CAM) and thus determine the type of vegetation (terrestrial or aquatic) that colonized the area and the local humidity condition. The objective of this study was to evaluate the soil isotopic composition ($d^{13}C$ and $d^{15}N$) of a tropical peatland located in the Serra do Espinhaço Meridional (Minas Gerais State, Brazil). The study area is located in the Rio Preto State Park. A testimony of 3.71 meters of depth of the Rio Preto peatland (18° 14.5 '25" S, 43° 19.7 '24" W, 1.593m.sm) was sampled. Samples were sectioned every 5 cm and were used to determine the values $d^{13}C$, $d^{15}N$ and C/N ratio. ^{14}C dating was also performed at 4 depths (20, 172, 330 and 368cm). The results indicate the occurrence of five environmental conditions from Late Pleistocene to present: I) 23,037 to 13,555 years cal. AP (371-272 cm layer); the values of $d^{13}C$ ranged from -24 to -20‰, $d^{15}N$ between 0.35 and 5‰ and the C/N ratio of 20 to 45, indicating a predominance of C3 plants and a humid condition; II) 13,555 to 11,720 years cal. AP (272-197 cm layer); the values of $d^{13}C$ ranged from -25 to -21‰, $d^{15}N$ between 2 and 4‰ and C/N of 33 to 44, indicating an even greater predominance of C3 plants and elevated humidity; III) 11,720 to 8,564 years cal. AP (197-97 cm layer); the values of $d^{13}C$ ranged from -24 to -19‰, $d^{15}N$ between 3 and 4‰ and C/N of 28 to 46, indicating a large influence of C4 plants (field vegetation) and a accentuated decline of humidity; IV) 8,564 to 6,987 cal. AP (97-50 cm layer); the values of $d^{13}C$ varied from -22 to -21‰, $d^{15}N$ of 4 to 5‰ and C/N of 34 to 42, indicating greater influence of C4 plants and even lower humidity; V) 6,987 cal. AP to the present (50-0 cm layer); the values of $d^{13}C$ varied from -23 to -20‰, $d^{15}N$ from 4 to 6‰ and C/N from 21 to 48, indicating a mixture of organic matter of terrestrial origin (C3 and C4) and aquatic, with predominance of terrestrial plants and increased humidity conditions, similar to current conditions. Stable isotope analysis allowed us to infer changes in the vegetation cover and in the moisture conditions of the Rio Preto peatland.

(7409 - 1232) Palynofacies and carbon isotope analysis as indicators of pedogenesis and paleoenvironmental changes of upper montane soil in Espírito Santo State, Brazil.

Eduardo Carvalho da Silva Neto[1]; Marcos Gervasio Pereira[1]; Jolimar Antonio Schiavo[2]; Marcelo de Araújo Carvalho[3]; Natália de Paula Sá[3]
Federal Rural University of Rio de Janeiro[1]; State University of Mato Grosso do Sul[2]; National Museum, Federal University of Rio de Janeiro[3]

Records of changes in the landscape can be observed more clearly in soils that present high accumulation of organic matter, such as Histosols. The objective of this work was to describe the pedogenetic process in the formation of an Histosol profile in a upland environmental of the Espírito Santo State, southern Brazil, through the palynofacies analysis and carbon isotopes. The samples were processed following the standards of preparation for palynofacies and later analyzed in organopalinological slides using the microscopy in transmitted white light. The genesis of the Histosol is associated to the pedogenetic process of paludization, influenced by relief, conditioning poor drainage, and organisms, providing and transforming the added organic matter. According to the dating (^{14}C) performed at the base of the profile, its formation corresponds to Holocene deposits. It was observed the predominance of components of the particulate organic matter of the groups amorphous organic matter and phytoclasts. The results of the palinofacies analysis indicated variations in the proximal-distal tendency and a depositional environment of low energy and reducing conditions. Through the characterization of the particulate organic components and the correlation between the variations of their percentages, it was possible to identify three depositional intervals: phase I, characterized by the deposition of transported sediments, marked by the amorphous organic matter group associated to the predominance of opaque phytoclasts; phase II, with evidence of sedimentation typical of a lacustrine environment with the most significant records of amorphous organic matter and freshwater microplankton; phase III, which corresponds to the current plant cover, with greater abundance of non-opaque and sporomorphic phytoplasts. The variations in the isotopic composition (^{13}C) of the carbon indicated changes in the organic matter sources, suggesting a mixed vegetation (C_3 and C_4) at the beginning of the formation of the soil, aquatic organic matter (freshwater algae) during the pedogenic evolution of the profile and a predominantly herbaceous vegetation (C_4), reflecting the current conditions. The analysis of palinofacies was effective to complement the soil characterization results, agreeing with the paleoenvironmental interpretation of the paludization process and making possible inferences about the changes in the soil formation environment.

(8032 - 2423) Pedogenic carbonate crusts (caliches) in tropical karst landscapes as archives for paleoenvironmental reconstructions – a case study from Yucatan Peninsula, Mexico)

Daisy Valera Fernández[1]; Héctor V. Cabadas Báez[2]; Elizabeth Solleiro Rebolledo[3]
Universidad Nacional Autónoma de México (UNAM)[1]; Universidad Autónoma del Estado de México[2]; Universidad Nacional Autónoma de México (Instituto de Geología)[3]

In the Yucatan Peninsula (southeast of Mexico), several outcrops have been observed with the presence of compact limestones in the form of thick sheets. The pedogenetic origin of these carbonated crusts (caliches) allows us to infer paleoenvironmental information about climatic regimes in this región for the uplifting periods of the carbonate platform and the development of pedogenic processes. Caliches were studied in quarries located in the Cancun-Tulum corridor in littoral carbonates sequences from the northeast of the Quintana Roo state, which are derived from shallow marine and eolianites facies. Micromorphological observations indicate the presence of a edaphic environment attending to features such as microgranular relict structure, acicular carbonates (typical for soil and fungi environment) and traces of roots. The stable isotope signatures ($\delta^{13}C$ and $\delta^{18}O$) point to the formation of caliches under a higher proportion of C4 plants therefore a drier or more seasonal climate. Uranium-thorium (U/Th) dating indicate that these caliches were formed more than 100,000 years BP; during previous glacial episodes (marine isotope stage (MIS) 6 and 8) in contrast with moments of eolianites deposition during interglacial periods (insufficiently rainfall to support vegetation) and karst develoment (glacial-interglacial transicion). This pedogenic carbonates represent an ancient phases of soil formation, whose remains are no longer visible today, due to the strong eroción that takes place in this karstic región.

(9166 - 509) Reconstruction of the environment on the basis of complex study of steppe buried palaeosols

Valentina Prikhodko[1]
Institute of physicochemical and biological problems in soil science RAS[1]

The reconstruction of the environment on the basis of complex study of steppe palaeosols buried under archaeological monuments of the Bronze, Early Iron and Medieval Ages of the Urals region and Southern Siberia was done. Separation of pollen plants into ecological groups: xerophytes, mesophytes, hydrophytes and ruderals allowed to restore landscapes more detail based on the composition and ratio of plant communities, which grow in more humid, dry, warmer and colder conditions. Use of different geochemical weathering coefficients helped to clarify the palaeoclimate humidity. The multidisciplinary study of four Scythian burial mounds (2565-2390 ca, 1 s) of the Turan-Uyk intermountain plain in Tuva, southern Siberia revealed that after 95 years from the beginning of their erection, there were signs of dry climate, in other chrono-intervals natural conditions were slightly wetter than modern. This is evidenced by soil properties, greater amount of pollen of mesophytic and hydrophytic plants in Scythian times than now. Such conditions favored by the Scythian tribes appearance there the first than in other territories, spread in the region and increased anthropogenic pressure on the landscape in the final phase of mounds erection. For the forest-steppe of Sic-Urals area it was shown that climate of the Srubnaya epoch (3900-3600 ca, 1σ) was wetter and cooler than now, these are indicated by the greater content of organic matter, landscapes with more content of mesophytic grasses and less xerophytes and small birch and pine forests with less area of thermophilic broad-leaved species. The landscape placement of 120 archaeological monuments of the Medieval Srostki culture of the Altai area was done and their distance from water and mineral resources was determinated based on use the space images and GIS technologies (Schayakhmetov, 2017). The "cascade" filtration of bacteria on nuclear filters with a diameter of 0.1 to 1.85 μm shown that large bacterial cells (1.4-1.85 μm) predominate in forest soils and former plowlands, small ones (0.2-0.4 μm) - in palaeosols as an adaptation to lack of nutrients and moisture; biomass of bacteria is in 2-20 times greater than that found in luminescence microscopy; the biomass of microfungi (91-99%) dominates

(Polyanskaya et al., 2016). It was established by phosphate and geochemical methods that composite food, milk porridge, cheese and water were initially in the ceramic vessels from the Srubnaya and Sarmatian epochs barrows.

(3165 - 720) Soil chronosequence of the Early Iron Age in the central part of the forest-steppe zone of the East European Plain

Tatiana Puzanova[1]; Alexander Makeev[1]; Fatima Kurbanova[1]

Lomonosov Moscow State University[1]

The hillforts were widespread in the steppe, forest-steppe and forest areas in the centre of the East European Plain during the Scythian time. Soils buried under defensive ramparts keep unique information on the paleoclimatic conditions that existed at the time prior to burial. The hillforts often had several lines of defense that allows revealing short-term environmental changes. Soils buried under the defensive ramparts of different age at the three archaeological sites in Lipetsk region were investigated to reveal environmental changes during the second half of the Holocene. The study includes soils buried under two defensive ramparts of the Mukhino hillfort (2500 ± 150 and 1500 ± 150 cal BP), the earth wall of Ksizovo fortified settlement (2090 ± 70 cal BP), the earth wall of the Degtevoe hillfort (2500 ± 150 cal BP), and the surface soils formed in similar landscape positions. All hillforts were built on a narrow promontories formed by a junction of several gullies with steep slopes heading to local stream valleys. Both buried and surface soils are formed in similar loess sediments. The surface soils and the buried soils of the early Scythian time are similar: Greyzemic Luvic Phaeozems, formed under broadleaf forest vegetation. The soil buried 1500 ± 150 cal BP is presented by Luvic Chernozem indicating more arid environment and the onset of steppe ecosystem within the interval of I century BC - I century AD. The soils have chernic horizon, the secondary carbonates are presented by abundant pseudomycelium and carbonate coatings above clay cutans that were formed earlier. More humid environments during the V-VIII and XIII-XVI centuries AD resulted in the advance of broadleaf forests and the formation of Greyzemic Luvic Phaeozems with deeply leaching of carbonates. The study shows that surface Greyzemic Phaeozems of the forest-steppe areas are polygenetic and reflect dynamic changes in the border between forest and steppe landscapes.

(4316 - 2565) Aggregate Stability in Soil with Humic and Histic Horizons in a Toposequence under Araucaria Forest

Daniel Hanke[1]; Deborah Pinheiro Dick[2]
UNIPAMPA[1]; UFRGS[2]

Aggregate stability is one of the most important factors in soil conservation and maintenance of soil environmental functions. Aggregation affects soil capacity to store and stabilize organic C, as well as soil water storage capacity and soil structural stability against erosive agents and compaction. The objective of this study was to investigate the aggregate stability mechanisms related to chemical composition of organic matter in soil profiles with humic and histic horizons in a toposequence under Araucaria moist forest in southern Brazil. The soils sampled were classified as Humic Hapludox (highest position), Fluvaquentic Humaquepts (lowest slope position), and Typic Haplosaprists (floodplain). The C and N contents were determined in bulk soil samples. The chemical composition of soil organic matter was evaluated by infrared spectroscopy. Aggregate stability was determined by applying increasing levels of ultrasound energy. Results were analyzed by descriptive statistics and multivariate analysis. To support the multivariate studies, simple linear regressions were also applied. Carbon content increased from the top of the slope to the alluvial plain. The SOM_{HF} samples showed the same FTIR spectrum pattern; in figure 1, the FH spectra are shown as an example. The absorption bands observed in the spectra were 3420 cm^{-1} - O-H stretching in H-bonds; two bands at 2950 and 2840 cm^{-1} - C-H of aliphatic groups; 1710 cm^{-1} - C=O of carboxyls; 1630 cm^{-1} - C=C of aromatic groups; 1540 cm^{-1}, - N-H and C=N; 1245 cm^{-1} - C-O of OH deformation of the carboxyl; and 1075 cm^{-1}, - the C-O bond of primary and secondary alcohols. In SOM studies, this organic function is considered a part of the carbohydrate-like structures (C-O-alkyl). Higher ultrasonic energy values for clay dispersion were observed in the C-rich soils in the lower landscape positions, indicating that organic compounds play an important role in the structural stabilization of these profiles. Both aliphatic and carbohydrate-like structures were pertinent to aggregate stability. In the Oxisol, organo-mineral interaction between carbohydrates and the clay mineral surface was the most important mechanism affecting aggregation. In soils with a higher C content (Humaquepts and Haplosaprists), stabilization is predominantly conferred by the aliphatic groups, which is probably due to the structural protection offered by these hydrophobic organic groups.

(8269 - 2279) Aggregation and organic carbon in Oxisol under areas with and without tillage

Mariele Monique Honorato Fernandes[1]; Matheus Flavio da Silva[1]; Carolina Fernandes[1]
Faculdade de Ciências Agrárias e Veterinárias FCAV/UNESP Câmpus de Jaboticabal[1]

The intensive preparation consists in soil revolving and incorporation of the vegetal residues. This process accelerates the decomposition of the organic matter, reducing the carbon stock in the soil, besides favoring the rupture of the aggregates, damaging the soil structure. On the other hand, the no-tillage of the soil increases the carbon stock and preserves the larger aggregates. The objective of this study was to evaluate soil attributes in an area where the soil is prepared (PA) and in an area that does not receive this preparation with fallow (NTA). The experimental areas are located in Jaboticabal, state of São Paulo, Brazil. The soil of the areas is characterized as Red Oxisol clay-textured (564 g kg-1 clay, 180 g kg-1 sand, 256 g kg-1 silt). In each area 20 points were sampled in three layers: 0.00-0.05 m (L1); 0.05-0.10 m (L2) and 0.10-0.20 m (L3). Weighted mean diameter (WMD), aggregate mass (AM) and organic carbon (OC) were analyzed. Data descriptive statistics were performed. The mean and standard error of WMD (mm) in NTA were: 3.4 ± 0.08 (L1); 2.3 ± 0.07 (L2); 1.7 ± 0.04 (L3). For the PA they were: 3.1 ± 0.09 (L1); 2.8 ± 0.08 (L2); 2.3 ± 0.07 (L3). From the mean values, a higher WMD was observed in NTA in L1, however, in L2 and L3 the highest WMD values occurred in the PA. AM (g g-1 soil) greater than 4 mm was higher in NTA (0.48 ± 0.02) in L1, but lower in L2 (0.24 ± 0.01) and L3 (0.13 ± 0.008) compared to PA (0.43 ± 0.02 (L1), 0.36 ± 0.02 (L2), 0.24 ± 0.01 (L3)). AM between 4 and 2 mm was greater in NTA (0.19 ± 0.004 (L1), 0.17 ± 0.003 (L2), 0.13 ± 0.002 (L3)) than in PA (0.16 ± 0.004 L1), 0.16 ± 0.004 (L2), 0.16 ± 0.005 (L3)) in L1 and L2, but lower in the L3 layer. AM between 2 and 1 mm was equal in NTA (0.12 ± 0.006) and in PA (0.13 ± 0.008) in L1, but was higher in NTA in L2 (0.19 ± 0.004) and L3 (0, 20 ± 0.005) relative to PA (0.14 ± 0.004 (L2); 0.18 ± 0.008 (L3)). The OC content (g kg-1) was higher in NTA in all layers (21.1 ± 0.6 (L1), 15.3 ± 0.4 (L2), 13.8 ± 0.3 (L3)) when compared to PA (12.2 ± 0.32 (L1), 11.9 ± 0.36 (L2), 10.6 ± 0.36 (L3)). Soil preparation caused the aggregates rupture, decreasing WMD in L1 and increasing in L2 and L3. The no-tillage preserved the aggregates in L1. Soil preparation decreased OC soil content.

(5071 - 3135) Assessment of soil compression stress and organic carbon content under grazing and swine manure application

Douglas Leandro Scheid[1]
Universidade Federal de Santa Maria[1]

The raise of swine produces a great amount of slurry, in their composition had nitrogen, phosphorus and organic material. Because of that composition swine slurry can be applied on the soil, and the areas with cultivation of *Cynodon dactilon* to feed ruminants need a great quantity of nutrients so the application of swine slurry is a good option. However, the physical attributes of this areas can be influenced with the addition of carbon and cattle trampling. The aim of this work was to study the impact of swine slurry application on fields with cultivation of *Cynodon dactilon* under grazing on the soil physical attributes. The soil in the field is a Rhodic Oxisol with 490 g kg^{-1} of clay, 154 g kg^{-1} of sand and 356 g kg^{-1} of silt. The field have different times of cultivation with *Cynodon dactilon* and application of swine slurry, with grazing: three, eight and 15 years. The average application rate of swine slurry was approximated to 200 m^3 ha^{-1} $year^{-1}$. The soil sampling was done with cylinders having a average of 100 cm^3. The soil samples were collected on four layers: 0.02-0.07 m, 0.1-0.15 m, 0.15-0.20 m and 0.20-0.25 m depth. The pre compression stress was determined under static loading with steps of 12.5, 25, 50, 100, 200, 400, 800 and 1600 KPa. The total organic carbon content was determined by the wet oxidation method. The bulk density with three years was greater than with 15 years in the superficial layer. We did not find difference in the others layer for bulk density. The preconsolidation pressure (σp, KPa) was greater with three years than eight and 15 years. The σp was greater in the layer 15-20 cm with three years, and was greater in the layers 10-15 cm with eight and 15 years. The results shows that higher σp in subsuperficial layers were because the cattle trampling effect. Cattle trampling results in compaction in subsuperficial layers because the little foot area. The compaction degree did not show difference. The compression index was greater with three and eight years, that shows that the soil had more settlement when cultivated a short period with *C. dactilon* and grazing. The total organic carbon was greater in the superficial layers

(0.02-0.07 m and 0.10-0.15 m). The time of application did not change the total organic carbon content. The bulk density and σp show that with more time of *C. dactilon* cultivation can have better conditions for plant growth than shorter time.

(8566 - 2342) Assessment on Soil Aggregate Stability Relations with Organic Carbon Pools at different Tropical Climates and Soil Use Systems in Colombian Andes.

Efrain Francisco Visconti Moreno[1]; Ibonne Geaneth Valenzuela Balcazar[1]
Universidad Francisco de Paula Santander[1]

Measurements of stable aggregates (SA) at 2.36; 1.18; 0.60 and 0.30mm, stable aggregates weighted mean diameter (WMD), organic carbon (OC) at particulate organic matter (OM) pool (POC), OC at mineral associated OM pool (MAOC), total OC (TOC) and humification rate (HR) on soils sampled at 2 altitudinal sites: Humic Dystrudepts in cold tropical climate (CC) with 3 use plots; tropical mountain rainforest (MF), pastures (PA) and crops (IC). Fluvaquentic Dystrudepts in warm tropical climate (WC) with 3 use plots; tropical rainforest (RF), oil palm pastures association (OP) and irrigated rice (RC). Soil sampled at 3 depths: 0–5, 5–10 and 10–20 cm. Also mineral particles distribution, bulk density (Bd) was measured. Results of SA >2.36mm was higher at CC soil (51.48%) than WC soil (9.23%). SA 1.18-2.36mm was also higher at CC soil (7.78%) than WC soil (0.62%). SA 0.60-1.18mm resulted indifferent. SA 0.30-0.60mm was higher at WC soil (13.95%) than CC soil (4.67%). SA <0.30mm was higher at WC soil (72.56%) than CC soil (32.15%). Analysis reveals significant effect of climate on SA; SA 0.60-1.18mm is excluded, CC soil had highest values. Significant effect of use on SA was partial (only for SA 0.30-0.60mm), being higher in IC. Higher aggregation stability is remarkable at CC and between soil uses the MF is most favorable for higher SA content. MWD at CC soil is higher in layer 1 and layer 2, of MF (2.93 and 2.91 mm respectively). The layers 1 and 2 of IC presented MWD values of 1.96 and 1.73 mm, respectively. Having the lowest values of MWD the layers 1 and 2 of PA. For layer 3, MWD is higher at IC (2.13 mm), followed by MF and PA. With regard aggregates MWD at WC soil, layer 1 of RC presents the highest value (1.08 mm). All other values of MWD are 0.50 mm and less. A depth stratification of AS content is observed, top soil has bigger size classes of SA. At CC the PA has higher TOC and the MF together with IC present lower TOC. Comparing TOC and mineral particles distribution with SA, results that higher TOC improves presence of bigger size of aggregates at sandy soils. POC is highest at CC soil. Despite no significant effect of use system or depth, layer 1 at both MF and PA had the higher values. So the dominant presence of SA > 2.36 mm in CC soil is directly related to higher POC. It is observed that MWD and SA > 2.36 mm increase linearly with a higher POC. But decrease linearly with a higher HR. For SA < 0.30 mm, a linear decrease is observed at higher POC.

(3672 - 2138) Biological and mechanical decompaction of an Oxisol in the Brazilian Western Amazon.

Anderson Cristian Bergamin[1]; Fábio Lucas de Mattia1[1]; Emerson Oliveira Souza1[1]; Wesley Santana Ferreira[1]; Diogo Arthur Valiati Dantas[1]; Fábio Régis de Souza[1]; Renan Marré Biazatti[1]
Universidade Federal de Rondônia[1]

Soil compaction is a problem in the Brazilian agricultural activity due to the intense traffic of agricultural machinery and the animal trampling, being necessary the decompaction of the soil to maintain the productivity in these productive systems. This study aimed to evaluate the influence of soil compaction induced by the traffic of a tractor, submitted to mechanical and biological decompaction, on soil density and dry matter yield of soil cover crops. The experiment was installed in a clayey Oxisol at the experimental farm of the Federal University of Rondônia (UNIR), in Rolim de Moura, Rondônia state, Brazil. A randomized complete block design was applied, with a split plot arrangement and three replicates. In the split plot, three soil cover crops were introduced: Brachiaria brizantha, Crotalaria grahamiana, Crotalaria spectabilis, plus mechanical chiseling (soil with B. brizantha cover); and in the main plot five induced levels of compaction by tractor traffic (mass of 3.2 Mg) in zero, one, two, four and eight passes. Soil density was determined by the volumetric ring method at depths of 0.0-0.05 m, 0.05-0.10 m and 0.10-0.20 m. For the 0.0-0.05 m layer, with the exception of mechanical chiseling, there was an increase in soil density with the tractor traffic. Without the traffic tractor, and with a passes, there was no difference between the cover crops for the density of the soil. With two to eight passes of the tractor, there was only effect of reducing the soil density with the use of mechanical chiseling and cultivation of C. grahamiana, showing a better effect of these treatments in the recovery of compacted areas. For the subsurface layers (0.0-0.05 to 0.20 m) only mechanical chiseling reduced soil density. There was a reduction in the production of dry mass in all the cover crops with the increase of the tractor passes. The B. brizantha in all tractor passes and C. grahamiana with up to two passes of the tractor produced greater amount of dry mass. Thus, it was observed that the mechanical decompaction was more efficient to reduce the soil density and the B. brizantha had a higher dry mass production, in addition, C. grahamiana can be used as a practice for the decompaction of lightly compacted soils.
Keywords: soil cover crops; soil density; mechanical chiseling.

(6904 - 1393) Clay fraction flocculation degree of Mato Grosso do Sul State soils

Rafaela Silva Santana[1]; Felipe Ceccon[1]; Thais Stradioto Melo[1]; Izabela Richena Barboza[1]; Leandro Escobar Dalarosa[1]; Gabriele Bezerra Diolindo da Silva[1]; Matheus Anghinoni[1]; Lucas Costa Soares[2]; Alessandra Mayumi Tokura Alovisi[1]
Federal University of Grande Dourados[1]; State University of Mato Grosso do Sul[2]

Mato Grosso do Sul has 35.7 million hectares of extension, and 4.5 million of these were used for growing crops on 2017/18 harvest. The change from native vegetation to agricultural exploitation significantly affects soil physics, so as the soil management adopted directly influences the physical attributes of the soil. Red-yellow ultisol, haplic albaqualf, chromic alfisol, quartzipisamment entisol, red-dystrophic oxisol, red dystroferric oxisol, dystrophic oxisol, dystroferric oxisol, red nitosol, hydromorphic albaqualf, red alfisol, rendzic chernosol, regolith entisol, ultic entisol, vertisol and gley soil were induced to two methods of clay dispersion in three replications. The variables water-dispersed clay (WDC), total clay (TC) and flocculation degree (FD) were induced to analysis of variance and when significant were compared by the Scott-Knott test (p <0.05). Soils that had a clay textural classification in the NaOH dispersion method (total clay) represent statistically the group of soils with the highest flocculation. The water-dispersed clay method overestimates the silt fraction. The clay flocculation degree varies along with the mineral composition of the soil. Clay dispersion methods can generate different textural classes of soils.
Keywords: soil physics; soil texture; dispersion methods.

(1510 - 249) Coffee conilon shaded by rubber tree improving the soil structure

Gustavo Soares de Souza[1]; Henrique de Sá Paye[1]; Lucas Calazans Santos[1]

INCAPER[1]

The state of Espírito Santo, southeastern Brazil, is one of the main conilon coffee (*Coffea canephora*) producing areas in the world. However, it presents in these areas one of the highest proportions of soil degradation in the state. Poorly managed conilon coffee plantations have negative soil consequences, such as compaction, erosion, loss of water and nutrients, and accelerated mineralization of organic matter. The occurrence of high temperatures and a long period of drought can accelerate soil degradation, with a negative influence on productivity and longevity of crop. The implantation of coffee plantations in intercropped or agroforestry systems is an option to minimize the soil degradation process, since it can better promote the soil structure and increase the soil carbon stock. The objective of this study was to evaluate the soil bulk density, soil porosity, plant-available soil water capacity, soil water content, soil temperature and soil carbon stock of an Argissolo Amarelo under coffee conilon shaded with rubber tree in the Sooretama, ES. The treatments under study were: T1- conilon coffee shaded with rubber tree and T2- monoculture of the conilon coffee in full sun. Deformed and undisturbed soil samples were collected with four replicates of the layers 0-0.1, 0.1-0.2 and 0.2-0.4 m. Statistical analysis was performed using the F test ($p<0.05$) and Tukey test ($p<0.05$). The conilon coffee shaded with rubber tree showed a lower soil bulk density and greater total porosity and macroporosity in relation to treatment in full sun in the soil layers. The plant-available soil water capacity and soil water content did not differ significantly between treatments. The conilon coffee shaded presented lower soil temperature in the three layers in relation to treatment in full sun. The soil carbon stock did not differ between the treatments in the three layers. The conilon coffee shaded with rubber tree improved soil structure and reduced soil temperature, contributing to soil conservation and maintaining its productive potential.

Keywords: Soil bulk density; soil porosity; agroforestry system; *Coffea canephora*

(1705 - 1281) Compaction of the soil in sugarcane cultivation area under different soil preparations

Ciro Pozzi Garcia[1]; Juliano Carlos Calonego[1]; Carlos Alexandre Costa Crusciol[1]; Tiara Moraes Guimarães[1]; Jorge Martinelli Martello[1]; Ariane Garcia[1]

UNESP - São Paulo State University, College of Agricultural Sciences.[1]

Soil compaction in sugarcane cultivation areas is common, mainly due to the end of burning and the replacement of human labor by mechanized means. The increase of the frequency of agricultural machinery passing through the soil, especially during the harvesting process with the transshipments and harvesters, leads to the densification of the soil particles. Soil compaction is detrimental, as it causes restriction of the root system development, reduction of water absorption and retention, and reduction of soil aeration. These factors directly interfere in the vegetative development of the crop, which can lead to productive losses. The objective of this study was to evaluate soil penetration resistance (SPR) in different soil preparation systems. The experiment was installed in 2015 under Red-Yellow Latosol (sandy texture), located in Borebi, a city in the interior of the state of São Paulo, Brazil. The experimental design was a randomized complete block design, with two treatments (conventional soil preparation - CSP (control / standard), deep soil tillage – (DST) with four replications each. The CSP system is characterized by tillage with disk harrow, chiseling and disk harrow again. In the DST was used deep tillage with rod up 0.80m and rotating hoe. The planting of the crop was in double lines spacing (0.9m x 1.50m). All the machines were equipped with GPS in order to control the traffic and to allow the definition of the plant growth zone and traffic zone. The SPR evaluations were carried out by the Stolf method, and the readings were carried out shortly after planting and after harvesting (1.5 years after planting). A rule of 1.20m (transcept) was used, which was placed perpendicularly over the center of the site, in order to obtain a reading every 0.15m, thus totaling 9 points per evaluation, covering the site and the traffic line. The reading was performed up to 0.70m depth, so that 7 layers were layered (spaced 0.10m). The CSP presented values higher than the DST in the layers from 0.10m to 0.60m at the site (up to 0.45m from the ruler). The values found in the two soil preparations were not the limiting factor for the development of the root system, which according to the literature is 2.5MPa. After harvesting the cane, in the second evaluation, the bed was still preserved in the DST treatment.

Keywords: Minimal tillage; Beds; Traffic control; Sandy texture; Penetrometer.

(2417 - 1920) Correlation between tensile strength and clay and organic matter content in a transect in the Micaela basin, RS, Brazil

Thais Palumbo Silva[1]; Cláudia Liane Rodrigues de Lima[1]; Maria Cândida Moitinho Nunes[1]; Mateus Rodrigues Fonseca[1]; Ana Paula Knapp[1]; Gabriel Luís Schroeder[1]; Luana Nunes Centeno[1]; Marlon Rodrigues[2]

Universidade Federal de Pelotas[1]; Universidade Estadual de Maringá[2]

The study of the soil physical quality indicators aims to identify the conditions that the soil is under its current use and management, in order to provide subsidies for agricultural and environmental planning. A sensitive indicator for the impact of the system of use and management is the tensile strength soil aggregates (TS), due to the soil response to the physical and mechanical processes related to the manipulation, such as the preparation, the formation of superficial crusts, the emergence of seedlings and the root penetration. TS is defined as the stress or force per unit area required to fracture soil aggregates when subjected to a pressure. This is influenced mainly by agricultural management, clay content and organic matter. The objective of this study was to evaluate the behavior of the tensile strength in different uses of the soil and to correlate spatially with the content of clay and the organic matter. The study was carried out in the Micaela basin, located in Pelotas, RS, Brazil. This basin has an area of 37.36 km^2, a transect of 11.2 km with 101 georeferenced points, which includes all predominant soil classes in the basin. Soil samples were collected in the layer of 0.00 to 0.10 meters for the evaluation of the clay content, organic matter and tensile strength. Thus, they were subjected to autocorrelation analysis, which evaluates the spatial dependence of a variable with itself, and crosscorrelation, which considers the distance in the space in which two variables are related. When the results were obtained, a spatial dependence of 1 lag for clay and organic matter, corresponding to 112 meters, and 5 lags for tensile strength were observed that is, up to 560 meters are spatially influenced, after that distance the samples are independent of each other. When performing the crosscorrelation of these variables, it was observed that between the tensile strength and the clay content they presented only a simple correlation, that is, a correlation only at point 0, considered as a relation of weak dependence, as well as between TS and matter organic, and can conclude that these variables did not present spatial relationship.

(3861 - 770) Cover crops in the Ocidental Amazon

Alam Carlos da Silva Costa[1]; Reginaldo Almeida Andrade[1]; Fábio Régis de Souza[1]; Anderson Cristian Bergamin[1]; Adriano Reis Prazeres Mascarenhas[1]; Rhayra Zanol Pereira[1]; Ivair Miguel da Costa[1]; Gabriel Ferreira Soares[1]; Luciana Sônia da Silva[1]
Foundation Federal University of Rondônia.[1]

The cultivation of cover crops has been adopted to be a new way of conservationist agriculture. Can be use grasses like brachiaria and millet or leguminous plants like sunn hemp. These plants are cultivated and after it reaches the maximum development they are cut, bedridden in surface or incorporated in the soil, increasing the organic matter, improving the chemical physics and biology characteristics of the soil. The objective of this work was evaluate the agronomic characteristics of the cover crop and his effects in the physical attributes of the soil. The experimental delineation was randomized in blocks with five (11) treatments and four (4) repetitions. The treatments consist in the evaluation of the species; *Crotalaria breviflora, Crotalaria juncea, Crotalaria ochroleuca, Cajanus cajan* cv. IAC/Fava-larga*, Cajanus cajan* cv. IAPAR 43*, Mucuna cinereum, Mucuna aterrima, Brachiaria brizantha* Hochst. Stapf, *Pennisetum glaucum, Canavalia ensiformis and S. capitata + S. macrocephala* crotalária breviflora; crotalária ochroleuca; crotalária juncea; two pigeon pea; two velvetbeans; brachiaria; millet; jack bean and estilosantes Campo Grande. The variables evaluated were: coverage rate of the soil, fresh mass, dry mass, rate of decomposition, density and porosity of the soil. The bean (*Canavalia ensiformis*) and the (*Mucuna cinereum, Mucuna aterrima.*) totally covered the soil in the evaluated period. The brachiaria, the millet and the (Cajanus cajan cv. IAC/Fava-larga) present the highest values of fresh mass, however, was (*Crotalaria juncea*) that produced more dry mass. The millet, brachiaria, the (*Cajanus cajan* cv. IAPAR 43, Cajanus cajan cv. IAC/Fava-larga) and common was the species with minors rate of decomposition in 60 days. The physical attributes of the soil were not influenced by green manure.

(4561 - 1530) Determination and analysis of curve of soil water retention under different ground coverings, wetland matogrossense

Osvaldo Borges Pinto Junior[1]; Heloisa Agnes Bodnar Massad[2]; Eduardo Guimarães Couto[2]
Universidade de Cuiabá[1]; Universidade Federal de Mato Grosso[2]

In general, "pantaneiros" soils closely related to the nature of deposited sediments, which in turn are a consequence of the physical nature of the "source material" and arranged in each place in the order of event of the processes of deposition/sedimentation. The objective of this work was to determine the water retention curve, the unsaturated hydraulic conductivity of the soil and to characterize and analyze soil density and moisture in different soil coverings on a typical haplic soil. This study carried out in the Brazilian Northern Pantanal, in a region with predominant palm tree *Scheelea phalerata* (Mart. Ex Spreng), under different soil coverages (with litter, without litter and an area of control). The unsaturated hydraulic conductivity of the soil used the pressure infiltrometer. WRCS performed using the tension table, the *Richards* chamber and the automated method using the WP4-C equipment. The soil density presented similar values in the withdrawal and control treatments, 1.27 g cm^{-3} and 1.28 g cm^{-3}, respectively, and were higher than the soil density value of the litter treatment, 1, 14 g cm^{-3}. The lower soil density in litter treatment may be caused by the higher amount of organic matter deposited under the control treatment. Soil moisture had a mean value of 52% for litter treatment, and 43% and 40% for treatment without litter and control, respectively. The results of the unsaturated soil conductivity were higher in the control treatment, being 31.6 mm h^{-1}, the treatments without litter and litter the values were similar (17 mm h^{-1} and 16.18 mm h^{-1}). The greater amount of soil moisture may reflect lower unsaturated hydraulic conductivity. Regarding WRCS, even with the presence of a greater amount of organic matter in one of the treatments, there were no significant differences between treatments after having performed ANOVA. The soil water content in the field capacity and the permanent wilt point reached the maximum value of 0.38 $m^3\ m^{-3}$ and 0.21 $m^3\ m^{-3}$, respectively, in the treatment that had the and the minimum values were found in the treatment without litter respectively of 0.32 $m^3\ m^{-3}$ for FC and 0.09 $m^3\ m^{-3}$ for PWP. In this way, the objectives of this work reached, concluding that regardless of the soil cover, the variables did not present significant differences.

(8395 - 1756) Determination of optimized soil matric potential thresholds for potatoes.

Jean-Pascal Matteau[1]; Guillaume Létourneau[1]; Thiago Gumiere[2]; Lotfi Khiari[1]; Jacques Gallichand[1]; Silvio Gumiere[1]
Université Laval[1]; INRS[2]

The human use of fresh water has expanded at a rate twice that of the population increase. Nowadays, 70 percent of the 3 830 cubic km of water use is being taken by the agricultural sector. Among the major crops, the potato stands on top of the calories production per liter of water. Ironically, potato yields are particularly sensitive to soil water deficit. Therefore, to ensure optimized potato yield and a high water efficiency, an intelligent water management method needs to be developed. Irrigation management based on soil matric potential increases water efficiency. However, soil matric potential thresholds need to be clearly defined for the different growth stages. In this study, four different irrigation thresholds (wet, optimal, dry and ETP) were tested to determine the optimal matric potential range for optimizing potato yield and water efficiency. This experiment was performed in a greenhouse using a highly monitored experimental setup including two tensiometers for two potato plants, 8 soil moisture probes and meteorological sensors controlling the greenhouse climate. The wet and the optimal treatments showed a significantly higher total yield than the dry and ETP treatments. However, the commercial yield of the optimal treatment was significantly higher than the wet treatment, due to a disease. This irrigation management produced almost no runoff for every growth stage and very little nutrient leaching. Results suggests that the irrigation management and the water content have a significant impact on potato growth and on the disease occurence. Hence, irrigation management based on matric potential can optimize the potato yield. Finally, the little quantity of runoff water collected under our treatments suggests that an irrigation management based on matric potential have the ability to reduce runoff, thus helping reduce water contamination. The irrigation thresholds identified in the study will benefit the potato growers and may serve as guide-lines for a more intelligent water management reducing water and nutrient loss in potato production.

(9747 - 2191) Determination of the physical quality of sandy soil at different depths by computed tomography Rx in microtomograph.

Luanda Torquato Feba[1]; Jacqueline Leal Marques[2]; Luis Gustavo Torquato Feba[1]; Everton Luís Santos[1]; Maik Sérgio Lopes da Silva[1];

Aline Saraiva Viudes[1]; Carlos Sérgio Tiritan[1]; Edemar Moro[1]; Henrique Debiasi[3]

Unoeste[1]; Université de Rennes[2]; Embrapa Soja[3]

Changes in soil structure and breakage of aggregates from intensive agricultural use restrict root growth and reduce the exploitation of water and nutrients by crops. These changes are manifested by high levels of compaction, porosity and water infiltration velocity in the soil, water accumulation on the soil surface and water erosion. With the objective of evaluating the physical quality of sandy soil degraded at different depths, it was proposed in this work to apply the Computed Tomography (X-ray) method, more precisely the use of a non-medical microtomograph. The experiment was conducted at the Experimental Farm of University of West of São Paulo (Unoeste) in Presidente Bernardes - SP, at 22º17'27 "S, 51º40'51" W and 385 m altitude. The soil of the experimental area is classified as Dystrophic Red Argisol, with smooth undulating relief. Soil samples were collected in soil profiles with 5 different depths (0-5, 5-10, 10-20, 20-30, 30-40 cm) in the treatments with 0 t / ha^{-1} of limestone with and without gypsum (4 t / ha^{-1}). Initially, a basic study was made on the fundamentals of soil physics, the Computed Tomography method and soil recovery techniques. Afterwards, the tomographic images were obtained by microtomograph and NRCon software, belonging to Embrapa Instrumentacion. Based on these images, the CT-Analyzer software was used to obtain the physical attributes such as pore size and size, which are fundamental for the evaluation of soil environmental quality. The results showed qualitative and quantitative differences in the 5 depths of the treatments with and without agricultural plaster by means of the image analysis. With this, the work showed the potentiality and the application of the C.T. in the soil investigations, in particular in the physical quality indicators, since the surface samples have larger amounts of pores than the subsurface samples.

(9311 - 3150) Direct shear resistance parameters of a Bt horizon: under field and saturated moisture

Carlos Vítor Oliveira Alves[1]; Tiago de Oliveira Santos[1]; Wagner Luís de Souza Silva[2]; José Ramon Bastos Cantalice[1]

Universidade Federal Rural de Pernambuco[1]; Instituto Federal de Pernambuco[2]

Soil shear strength is one of the most important dynamic properties for the evaluation of soil interaction with the use of agricultural implements and with the management practices adopted for the soil. The present study was carried out to evaluate the shear strength of the soil from shear wraps in samples of a clayey Bt horizon subjected to different moisture contents different normal stresses and also to evaluate the changes in cohesion and internal friction angle. The study was carried out at the sugarcane experimental station of the Federal Rural University of Pernambuco (UFRPE), located in the Carpina town. Samples with preserved structure were collected to perform direct shear tests and determination of physical parameters and organic carbon content of a Tb Dystrophic A moderate Red-Yellow Argisol, medium / very clay texture. Direct shear tests were performed according to ASTM D-3080/98. The shear rate was 0.125 mm min^{-1}. The normal stresses used during the tests were: 50, 100, 150 and 200 kPa. The shear stresses were higher for the field moisture condition and lower for the saturation condition. Despite the high clay content of the soil, according to the pearson correlation matrix and the multivariate grouping technique, this fraction was not important for the soil cohesion parameter. Only with the use of the multivariate aproach of principal component analysis was possible to visualize the importance of the silt fraction in the parameter of apparent cohesion in the soil, demonstrating the importance of the multivariate aproach in the understanding of the phenomenon.

(1630 - 2599) Does land use change the spatio-temporal nature of soil moisture? A multi-spectral analysis in the Caatinga

Cynthia Wright[1]; Eduardo Souza[2]; Jason West[1]; Brad Wilcox[1]

Texas A&M University[1]; Universidade Federal Rural de Pernambuco[2]

Soil water is central to ecohydrology. In addition to driving the partitioning of rainfall into runoff and evapotranspiration, soil water drive vegetation response. Soil water has a particularly strong role in water-limited systems, such as the Caatinga, a seasonally dry forest/shrubland in Northeast Brazil. In the Caatinga, rainfall seasonality is more dramatic than temperature seasonality, and thus ecological processes can be thought of as pulse-driven, where rainfall feeds soil water in pulses. Yet, the Caatinga is plagued by an accelerated rate of deforestation and potentially degradation, which likely impacts the soil water reserve available to vegetation. Thus, the objective of this research is to understand the temporal dynamics of soil water for different vegetation covers. Soil water was measured for two cover types: a native Caatingta stand ~50 years old vs. a pasture site near Serra Talhada, PE, Brazil. Soil water for each site was measured at three different spatio-temporal scales: a) small (point) scale measurements continuous in time; b) medium (pedon) scale measurements taken weekly using a portable probe; both small and medium scale measurements used FDR-type probes; and c) large (plot/pixel)-scale measurement obtained via remote sensing (SMAP L4 9 km data available since 2015). Discrete and continuous wavelet analysis was conducted on each time series to better understand soil moisture dynamics at different spatio-temporal scales. Because rainfall seasonality drives soil water, these dynamics are important to understanding potential shifts in vegetation composition and distribution, plant phenology, and trends regarding deforestation and agricultural activities.

Keywords: soil moisture; wavelets; spatio-temporal scales; ecohydrology; dry forest

(6568 - 471) Effect of agricultural plaster, soil scarification and culture succession systems on physical attributes of a distrophic red-yellow latosol, in Porto Velho - RO

Elyenayra Nogueira Pinheiro[1]; Eduardo Antonio Neves dos Santos[1]; Roneres Deniz Barbosa[1]; Milton César Costa Campos[1]; Elilson Gomes de Brito Filho[1]; Carlos Henrique Gima Relvas[1]; Anderson Vieira Rodrigues[1]; Ludimila Souza de OLiveira[1]; Fernando Gomes de Souza[1]; Luana Celestino Calista[1]

Federal University of Amazonas[1]

Understanding and quantifying the impact of land use and management on physical quality is critical to the development of sustainable agricultural systems. Thus, the objective of this work was to evaluate the effect of gypsum, soil scarification and crop succession systems on the physical attributes of a Red-Yellow Dystrophic Latosol. The experiment was implemented in the agricultural year 2013 crop 2014 in an area in the experimental field of Embrapa Rondônia. The area was being cultivated with *Brachiaria brizantha cv. Marandú* during eighteen years (1990 to 2008) and after that was kept in fallow for four years (2009 to 2013), when the experiment was installed. The treatments consisted of the absence and addition of 2 ton ha-1 of agricultural gypsum, absence and presence of soil scarification, and three crop succession systems: SP (soybean/fallow), SMP (soybean/corn/fallow) and SMBP (soybean/corn/brachiaria/fallow). The experimental design was in randomized blocks arranged in a

2x2x3 factorial scheme with eight blocks. Four years after the implementation of the experiment, soil samples were collected in the layers of (0.00-0.05, 0.05-0.10 and 0.10-0.20 m). With the aid of volumetric rings soil samples were collected for determination of macroporosity, microporosity, total porosity, soil density, soil moisture and penetration resistance. Blocks with preserved structure were manually collected and defragmented in aggregates. With the aid of sieves, aggregates with a diameter of between 8 and 4.75 mm were separated for stability analysis of aggregates in water. The hypothesis of normality of the data was tested by the Shapiro-Wilk test, and submitted to analysis of variance (ANOVA). When the significance test was found, the means were compared by the Scott-Knott test at the 5% probability level. The agricultural gypsum caused alterations in soil porosity and stability of aggregates, with better values of MaP in the first two layers evaluated, observed in the treatments where there was application of agricultural gypsum. Crop succession systems can influence the physical characteristics of the soil. The best values of aggregate stability were observed in the SMBP and SMP succession systems, which, besides preserving the structure of the aggregates, allowed a reduction in soil resistance to penetration. Taking into account these facts, the levels of sand, silt, clay and soil density were not altered by the agricultural gypsum and scarification of the soil.

(8538 - 345) Effect of land use, location and depth on soil organic carbon stock and aggregate dynamics of degraded ultisol in Nsukka, Southeastern Nigeria.

Azuka Chukwuebuka Vincent[1]; Odoh Chidimma Peace[1]
Department Of Soil Science, University Of Nigeria, Nsukka[1]

Changes in agricultural practices and land use influence the storage and release of soil organic carbon, and soil structural dynamics. To investigate this in Nsukka, southeastern Nigeria, soil samples were collected at 0-10 cm, 10-20 cm and 20-30 cm from three locations; Ovoko (OV), Obukpa (OB) and University of Nigeria, Nsukka (UNN) and three land use types; cultivated land (CL), forest land (FL) and grass land (GL)). The result showed that Ksat was significantly ($p < 0.05$) influenced by location with mean values of 68 $cmhr^{-1}$,121.63 $cmhr^{-1}$, 8.42 $cmhr^{-1}$ in OV, OB and UNN respectively. The MWD and aggregate stability (AS) were significantly ($p < 0.05$) influenced by land use and depth. The mean values of MWD are 0.85 (CL), 1.35 (FL) and 1.45 (GL), and 1.66 at 0-10 cm, 1.08 at 10-20 cm and 0.88 mm at 20-30 cm. The mean values of AS are; 27.66% (CL), 46.39% (FL) and 49.81% (GL), and 53.96% at 0-10cm, 40.22% at 10-20cm and 29.57% at 20-30cm. Clay flocculation (CFI) and dispersion indices (CDI) differed significantly ($p < 0.05$) among the land use. Soil pH differed significantly ($p < 0.05$) across the land use and locations with mean values ranging from 3.90-6.14. Soil organic carbon (SOC) significantly ($p < 0.05$) differed across locations and depths. SOC decreases as depth increases depth with mean values of 15.6 gkg^{-1}, 10.1 gkg^{-1}, and 8.6 gkg^{-1} at 0-10 cm, 10-20 cm, and 20-30 cm respectively. SOC in the three land use were 8.8 g kg^{-1}, 15.2 gkg^{-1} and 10.4 gkg^{-1} at CL, FL, and GL respectively. The highest aggregate associated carbon was recorded in 0.5 mm across the land use and depth except in cultivated land and at 20-30 cm which recorded their highest SOC at 1mm. SOC stock, total nitrogen (TN) and CEC were significantly ($p < 0.05$) different across the locations with highest values of 23.43 t/ha, 0.07g/kg and 14.27 Cmol/kg respectively recorded in UNN. SOC stock was significantly ($p < 0.05$) influenced by depth as follows; 0-10>10-20>20-30 cm. TN was low with mean values ranging from 0.03-0.07 g/kg across the locations, land use and depths. The mean values of CEC ranged from 9.96-14.27 Cmol kg^{-1} across the locations and land use. SOC stock showed correlation with silt, coarse sand, N and CEC (r = 0.40*, -0.39*, -0.65** and 0.64** respectively. AS showed correlation with BD, Ksat, pH in water and KCl, and SOC (r = -0.42*, 0.54**, -0.44*, -0.45* and 0.49** respectively. Thus, land use and location plays significant role in sustainable management of soil resources.

(3841 - 1430) Effect of soil texture and structure on the K(θ) function parameters.

Fernando Henrique Setti Gimenes[1]; Cezar Augusto Medeiros Rebouças[1]; Ismael Meurer[1]; Paulo Leonel Libardi[1]
University of São Paulo, 11 Pádua Dias Ave, Piracicaba, 13418-900, Brazil[1]

The instantaneous profile method, IPM, is one of the most used to determine the unsaturated soil hydraulic conductivity, K(θ) function. Thus, the objective of this work was to compare the K(θ) function, determined by IPM under field conditions, in the pedogenetical horizons of an Oxisol (Bw) and an Ultisols (Bt), as related to texture and structure. The Bw texture was defined as sandy clay loam and its structure as weak, small to medium subangular blocks that break to moderate small to medium granular. With respect to the Bt, the texture is very clayey and the structure is moderate, large subangular blocks. The soil water retention curves, determined in the laboratory using funnels and pressure chambers with porous plate, were used to convert the matric potential values obtained by the tensiometers, installed along the soil profile, in values of volumetric water content. According to the results, the Bw horizon presented a very high value of hydraulic conductivity at the initial redistribution time, K_0, directly related to the soil texture and structure, which provided higher total porosity and, mainly, macroporosity. The dimensionless parameter γ, exponent in $K(\theta) = K_0 \exp [\gamma (\theta - \theta_0)]$, was slightly larger in the Bw horizon than in the Bt, being close to those found in the literature. The value of volumetric soil water content at the initial redistribution time, θ_0, was higher in the Bt horizon than in the Bw due to the higher clay content and microporosity in Bt, emphasizing the influence of soil texture and structure attributes on the water retention. The fitted values to the model were close to the calculated values, confirmed by values greater than 0.98 for the determination coefficients, indicating that the dependent variable can be explained by the model. It could be concluded that soil structure and texture directly affected K_0 and θ_0 values of the K(θ) function, with the Bw horizon conducting water more easily than the Bt due to its greater macroporosity, while the Bt horizon retaining more volume of water due to its texture and microporosity.

(3233 - 2914) Effective hydraulic conductivity and its relationship with soil attributes of cerrado Mato-Grossense

Edwaldo Dias Bocuti[1]; Ricardo santos silva Amorim[1]; Tulio gonçalves dos Santos[1]; Yuri william Santos Duarte[1]
Universidade Federal de Mato Grosso[1]

The objective of this work was to determine the values of the effective hydraulic conductivity for soils of Cerrado Mato-Grossense, as well as to indicate physical attributes of soil with predictive potential of Ke. The work was developed in six areas located in the Mato Grosso state, that they contemplate texture soils very sandy, clayey and sandy average and the uses following: pasture (Pp1 and Pp2), agricultural (Ap1, Ap2 and SV1) and Cerrado (C1). The study was performed in three steps: characterization of the attributes physicals an physicals-hydric the of soils; determination of the effective hydraulic

conductivity (K_e); evaluation of the correlation between K_e and the chacteristcs of the soils. In order to determine the soil properties, preserved, semi-preserved and deformed soils samples were collected and was utilized proposal metodology in Manual of method of soil analysis of Embrapa. For the k_i determination was utilized proposal methodology by US Department of Agriculture Agricultural Research Service - ARS / USDA. The statistical treatment of the informations consisted in the application of Kruskal-Wallis test and Pearson's correlation between variables. Due to the different soil characteristics of the areas, the test durations were different, corresponding to an average of 114, 118, 115, 98, 204 and 126 minutes per repetition for the areas, Pasture point 1 (Pp1), Pasture point 2 (Pp2), Agricultural point 1 (Ap1), Agricultural point 2 (Ap2), Cerrado 1 (C1) and São Vicente 1 (SV1), respectively. The effective hydraulic conductivity (Ke) was determined when the infiltration rate was stable, which corresponded to 81.52; 109.94; 30.63; 24.49; 48.31; and 28.37 mm h^{-1} for Pp1, Pp2, Ap1, Ap2, C1 and SV1, respectively. Through the Kruskal-Wallis test ($p \leq 0.05$) it was verified that there is significant difference between the Ke of the studied areas. This difference was observed only between Ap2 and Pp2, and the effective hydraulic conductivity was higher for the Pp2 area. The attributes total sand, organic matter and clay presented a significant correlation with the effective hydraulic conductivity of the soil, evidencing that these attributes are good predictors of the effective hydraulic conductivity of Cerrado soils.

Keywords: hydraulic conductivity; Physical-hydrics Attributes, Soil erosion

(3220 - 2819) Erodibility Interril and its relationship with attributes of Cerrado soils Mato-Grossense

Edwaldo Dias Bocuti[1]; Ricardo Santos Silva Amorim[1]; Tulio Gonçalves dos Santos[1]; Luis Augusto0 Di loreto Di Raimo[1]; Wellington de Azambuja Magalhães[1]

Universidade Federal de Mato Grosso[1]

The objective this work was to determine in field the erodibility interrill (K_i) in soils of the Cerrado Mato-Grossense and find characteristcs physicals and physicals-hydric that better correlate and are predictors of K_i. The work was developed in six areas located in the Mato Grosso state, that they contemplate texture soils very sandy, clayey and sandy average and the uses following: pasture (Pp1 and Pp2), agricultural (Ap1, Ap2 and SV1) and Cerrado (C1). The study was performed in three steps: characterization of the attributes physicals an physicals-hydric the of soils; determination of the interrill erodibility (k_i); evaluation of the correlation between K_i and the chacteristcs of the soils. In order to determine the soil properties, preserved, semi-preserved and deformed soils samples were collected and was utilized proposal metodology in Manual of method of soil analysis of Embrapa. For the k_i determination was utilized proposal methodology by US Department of Agriculture Agricultural Research Service - ARS / USDA. The statistical treatment of the informations consisted in the application of t-student test, Kruskal-Wallis test and Pearson's correlation between variables. The mean values obtained for K_i were $1{,}56 \times 10^5$; $2{,}47 \times 10^5$; $2{,}44 \times 10^5$; $1{,}32 \times 10^6$; $8{,}56 \times 10^4$ e $5{,}93 \times 10^5$ kg s m^{-4} for subáreas Pp1, Pp2, Ap1, Ap2, C1, SVp1, respectively. The interrill erodibility was bigger in Ap2, when compared whit C1. Larger correlations between K_i and the physicals characteristics or physicals-hydric characteristics of the soils can be obtained if the soils of similar textural class are initially grouped to later be carried out the statistical treatment of the data. For group soils A (Pp1,Pp2 and C1) the attributes coarse sand,very fine sand and aggregate stability index presented greater potential of prediction of the K_i. For group soils B(Ap1,Ap2 and SV1) the attributes coarse sand, average sand,weighted mean diameter, geometric mean diameter and aggregate stability index present a higher prediction potential of k_i.

(9622 - 686) Estimation of soil temperature based on climatic parameters with artificial neural network model and artificial neural network - firefly hybrid model (case study, Tabriz, Ahar)

Fatemeh Esmaeilbeyki[1]; Davoud Zarehaghi[1]; Mohammadreza Neyshabouri[1]

University of Tabriz[1]

The soil temperature (ST) varies in different depths of the soil and fluctuates throughout the day, month, and year. Surface temperature and depth of soil are not measured continuously. So, in terms of soil temperature data, we face a lack of statistics. Considering the continuous measurement of climate variables in meteorological stations, establishing a relationship between soil temperature and climatic characteristics of the area is of particular importance. In the meantime, smart models can play an effective role. In this study, measured data are related to the weather stations of Tabriz and Ahar and meteorological variables including air temperature, relative humidity, wind speed, sunshine and soil temperature at depths of 5, 10, 20, 30, 50 and 100 cm with a 3-year statistical period than 2014 to 2016 using artificial neural network model (ANN) and artificial neural network-firefly hybrid model (ANN-FFA) for estimating and comparing soil temperature in the next two days at a depth of 5 cm. Results showed that ANN-FFA with RMSE= 1.71 was more successful than ANN with RMSE= 3.26 in soil temperature estimation two days ahead. Also, in Ahar, MLP-FFA with RMSE= 5.03 was more successful than ANN with RMSE= 6.34 in soil temperature estimation of the next two days. ANN-FFA with high precision in estimating soil temperature, was introduced as the top model which can be used in modeling and soil science and the modeling error rate dramatically decreases.

Keywords: Firefly algorithm, soil temperature estimation, artificial neural network- firefly hybrid model.

(3402 - 2297) Evaluation of a physical-empirical ptf for soil water retention

Daniel Boeno[1]; Paulo Ivonir Gubiani[1]; Rodrigo Pivoto Mulazzani[1]

Universidade Federal de Santa Maria[1]

The soil water retention curve (SWRC) is useful for understanding the water availability for plants and for modeling water flow in soil. Since the determination of SWRC is a laborious and time-consuming task, pedotransfer functions (PTFs) has been used by soil scientists to estimate the SWRC. As the most of the currently available PTFs are empirical, its use is restrict to soils where the model was calibrated. Thus, there is a demand for physical or physical-empirical PTFs that consider the mechanisms and soil physical characteristics to estimate soil water retention. The physical-empirical model proposed by Mulazzani (2016) considers that the specific soil surface available for water retention (SSa) and the bulk density (ρ_b) can satisfactorily predict soil water retention. The SSa depends on particles characteristics (shape, size distribution) and is estimated from total SS (SSt) and degree of arrangement, represented by ρ_b. The model calculates a factor 'fa', which represents the mass of water per unit of SSa, at a given water potential (ψ), and relates it to SSt for estimating the gravimetric water content (W): $W = [SSf = f(SSt, \rho_b)] \times [fa = f(\psi,$

SSt, ρ_b)]. Mulazzani (2016) parameterized the model for samples with non-preserved structure. In this study, the objective was to evaluate the model in soil samples with preserved structure. Stainless rings were used for collecting samples at depths of 5, 15, 30 and 50 centimeters in a field experiment. Water retention was measured at potentials of 0, -0.1, -0.6, -1, -3.3, -10, -50 and -150 m. The estimates obtained with the model were not satisfactory in the potentials of -0.1, -0.6, -1, -3.3, -10, -50 and -150 m. The coefficient of determination (R^2) of the regression ranged from 0.777 to 0.001 (mean of 0.12) in the comparison between experimental and estimated W by the model. The results show that the model failed to predict SWRC with adequate accuracy for the undisturbed sample set. Thus, the model needs adjustments to allow its application in undisturbed soil.

(7555 - 263) Evaluation of the application of anthropic load on a trail in the serra da canastra national park

Ian Lucas de Oliveira Rocha[1]; Rita de Cássia Ribeiro Carvalho[1]; Welligton Willian Rocha[2]; Maria José Reis[1]; Bruno Silva Pires[1]
Universidade do Estado de Minas Gerais[1]; Universidade Federal dos Vales Jequitinhonha e Mucuri[2]

It is fundamental to study issues related to anthropogenic capacity to assess the intensity of public use in Conservation Units that do not compromise the sustainability of this ecosystem. Each trail should be designed considering the physical characteristics of the place, seeking to have the least possible impact on the soil, vegetation and fauna. The objective of this work was to analyze the resistance to penetration in the soil moisture of the soil, to detect possible impacts caused by the anthropic trampling, allowing the access to the information regarding the evaluation of the anthropic load capacity of a trail in the Serra National Park of the Canastra-MG through compaction indices (penetrometry) inside and outside the bed of the track investigated. In this way, it is possible to propose management measures that ameliorate environmental impacts. The Resistance to Penetration (RP) in the field capacity moisture was compared by the Snedcor and Cochran (1989) test. The values are derived from the mathematical modeling of RP x Humidity. The resistance to penetration in the center of the trail presented the greatest value, certainly due to the fact of the intense trampling. Considering the lateral evaluations, outside the trail, a lower resistance was perceived, which can be explained by the fact that they are not submitted to anthropic loads. These values from the agronomic point of view do not constitute compaction, which can be justified by the soil presenting sandy texture. However, because it is a trail, this resistance to penetration, even if reduced, can cause long-term degradation, since it can suffer erosion, since these signs are already present in some stretches of the trail. Therefore, due to the characteristics of the texture, and even with low RP values for this trail, an alert for a good planning of the number of visitors, certifying that in the long term, the possible impacts will not compromise the corresponding space. The combination of these indicators is of fundamental importance for the monitoring of the impacts of the trails, since it generates information for the creation of proposals and management strategies for them.

(4635 - 2620) Evaluation of the stability of soil aggregates in the forest islands of two agro-ecological zones in Burkina Faso.

B. Amelie Bougma[1]; Korodjouma Ouattara[2]; Halidou Compaore[2]; B Hassan Nacro[3]; Caleb Melenya[4]; A. Samuel Messele[5]; Vincent Logah[4]; J. Azeez Oladipupo[5]; Jon Lioyd[6]
Inera, Polytechnic University Of Bobo Dioulasso[1]; Inera[2]; Polytechnique University Of Bobo Dioulasso[3]; Knust[4]; Funaab[5]; Imperial College Of London[6]

In the more mesic savanna areas of West Africa, significant areas of dense vegetation with the species and structural characteristics of forest are often found around village areas (of areas of less than 1 to more than 10 ha). It is thought that these 'forest islands' may the direct consequence of human activity and to help understand the processes giving rise to these patches of relatively luxuriant vegetation we studied the stability of soil aggregates for forest islands in the north and southern Sudan savanna zone of Burkina Faso. Aggregate stability is one key soil physical variable influencing biogeochemical processes and soil fertility in natural ecosystems. Soil samples were taken from the 0-5, 5-10, 10-20, 20-30 cm soil horizons of forest islands, comparing them with nearby savanna and cropland and with three aggregate fractions: diameter> 500 µm, 500-250 µm and 250-53 µm, respectively *viz* "macro-aggregates", "meso-aggregates" and "micro-aggregates" subjected to stability testing under water sieving (Kemper and Rosoneau, 1986). Comparing the forest island soils with those of surrounding savanna and cropping areas, we found a highly significant difference in aggregate distributions between agro-ecological zones (p <0.001) with the largest proportion of stable aggregate observed for forest island soils. Regardless of the class of aggregates, the lowest proportions were found in cropland soils. The proportion of aggregates was also found to vary according to the soil depth being highest for the 0-5cm surface layer and decreasing with soil depth. Micro-aggregates dominated all three soil types.

(9028 - 3023) Impact of land use on physical quality and GHG emissions in the Atlantic Forest Biome

Reginaldo Barboza da Silva[1]; Marina Pedroso Carneiro[1]; Ana Paula Parker[2]; Piero Iori[3]; Francisca A. Melo Silva[1]
UNESP[1]; Embrapa Meio Ambiente[2]; UFG[3]

In Brazil, land use and occupation in environmentally vulnerable areas protected by law has been a recurring practice and difficult to combat. Permanent preservation areas (PPPs), especially those adjacent to the watercourses, are used by agricultural activities, causing land losses and soil degradation. The objective of this study was to assess the impact of soil use in the physical quality and emission of greenhouse gases (GHG) in PPPs of the Atlantic forest biome. The study was conducted in Haplic Cambisol (Inceptsol), located in marginal strips of vegetation (70 m) adjacent to the Ribeira de Iguape River, in Registro, a county in the South of São Paulo State, Brazil, There were identified and selected four kinds of land use in the experimental area: banana cultivation (BC), extensive pasture (EP) and native forest (NF). Physical and chemical soil analyses were carried out to assess bulk density, macro and microporosity and total porosity, total organic carbon (TOC), mean weight-diameter of soil (MWD), stability index (SI) and soil erodibility (SE). Soil analyzes were evaluated according to Embrapa (2011). The method used to capture GHG was the closed chamber. Subsequently, from GC Shimadzu® gas chromatograph model GC 2014, N_2O and CO_2 concentrations were determined by ECD (electron capture) detector, operating at 300°C, and CH_4 concentrations by type detector FID (flame ionization). The results from this study showed that, BC area had an average annual loss of 10 times greater than EP, even with higher soil organic matter and structural stability. The values for CO_2 and N_2O emission were higher in EP, probably due to the type of vegetation, presence of animals, soil

exposure to solar radiation and soil compaction by animal trampling. MN area had higher CH_4 emission values, probably due to the humidity, favoring anaerobic respiration and greater presence and mineralization of soil organic matter. About soil erodibility and GHG emissions, in the BC area lowest rates of gas emissions found are due to the loss of soil physical properties related to soil structure, to the transport and eluviation of particles, and losses the chemical fertilizers in these areas.

(4207 - 2664) Impact Of Mechanized Forest Management On Soil Penetration Resistance In Eucalyptus Cultivation

Judyson de Matos Oliveira[1]; Teógenes Senna de Oliveira[1]; Gerson Rodrigues dos Santos[1]; Raphael Bragança Alves Fernandes[1]; James Stahl[2]

Universidade Federal de Viçosa[1]; Klabin S/A[2]

The objective of this study was to evaluate the cumulative effect of machine traffic after forest harvesting and soil preparation over soil penetration resistance (PR) in an eucalyptus planting. The relief is classified as gently undulating and the predominant soil is Oxisol, medium texture. The treatments involved two systems of harvesting "with" and "without" subsoiling, being: Cut-to-Length; using Harvester + Forwarder (HF-N) machinery and Full-tree; using Feller + Skidder (FS-N) no subsolings, and both subsoling (HF-S and FS-S). In treatments, an assessment of PR "in situ" evaluation was made using a digital electronic penetrometer, up to a depth of 0.55 m. A systematized sampling scheme, with points collected at the vertices of isosceles triangles distributed in a mesh with 225 m^2 each one, was adopted, totaling 22 points per treatment. Besides, deformed sample were collected to determine the gravimetric moisture (θ) between the layers 0-0.20, 0.20-0.40 and 0.40-0.60 m, in 50% of total PR points. Statistically, the confidence intervals were calculated for the mean of θ and PR, with significance level (1-α) of 0.10, considering the number of samples and the standard deviation of sample. The θ levels were similar between treatments and presented an overall mean of 0.23 g. g-1, denoting the homogeneity of soil moisture conditions during PR sampling. Comparing harvest systems, the mean of PR were similar to each other. However, for the same harvesting system, the PR mean were significantly different in the subsoiling treatments compared to the no-subsoiling treatments. The highest values of PR were observed between the depths 0.10 - 0.40 m and 0 - 0.30 m, with maximum PR of 2.75 and 2.38 MPa, in layers of equal thickness (0.30 m), for HF - N and FS - N, respectively. The PR values in these layers were above the critical level for this soil physical indicator (PR> 2 MPa). Considering the same layers of the subsoiling treatments, there was a mean reduction in PR of 1.3 and 1.2 MPa for HF-S and FS-S, respectively. The subsoling treatments did not present PR critical values. The results showed that the depth of the critical PR can diversify between different harvest systems and that the subsoiling was efficient to reduce PR in the soil profile. The depth of the critical PR layer in forest management systems should be considered in the correction operations, as it may result in lower energy costs and reduced environmental impact.

(1671-1542) Importance of long-term experiments in soil management of productive processes

Tiago Stumpf da Silva[1]; Leonardo Pereira Fortes[1]; Amanda Duarte de Duarte[1]; Leonardo Nascimento dos Santos[1]; Michael Mazurana[1]; Renato Levien[1]

Departamento de Solos; Universidade Federal do Rio Grande do Sul[1]

Long-term experiments have been the key to the understanding of productive processes, such as those occurring in soil-machine-plant-atmosphere relations. Under the yield aspect, great variations are be observed due to different reasons. The soil structure (and their quality, for example, to provide best conditions to plant grow, environmental filter) coordinate all process in the soil. These processes are water, nutrient and gas flow, biological activity and root growth, the plants depend directly on the quality structural. Thereby, different management practices carried out over time can be influenced the structure. This work aimed to evaluate the soil structural reorganization under different management systems and relate to growth of corn plants. The study was carried out in South Brazil, under Ultisol (25% of clay) locate in Experimental Station at Federal University of Rio Grande do Sul. Soil samples were collected in the 0-0.1, 0.1-0.2 and 0.2-0.3 m soil depth in randomized blocks subdivided into plots in which three treatments were distributed: 16-year no-tillage system (NT16); no-tillage system with three years after 13 years of reduced tillage system (NT3-RTS) and no-tillage system with three years after 13 years of conventional tillage system (NT3-CTS). The saturated hydraulic conductivity (Ksat), bulk density (Bd) and plant height in the V7 stage were evaluated. Our data show significant differences in depth of 0-0.1 m to Ksat with best result to NT16 (29.12 mm h^{-1}) followed by NT3-RTS (20.52 mm h^{-1}) and NT3-CTS (2.3 mm h^{-1}). These results was correlate with those obtained for Bd where NT16, NT3-RTS and NT3-CTS show 1.32, 1.43 and 1.53 Mg ha^{-1}, respectively. Both conditions influenced the mean heights of corn, being 62.0, 58.8 and 51.6 cm in NT16, NT3-RTS and NT3-CTS, respectively. We believe that soil management conditions and root activity are influence this behavior, because the different management systems influence of soil structural quality, altering physical properties that affect the initial growth of corn plants. The reorganization of soil structure after management is occurring slowly, requiring further studies to analyze correlation with yield.

(2601 - 1750) Indicators of the physical quality of soils cultivated with rubber tree (H*avea brasiliensis)* in the brazilian cerrado biome

Roberta Ferreira Coutinho[1]; Letícia Custódio de Oliveira[1]; Wilber Pereira Machado[1]; Guilherme Camilo de Andrade[1]; Fabrício Messias Dias da Silva[1]; Wíslei Gomes Lima[1]; Gabriel Junqueira Pires[2]; Adriana Aparecida Ribon[3]; Taíza Nogueira Barros[4]; Larissa Gabriela Marinho da Silva[5]

UEG- Palmeiras de Goiás[1]; ue[2]; [3]; UF do Recôncavo da Bahia[4]; UFG[5]

The study of soil physical quality in areas cultivated with rubber tree (Hevea brasiliensis) associated to the use of organomineral fertilizers with chicken litter, aiming to establish sustainable use and management strategies in the Cerrado region, is scarce. The use of appropriate doses of fertilizers of organic origin can benefit the physical attributes of soils, reduce soil compaction and improve soil chemical and microbiological properties. The benefits of using green manure have also been reported in several recent studies that show a relation to soil physical attributes. This fertilization increases the soil porosity and the organic matter content, guaranteeing a greater stability of the aggregates, a reduction of soil compaction, since the green manure root system improves soil porosity, among other factors. Therefore, the objective of this work was to evaluate the management time in the alteration of the aggregation and physical quality in a soil under the rubber tree under different management systems in the Cerrado biome. The experiment started in 2016 and was developed at the Baru farm, in the municipality of Palmeiras de Goiás - GO. The experimental design was completely randomized blocks with three treatments (organomineral, brushcutter and pigeon pea), five replicates and two different rubber tree clones (PB312 and

RRIM600). The plots consisted of 10 plants in the spacing of 7 x 2.5 meters , where each plot has a size of 175m². The penetration resistance, aggregate stability and soil organic matter content were evaluated. The averages were compared statistically by the Tukey test at a probability level of 5%. All the treatments had a higher amount of aggregates retained in the 2 mm sieve, which is quite common in this type of soil (Latossolo) because it has a high structural stability, provided by the action of aluminum and iron oxides and also by organic matter. Experiments carried out in perennial crops evaluating soil physical quality require more evaluation time to obtain better results in the evaluated properties, such as soil penetration resistance, water aggregate stability, MOS, among others. The treatments with organomineral and pigeon pea, presented better results in relation to MOS, showing that these treatments can contribute to better results, in the physical quality of soils with this crop.

(3092 - 1029) Influence of biochar on microstructural behavior of a Brazilian subtropical soil

Amanda Romeiro Alves[1]; Dörthe Holthusen[1]; Qamar Sarfaraz[1]; José Miguel Reichert[1]; Mayara Torres Mendonça[1]; Leandro Souza da Silva[1]

Universidade Federal de Santa Maria[1]

Biochar, in general pyrolyzed biomass like plant residues, is commonly used as a soil conditioner. Recent research showed the benefits of its application on soil physical properties, both on macro and microscale. A promising method for the investigation of physical processes on the soil microscale due to mechanical stress is rheometry. The deduced rheological parameters allow for a semi-quantitative classification of structural degradation on the particle level. While composition parameters like water and nutrient retention are already quite well understood, studies on the effect of biochar on microstructural stability are rare. The objective of our study was to evaluate the effects of biochar on the microstructural stability of a Typic Hapludult. The experiment was conducted as a completely randomized 3x4 factorial design, where two types of biochar (rice and soybean biochar, 10 t ha^{-1}) and a control treatment were incubated for four periods (15, 30, 45 and 60 days). The used soil was classified as sandy (62% sand). Rheometry was done with a modular compact rheometer (Anton Paar MCR 102) with the help of amplitude sweep tests of constant frequency of 0.5 Hz, uncontrolled normal force, gap of 0.04 m, temperature of 20 °C, and amplitude ramp of 0.0001 to 100%. Soil-biochar mixtures were compacted to a density of 1.72 Mg m^{-3} and drained to a matric potential of -10 kPa. The following parameters were derived from the tests with the help of Rheoplus software: storage modulus (G'), loss modulus (G"), deformation at the limit of the linear viscoelastic range (γL), maximum shear strength (τ max), deformation, G' and G" at the yield point (γYP, G'G''$_{\gamma P}$), and integral Z. These parameters were subjected to ANOVA and Tukey test at 5% level of probability, using the R software. The soil treated with biochar showed a significantly higher elasticity by means of increased γL than untreated soil. Irrespective of incubation time, τ max was reduced due to biochar application, possibly because the fine-grained biochar reduced the interparticle friction. However, no statistical significant interaction was found between the factors biochar and incubation time on the other parameters. It seems that biochar is not only changing the composition parameters, but also affects the microstructural stability. Further investigations of field application of biochar are necessary to reveal if there are also effects on aggregation.
Keywords: Reometry, Biochar, Typic Hapludult.

(4039 - 1589) Influence of different types of grasses on soil pore volume in silvopastoral system

Vanessa de Sousa Lourenço[1]; Brenner Cabalheiro dos Santos[1]; Murilo Silva Machado[1]; Thaisa Cambréa Silva[1]; Nathalia Siqueira Carvalho[1]; Talles Eduardo Borges dos Santos[1]

Universidade Estadual de Goiás[1]

In systems where grasses are cultivated, these can help to improve soil drainage and water retention rates, due to the development of the roots, decompressing the soil at different depths, improving the porosity and consequently the movement of water in the soil. The objective of this work was to verify the influence of different types of grasses on the soil pore volume of a silvopastoral system at Santa Brígida farm, located in Ipameri-GO. The experiment was carried out in a randomized complete block design, distributed in six main treatments in 5 grass species, as treatments: *Brachiariaruziziensis*(Syn. *Urochloaruziziensis*), *Brachiaria* (Syn. *Urochloabrizantha*) cv. Marandú, *Brachiaria* (Syn. *Urochloabrizantha*) cv. BRS Paiaguás, *Panicum maximum* cv. BRS Tamani and *Panicum maximum* cv. Zuri and one (control-fallow) and four secondary treatments as subplots: 4 soil depths (0-0.05 m, 0.05-0.10 m, 0.10-0.15 m, 0.15-0.20m) with four replications, grown in plots of 50 m^2 (2 x 25 m) and scrubbed with the height of 60 cm leaving them with 20 cm and the residuals left in the area. Three variables were analyzed: total porosity, macroporosity and microporosity. The data were analyzed by the Tukey test at the 5% probability level. For analysis after the first grass cutting, there were no significant statistical differences between the treatments for total porosity and macroporosity, but for *Brachiariabrizantha* (BRS Paiaguás) microporosity obtained the best result, differing from the fallow, which can be explained by the higher volume of organic matter incorporated into the soil by *Brachiariabrizantha* (BRS Paiaguás). In relation to depth all treatments obtained the best results in the 0.00 - 0.05m layer with respect to macroporosity probably due to the large root volume found up to 0.05m in the first year of experiment.

(9899 - 3132) Integral variable of soil penetration resistance as soil physical quality indicator

Cláudio Roberto Marciano[1]; Lucas Luís Faustino[1]; David Silva Gomes[1]

UENF[1]

Inadequate agricultural land use leads to environmental degradation, including structure depreciation and compaction of soil, which can be both identified by soil penetration resistance (PR). Since PR is closely related to bulk density (BD) and water content (WC), these soil attributes should be both accessed at the same time than PR, otherwise PR cannot be adequately interpreted. Based on Letey (1985), Silva et al. (1994) proposed a systematic methodology to obtain PR as function of BD and WC during the soil water retention curve determination from soil samples with undisturbed structure. This procedure allows obtaining the "least limiting water range" (LLWR) and the r critical value related to a PR value also critical. Particularly in Brazil, a significant amount of data regarding PR was obtained, which was possibly underutilized concerning to ecological significance in affecting plants throughout the year seasons. The objective of this work was to propose a soil quality indicator variable related to PR that can be obtained by the mathematical integration of the equation that expresses PR as a function of soil water tension (WT). Undisturbed soil samples were collected from the 0-0.10 and 0.10-0.20 m depth layers of a Typic Hapludult soil under five vegetation cover (secondary forest, pasture, and *acácia*, *ingá* e *sabiá* - leguminous tree species), in Conceição de Macabú, RJ, Brazil. Tests with lab penetrometer were performed to measure PR after sample was equilibrated in Richards pressure chambers at water tensions of 10, 33, 100, 500 e 1500 kPa. Equations for relating PR exponentially to

BD and WT were adjusted and then simplified as PR = a exp^(b WT) to correspond to the mean values of soil bulk density under each vegetation cover. Afterwards, the equations were integrated from field capacity (WT = 10 kPa) to permanent wilting point (WT = 1500 kPa), named IntPR, covering the whole of available water capacity to plants. The lowest PR values occurred in the area under secondary forest (0.51, 0.66, 0.88, 1.27 e 1.59 MPa for WT growing from 10 to 1500 kPa), resulting in IntPR = 1958. The highest PR values occurred under *acácia* (2.24, 3.07, 4.08, 6.44 e 9.95 MPa for WT growing from 10 to 1500 kPa), resulting in IntPR = 11711. The other vegetal covers presented intermediate values of IntPR (4409 for *ingá*, 5272 for *pasture*, and 7015 for *sabiá*), so that we concluded that proposed variable has the potential to discriminate soils with different quality levels.

(1019 - 326) Inter-relationship between physical attributes and carbon storage in Oxisol and Humic Inceptisol under tillage

Carla Eloize Carducci[1]; Jânio dos Santos Barbosa[2]; Letícia Salvi Kohn[2]
UFGD[1]; UFSC[2]

With a view to sustainable agriculture, we seek management systems that promote the lowest soil degradation, however physical, chemical and biological improvements from carbon interaction versus soil aggregation. It is known that the smaller aggregates, the greater its resistance to external factors, and therefore the greater its contribution to the carbon storage, which is dependent on the soil class, climate and current use. Thus, the study aimed to determine the relationship between soil physical attributes with the carbon storage in a Oxisol and Humic Inceptsol submitted to agricultural and forestry use. The experiment was conducted in two soil classes of a Red Yellow Latosol (RYL) under Araucaria plantation at 4 years of age and Humic Inceptisol (HI) with a 3 year old of linseed crop in a no-tillage system. Undisturbed soil samples were collected (0.010x0.010m) in two contrasting layers identified by the cultural profile method: 0-0.05 and 0.05-0.20 m depth in three replicates. The following physical attributes were determined: soil bulk density (BD) and total porosity (TP) by volumetric ring method, particle size by pipette method and particle density (Dp) by volumetric balloon method, chemical attributes: total organic carbon (TOC) and carbon storage (CS) in aggregates with 1-4.76 mm and 4.76-9.52 mm of diameter (size classes easily altered by soil management). The BD presented similar values among the soils, although they had distinct genesis (humic horizon in HI), the conservation management system used in RYL and HI improved or maintained, the low BD (0.97 and 1 g cm^{-3} HI and RYL, respectively) and high TP (> 0.55 cm^3 cm^{-3}) due to the high CS on evaluated layers. The RYL aggregates stored a large amount of TOC in the 0-0.05 m (± 45 g kg^{-1}) layer which represents in CS around 52 mg ha^{-1} with a small reduction in the subsequent layer, which is expected, due to the decrease supply of plant and animal waste in deeper, already in HI, the mean values of CS on two aggregate sizes in the two layers were homogeneous (≈44 mg ha^{-1}), which indicates a good carbon distribution along the soil profile, with a consequent reduction of Ds values, promoting in both soils the structure relief, as well as the environmental contribution to decreasing the greenhouse effect.

(7542 - 902) Interrill soil erosion and aggregate stability along a climate gradient (arid to humid) on hillslopes in Chile

Bernhard, N.[1]; Seitz, S.[2]; Kinkela, J.[2]; Klein, J.[2]; Kühn, P.[2]; Rivas, S.[3]; Schmidt, K.[2]; Seguel, O.[3]; Scholten, T.[2]

Department of Geosciences, Soil Science and Geomorphology, Eberhard Karls University Tübingen, Rümelinstr. 19-23, 72070 Tübingen, Germany (nadine.bernhard@uni-tuebingen.de)[1]; Department of Geosciences, Soil Science and Geomorphology, Eberhard Karls University Tübingen, Rümelinstr. 19-23, 72070 Tübingen, Germany[2]; Facultad de Ciencias Agronómicas, Universidad de Chile, Av. Santa Rosa N°11315, 8820808 La Pintana, Santiago, Chile[3]

As soil erosion is an environmental problem in vast parts of the world and fundamental mechanisms of soil surface stabilization are still unclear, it is important to improve our understanding of basic erosion processes. In particular, comparative studies over different climate zones are scarce. A broad latitudinal climate gradient in Chile together with its typical natural vegetation allows to investigate climate specific soil properties, which may consequently imply a specific aggregate stability and resistance against erosion. Furthermore, the topographic position along hillslopes is expected to play an important role due to downslope relocation of clays and soil organic matter, both parameters influencing aggregate stability. The objectives of our study are to examine to which extend aggregate stability and soil physico-chemical properties control surface resistance against initial soil erosion and how this system is influenced by climate and topography. The study took place in four national parks on similar granitoid parent material within the Chilean Costal Cordillera from Pan de Azucar (26 °S) in the north to Nahuelbuta in the south (38 °S). The research plots were located on four different topographic slope positions at each site. We analyzed bulk samples and implemented an on-site rainfall simulation experiment with 0.4 × 0.4 m runoff plot sizes and a standardized rainfall intensity of 60 mm h^{-1} at every plot. Runoff and sediment delivery were measured in austral autumn 2017. Linear mixed effects models to evaluate the impact of soil properties, topographic position and slope were compiled. First results revealed a significantly lower sediment delivery in the humid study site compared to the arid to mediterranean study sites. This can be explained by the increasing amounts of clay, soil organic matter and the hereby related aggregate stability from arid to humid climate. The most humid site showed also higher oxide contents than the arid to mediterranean study sites, also a major factors for aggregate stability. Topographic position and slope angle play a crucial role as the amount of sediment delivery increased in each site from the shallower south upper slope to the steeper south mid slope and south lower slope positions. We assume that the climate gradient along Chile has a major influence on soil stabilization. Further results will be presented at the World Congress of Soil Science 2018.

(2317 - 1689) Land levelling effects on the relationships of lowland hydro-physical soil attributes, southern brazilland

Alexssandra Dayanne Soares de Campos[1]; José Maria Barbat Parfitt[2]; Luana Nunes Centeno[3]; Dioni Glei Bonini Bitencourt[4]; Luís Carlos Timm[5]; Luiz Fernando Pires[6]; Klaus Reichardt[7]

FederalUniversityof Pelotas[1]; Embrapa – Brazilian Agricultural Research[2]; Post-Graduate Program in Water Resources[3]; Federal University of Pampa[4]; Federal University of Pelotas[5]; State University of Ponta Grossa[6]; State University of São Paulo[7]

Land levelling practice consists in leveling the soil surface to facilitate the management of irrigation and drainage operations forflooded rice cultivation.Due to soil movement while lower parts of a field being filled and higher parts being cut,severe soil surface disturbance occurscausing a significant decrease of the A horizon thickness with

possible exposure of subsoil layers. This study aimed to evaluate levelling effects on the relationships of lowland hydro-physical soil attributes using classical statistical tools. On a 1.0 ha field in Southern Brazil a grid of 10x10 m points was used to sample the 0-0.20 m soil layer, before and after levelling. In each sampling point, soil water retention curves (SWRC), sand and clay contents, soil bulk density (Ds), macroporosity and microporosity (Micro) values were determined. Each experimental SWRC was adjusted to the van Genuchten model in order to obtain the parameters a, n, qr and qs, considered here as an adjusted parameter. All data sets were submitted to descriptive statistics and the Kolmogorov-Smirnov test to check the data normality.In order to evaluate the levelling effects on the relationships among qs and all other soil hydro-physical attributes, two correlation coefficients were used: the Pearson correlation coefficient when the distributions of qs and the other variable followed normal distribution and the Spearman correlation coefficient, when not. Levelling altered mean, except for qs, and coefficient of variation values of all data sets. The tendency of data distributions was not altered by levelling. qs data presented significant Pearson correlation coefficients (p value <5%) with all soil attributes before levelling. All correlation coefficients were significant for qs and the other soil attributes after levelling, except for that between qs and clay content. Future studies should be carried out to evaluate effects of levelling on the soil water availability in lowland areas and for future operations of land recuperation as well.

Keywords: Keywords: Lowland; van Genuchten equation; soil attributes.

(5006 - 803) Least limiting water range in consortium of corn and forage grasses under no-tillage

Lucas de Oliveira Neves[1]; Camila Pereira Cagna[1]; Zieglenristen Karswegaard Pereira Calábria[2]; Osvaldo Guedes Filho[1]

Universidade Federal do Paraná[1]; Universidade Federal do Mato Grosso[2]

No-tillage system is based on crop rotation, no mobilization and soil cover. The soil cover may be maintained through crop straw involved in the crop rotation system as well the consortium with forage grasses. Least limiting water range (LLWR) is an indicator of soil physical quality that represent the real water availability to plant growth. The objective was to determine the LLWR of an Oxisol in consortium of corn and forage grasses under no-tillage. The experimental design was in randomized blocks with seven treatments distributed in three replications, resulting in 21 experimental plots. The treatments were: corn+ *U. brizantha* cv Marandu, corn + *U. ruziziensis*, corn + *U. humidicola*, corn + *U. decumbens*, corn + *P. maximum* cv Tanzânia, corn + *P. maximum* cv Mombaça and corn without consortium. Undisturbed samples were taken at 0 to 0.10 and 0.10 to 0.20 m soil depth and then split in eight groups corresponding to potentials of -0.002; -0.006; -0.01; -0.033; -0.07; -0.1 and -1.5 MPa. For water retention curve determination, it was used the tension table and Richards's chambers. For soil penetration curve determination, it was used an electronic penetrometer. The upper limits of the LLWR were field capacity at -0.01 MPa and the air-filled porosity of 10%. The lower limits of the LLWR were wilting point at -1.5 MPa and the penetration resistance of 2 MPa. The higher mean value of the LLWR at 0 to 0.10 m soil depth was found to consortium of corn + *U. ruziziensis* and the lower mean value to consortium of corn + *U. humidicola*. At 0.10 to 0.20 m soil depth the consortium of corn + *U. ruziziensis* presented the higher mean value of the LLWR and corn without consortium presented the lower one. The consortium of corn and forage grasses is a good option to improve the soil water availability, specially considering the combination of corn + *U. ruziziensis*.

(1992 - 215) Load support capacity of oxisol with and without controlled traffic in a sugarcane area

Diego Alexander Aguilera Esteban[1]; Elizeu de Souza Lima[1]; Lenon Henrique Lovera[1]; Ingrid Nehmi de Oliveira[1]; Náiade de Paula Ribeiro[1]; Fábio Henrique Barbosa Sandoval[1]; Zigomar Menezes de Souza1[1]

University of Campinas[1]

Intense traffic on the soil generated from sugarcane production system lead to harmful effects on its physical attributes as a result from the compaction caused by mechanization. To minimize such effects, a management system with controlled traffic emerges, in which traffic lines concentrate soil permanent compaction in a small area to avoid tire traffic at most part of the field. Such a physical soil degradation can be monitored by analyzing soil compressibility, since its compaction occurs when its load bearing capacity is exceeded generating increased soil density and redistribution of the porous space. Our research aimed at modelling the load support capacity of an Oxisol cultivated with sugar cane after the third cane cycle, planted with single spacing and combined double spacing in management systems with and without controlled traffic. We carried out the experiment at the Santa Fé Sugar Mill, Nova Europa, state of São Paulo – Brazil, using the following treatments: T1- single spacing (1.5 m) without the autopilot use; T2 - single spacing (1.5 m) using autopilot and T3- double combined spacing (1.50 x 0.90 m) with autopilot use. Load support capacity was assessed at the inter-row center and the seedbed at the depth of maximum soil resistance at penetration located at 0.20-0.30 m. The comparison of the load support capacity models obtained showed differences between T1xT2 and T1xT3 interactions at the inter-row center. The management systems with controlled traffic regardless soil water content at the inter-row center had higher pre-consolidation pressure in relation to the management without controlled traffic. In the soil friability region, suitable to agricultural operations, a pre-consolidation pressure ranging from 214 to 270 kPa for T1, 231 to 287 kPa for T2, and 239 to 311 kPa for T3. If larger loads are imposed to the soil friable region or the soil is managed above its plasticity limit, it occurs an additional compaction. Load support capacity models indicated a higher soil compaction at the inter-row center in relation to the seedbed in response to a cumulative effect of traffic machinery concentration along the crop cycles; therefore, managing sugarcane fields with controlled traffic systems preserves the physical quality of the soil at the ratoon region.

(6776 - 3000) Moving towards functional physical properties for an improved understanding of soil structure

José Miguel Reichert[1]

Federal University of Santa Maria[1]

The dynamics of soils and crops affected by soil management systems are better understood when using the concept of soil capacity and soil intensity properties or improved alternatives. Soil physical capacity property defines a general status, but not the soil's internal structure and function, while an intensity property includes dynamic aspects over time and space and thus covers the quantification of functionality and reaction or processes of systems within given environmental conditions. The terms "capacity" and "intensity" were later used for the distinction between composition properties in contrast to functional properties. The terms capacity and intensity properties should not be used as synonyms to composition and functional

properties. They should rather be reserved to the thermodynamically basic quantity-intensity-capacity concept, as widely used for example in description of potassium and phosphorus in soil. In a soil physics context, the water retention characteristic can serve as an example: the quantity Q is (volumetric) water content, the intensity I is the matric water potential, and the capacity is the change in Q with change in I. Recent research results will be presented to discuss these concepts in studies on soil tillage and management affecting composition and functioning soil structure.

(8381 - 3013) Nonlinear models for calibration of soil moisture capacitance sensors in tropical mountainous Inceptisols and Ultisols

Bárbara Pereira Christofaro Silva[1]; Diego Tassinari[1]; Marx Leandro Naves Silva[1]; Bruno Montoani Silva[1]; Nilton Curi[1]; Humberto Ribeiro da Rocha[2]; Pierre Vanhooydonck[2]

UFLA[1]; USP[2]

Capacitance sensors are now widely employed in monitoring soil water content (θ). However, for accurate measurements, calibrations specific to the monitored site are needed. This study aimed to conduct a thorough investigation on the regression models used for calibration of soil capacitance sensors and to generate specific calibrations for the soils and horizons studied. Additionally, we investigated the relation between soil attributes and the adjusted parameters of the specific calibrations, in order to develop a general calibration equation for all the studied soils and horizons. Undisturbed soil samples were collected in the A and B horizons of two Paleudults and two Dystrudepts from the Mantiqueira Range in Southeastern Brazil. After saturation, a time-domain reflectometry (TDR) sensor was used to measure the soil dielectric constant (ε). Several readings were made, ranging from saturation to oven-dry. After each reading, the samples were weighted so that θ (m^3 m^{-3}) could be calculated. Seventeen regression models (linear, linearized and nonlinear) were adjusted to the calibration data and checked for their residue distribution. The exponential models with three parameters performed the best and were the only ones that met the regression assumptions regarding residue distribution. Stepwise regression was used to obtain multiple linear equations to estimate the adjusted parameters ("a", "b" and "c") of the calibration model from soil attributes, with silt and clay content providing the best relations. Both the specific and the general calibrations performed well, with RMSE values of 0.02 and 0.03 respectively. The manufacturer calibration and the equations taken from the literature were much less accurate, reinforcing the need to develop specific calibrations for determining soil moisture with capacitance sensors. The chosen exponential model was $\theta = a + b (1 - c^{\varepsilon})$ and the parameters "a", "b" and "c" can be estimated from silt and clay contents with the equations a = -0.086 - 0.006*Silt + 0.004*Clay; b = 0.535 + 0.009*Silt - 0.003*Clay; c = 0.929 - 0.001*Silt.

(3661 - 961) Oxisol and Ultisol CO_2 emission and soil pore classes after soil tillage of sugarcane area in Brazil

Carolina Fernandes[1]; Luma Castro de Souza[1]; Mara Regina Moitinho[1]; Newton La Scala Junior[1]

UNESP, São Paulo State University[1]

Agriculture is considered an important source of CO_2 emission to the atmosphere. Thus, studies on the use of agricultural practices with less soil mobilization are promising in reducing soil CO_2 emission. The objective of this work was to characterize soil CO_2 emission, soil organic carbon and soil pore distribution in an Oxisol and Ultisol under chiseling in the planting row and in total area for sugarcane cultivation. The study took place in two experimental sites located at Brazil (21º 14' S, 48º 17' W), under Oxisol (at 0.10 m depth, clay content = 550 g kg^{-1} and sand content = 392 g kg^{-1}) and Ultisol (at 0.10 m depth, clay content = 130 g kg^{-1} and sand content = 809 g kg^{-1}). A large paired-plot design was used with two treatments and ten replications. The treatments were two soil tillages to sugarcane planting: soil chiseling only in row planting (CR) and soil chiseling on total area (CT). Soil samples were collected at 0.00 - 0.10 m depth. Soil CO_2 emission, soil temperature and soil moisture were assessed over 12 days in the Oxisol and 11 days in the Ultisol at 0.00 - 0.10 m depth. In Oxisol, the lowest average value of soil CO_2 emission (2.8 µmol m^{-2} s^{-1}) was observed in CR whereas CT presented the highest value (3.4 µmol m^{-2} s^{-1}). In Ultisol, CR and CT did not affect soil CO_2 emission. In Oxisol, 72% of the soil CO_2 emission variability in CR was explained by organic carbon associated with minerals and pore class C2 ($0.05 \leq \phi < 0.1$ mm), and 53% of soil CO_2 emission variability in CT was explained by soil moisture and soil temperature. In Ultisol, 82% of the soil CO_2 emission variability in CR was explained by soil moisture, pore class C1 ($\phi \geq 0.1$ mm) and organic carbon associated with minerals, and 67% of soil CO_2 emission variability in CT was explained by soil moisture, organic carbon associated with minerals and particulate organic carbon. The results showed that in Oxisol, CR and CT affected soil structure, causing changes in both soil porosity and soil CO_2 emission. On the other hand, in the Ultisol, soil CO_2 emission was not affected by soil tillages.

Keywords: soil organic carbon, pore distribution, chiseling, soil temperature, soil moisture

(5273 - 1729) Physical attributes of a soil submitted to biological decompaction and mechanical in Rondonia

Marcelo Henrique Gomes[1]; Emerson Oliveira Souza[1]; Fábio Lucas de Mattia[1]; Renan Marré Biazatti[1]; Anderson Cristian Bergamin[1]; Wesley Santana Ferreira[1]; Diogo Arthur Valiati Dantas[1]; Fábio Régis de Souza[1]

Fundação Universidade Federal de Rondônia[1]

The compaction of the soil caused by traffic of agricultural machinery or animal stamping promotes the limited development of explored crop in the system. The search of methods that can promote a decompacting of the soil is an important factor for a viability in the production system. The physical attributes of the soil are good parameters for analyses of the quality of the soil that will be explored. So the present work had as objective assesses the physical attributes of a soil under biological decompacting and mechanical. The experiment was installed in an Oxisol soil (Typic Haplustox) dystrophic in the experimental farm of UNIR at Rolim de Moura (RO). The experiment was in randomizing block with three repetitions, assessing macroporosity and total volume in four treatments: Brachiaria brizantha, Crotalaria grahamiana, Crotalaria spectabilis and mechanical scarification (soil cover with B. brizantha), in five induced states of compaction: 0, 1, 2, 4 and 8 passes of an agricultural tractor. Was collected samples of soil with structure preserved in the layers of 0,0-0,05 m, 0,05-0,10m and 0,10-0,20m, carried to laboratory for

obtain the macroporosity and total volume of pores. The mechanical scarification of the soil promotes higher macroporosity in all analyzed layers, showing more efficiency of this system in relation to biological decompaction. Was observed significantly reduces in macroporosity from two passes with tractor in the treatments with cover crops, already for mechanical scarification, can break the layers compacted in the passes leaving the soil in the same conditions of macroporosity. For the total volume the pores in the layer 0,0-0,05 m, was observed significantly reduces according to increase the compaction of soil, and between methods of decompacting the mechanical scarification was more efficiently, already for the deeper layers did not have effects by the decompacting soil methods, just reduced the total volume of pores with the increase of tractor passes. The mechanical scarification of soil promote better effects in the physical attributes of macroporosity and total volume of pores being an efficiently method of decompacting in degraded areas with physical limitations.
Keywords: Porosity; decompacting of soil, scarification.

(3819 - 2067) Physical attributes of soil cultivated under different species of cover crops

Juan Ricardo Rocha[1]; Ivne Franco Pires[1]; Yan Vinturini Vieira Dantas[1]; João Victor Fiorot Cescon[1]; Hugo Callegari Bonini[1]; João Vitor Furlan[1]; Allan Mendes de Araújo Lima[1]; Ivoney Gontijo[1]
Universidade Federal do Espirito Santo[1]

The management systems determine the conditions of the physical properties of the soil. The soils of the north of the Espírito Santo state have cohesive subsurface horizon, so the infiltration of rainwater is naturally lower when compared to soils with good drainage. The preferred route through which rainwater travels is the infiltration into the soil pores and consequent supply of the water table. As an alternative to soil management, cover crops, whether spontaneous or cultivated, that keep the soil covered mainly in the rainy season, are important for obtaining a more sustainable production, aiming to increase soil erosion resistance, supply of plant material to the surface. The litter has a fundamental role in the energy dissipation, because in the discovered soil (common condition in the conventional systems of cultivation), the clays are removed, the finer particles of the soil obstruct the porous ones, the soil roughness is overcome and it crosses a differentiated path giving beginning to the erosive process. The objective of this research was to study the potential of different species used as cover crops in *Piper nigrum* cultivation in the soil and climate conditions of the northern region of Espírito Santo state. The study was developed on a dystrophic Yellow Latosol. The experiment was conducted in DBC, with five treatments, being four species of cover plants and one control, totalizing four blocks. *Crotalaria spectabilis, Cajanus cajan, Pennisetum glaucum* and *Brachiria* were used, which were cut in flowering. Soil samples were collected in September, 45 days after the mowing of the cover plants. In each experimental plot an undisturbed sample was collected at depths of 0.0-0.10 m and 0.10-0.20 meters using an Uhland sampler, in the crop planting line, in the line of traffic of implements. These samples were used to determine soil density, total pore volume, macropores, micropores, moisture at field capacity and at the permanent wilting point. Analysis of variance was performed by GENES software. There was no statistically significant difference for the variables studied. Probably because they were collected only in one agricultural year. It is known that organic matter takes time to stabilize in the soil, since the region presents high rates of solar radiation and soil temperature, thus, the continuity of this experiment is necessary to be able to clearly state the possible improvements in the physical structure of the soil by the cover plants.

(7559 - 1327) Physical attributes of soil in the pineapple culture in miracema do tocantins - TO

Talita Maia Freire[1]; Thalline Rodrigues da Silva[1]; Michele Ribeiro Ramos[1]; Danilo Marcelo Aires dos Santos[1]; Dione Joaquim Pereira[1]; Lorena dos santos campos[1]; Sebastiana Patricia Alves Coelho[1]; Dara Chaves Paixão[1]
University of Tocantins[1]

Pineapple is a plant with specific characteristics. Its cultivation requires adequate knowledge and the application of a range of technologies indispensable to bring economic success to the activity. In Tocantins the pineapple culture presents as main characteristic the production in the Brazilian off-season, which gives it high profitability. The objective of this work was to evaluate the physical attributes of the soil in different slopes in a pineapple commercial plantation. Soil samples were collected at Providencia Farm in Miracema do Tocantins - TO, the area of 4.83 ha was divided according to the slope in 3 plots, being plot 1 (1.7 ha), plot 2 (0.62 ha) and field 3 (1.51 ha). Analyzes of total porosity, bulk density and hydraulic conductivity were performed using a methodology recommended by Embrapa (2011). Chemical and granulometry analyzes were also performed to characterize the areas. The results were analyzed in the statistical program SISVAR 5.6, and a mean test (Tukey, 5%) was applied. The average values of density found were 1.13 g/dm^3, 0.87 g/dm^3, 1.30 g/dm^3, respectively plot 1, plot 2 and plot 3. While for the total porosity attribute, there were 0.70 cm^3/cm^3, 0.76 cm^3/cm^3 and 0.59 cm^3/cm^3. The hydraulic conductivity was 61.41 mm.h^{-1}, 52.49 mm.h^{-1}and 26.62 mm.h^{-1}. From the application of the Tukey Test to 5% it was possible to conclude that there was a statistical difference between the values found for density between the plots; for the total porosity attribute the averages of plots 1 and 2 were not statistically different, but these were statistically different from the mean of plot 3; with respect to hydraulic conductivity there was no statistical difference between the plots. The values found will allow a greater effectiveness of the local productivity of the pineapple, corroborating for future studies of intercorrelation of the production of the cultivar in different slopes.

(4780 - 2170) Physical attributes of soil under management of cupuaçu (Theobroma grandiflorum) in the municipality of canutama, south of the amazonas

Juliana Malta de Assis[1]; Ludimila Souza Oliveira[1]; Milton César Costa Campos[1]; José Maurício da Cunha[1]; José Igor Silva Praça[1]; Luana Celestino Calista[1]; Estefani de Souza Oliveira[1]; Fernando Gomes de Souza[1]; Anderson Vieira Rodrigues[1]; Sabrina Isabela da Silva Fernandes[1]
Federal University of Amazonas[1]

The soil, when kept in its natural state, under native vegetation, presents physical attributes such as density, porosity, aggregation and permeability considered adequate. As the soil undergoes interferences in the use, changes in its physical attributes occur, such as increase in soil density, decrease in total porosity, pore diameter distribution, alteration in aggregation and organic matter content. Thus, this study aimed to evaluate the spatial variability of the physical attributes of the soil, carried out in the São Francisco Settlement Project, in the municipality of Canutama - AM. The collection was carried out in the Cupuaçu cultivation area, which was established a mesh of 90 m x 70 m with regular spacing of 10 m between the points, making a total of 80 sampling points, at depths of 0.00-0 , 05; 0.05-0.10; and 0.10-0.20

m. The undisturbed samples were collected using volumetric rings with a mean volume of 90.0 cm³. In the laboratory, samples were prepared by retreating the excess soil from its ends, and then saturated by raising a water slide in an aluminum form to about 2/3 of the sample height. After the analyzes were performed the statistics were run. By the descriptive statistics of the data, it behaved in a way where, where the mean and median values were close confirming the symmetric distribution of data by the asymmetry coefficients close to zero for both depths, the amount of micropores (MiP) was superior to that of macropores (MaP) at all depths, which formed soils with material of the upper clay in its textural composition and, consequently, indicating soils with good water retention, but with slow drainage as for the total porosity, it decreased in depth , as many the classification of the coefficient of variation (CV%) proposed by Warrick and Nielson (1980) for the soil variables, the attributes had medium and low variability ranging from 7 to 14%, from 12 to 27% and 10 to 20 %, to depths 0.00-0.05; 0.00-0.10 and 0.10-0.20 m respectively . Thus, the management did not influence in the pore reduction of the superficial part of the soil, by the porosity conditions this soil does not need a high frequency of irrigation.

(7725 - 3110) Physical quality and blocked pores in Humic Inceptsol under flax cultivation

Letícia Salvi Kohn[1]; Carla Eloize Carducci[2]; Leosane Cristina Bosco[1]; Jânio dos Santos Barbosa[1]; Wagner Tobias Haubert[3]
UFSC - Campus Curitibanos[1]; UFGD[2]; IFRS - Campus Sertão[3]

The dynamics of air and water in the soil has a direct influence on its physical attributes, which are of fundamental importance for the good development of the plants. Due to the growing need to favor soil structure, conservationist management practices are being used along with species that can bring benefits to the soil. Flax is a winter culture that has simple management and can be used in crop rotation to recover the soil from physical and chemical wear due to the action of its roots system, which occupies about 0.20-0.30 m in the soil profile. The aeration of the soil depends on the quantity, size and continuity of the pores, and the water content, and must have and ideal pore size for the entrance, movement and retetion of water and air. The objective of the present work was to evaluate the amount of blocked pores in a Humic Inceptsol under the cultivation of 3 genotypes of flax in Curitibanos - SC. The experiment was implanted in an area belonging to the UFSC, and the flax was sown in April 2016 and conduced in a minimum cropping system. The genotypes were: golden variety, and the brown cultivars, Aguará and Caburé. Samples with preseverd structure were collected for analysis of soil density and pore distribution, in two depths (0-0.05 and 0.05-0.20 m) in the row and interline of cultivation, in triplicate. Deformed samples were also collected to determine the particle density. The total and calculated porosity was determined from the data, the difference between them being the number of blocked pores. The analysis of variance was performed and when significative, the averages were compared by the Tukey test (5%). The average of the particle density was between 2.39-2.55 Mg m^{-3}, indicating homogeneity in the layers. The blocked pores volume did not differ statistically between the genotypes and the layers avaluated. In both study layers, in the cultivation line, the golden variety and the Caburé cultivar presented more than 1% of the total soil pores classified as blocked (1.1%); for the other genotypes, the soil had lower value of blocked pores. In the interline of cultivation, only the Aguará cultivar had more than 1% of blocked pores. The tendency of these pores is to evolve into micropores and assist in water retention and reduce the diffusion rate of gases in the soil. The results obtained from soil blocked pores on flax culture indicated good structural quality of the same.

(2672 - 2154) Physical attributes of soil in archaeological black land area (TPA) with cocoa cultivation in the south of Amazonas

José Igor Silva Praça[1]; Juliana Malta de Assis[1]; Ludmilla Colares Rodrigues[1]; Milton César Costa Campos[1]; Elyenayra Nogueira Pinheiro[1]; Ludimila Souza Oliveira[1]; Luana Celestino Calista[1]; Estefani de Souza Oliveira[1]; Francisca Xavier Quintino Neta[1]; Fernando Gomes de Souza[1]
Federal University of Amazonas[1]

Archaeological Black Lands (TPA) or Black Indian Lands comprise characteristically dark soils and ceramic and / or lytic fragments incorporated into their more superficial horizons, these soils usually exhibit high natural fertility, with high levels of P, Ca, Mg and stable organic matter, in addition to greater biological activity, when compared to adjacent soils. This work you've aimed to investigate the spatial behavior of soil physical properties in areas of Terra Preta Archaeological under use of pasture, cocoa and coffee in the southern Amazon region. The study is located in the municipality of apuí in the south of Amazonas, the climate classified with rainy tropical type Am. The mapping of the area of TPA was carried out with cocoa cultivation and in this was established a mesh of 88 m by 64 m with regular spacing of 8 m between the sampling points, the soils were sampled at the crossing points of the mesh, making a total of 88 sampling points. These points will be georeferenced with GPS equipment and then collected soil samples at depths 0.00-0.05, 0.05-0.10, 0.10-0.20. Physical analyzes will be performed texture, macroporosity, microporosity and total porosity. The data will be analyzed using descriptive statistical techniques.It was observed that the silt fraction corresponding to more than half the granulometric composition with a value of 572.83 g kg^{-1}, while the sand showed a value of 221.10 g kg^{-1} clay and 204.52 g kg^{-1}, the silt fraction is justified due to the high degree of weathering. As for porous spaces of the soil, the macroporosity had values ranging from 19,40 m 3 m -3 to 22.38 m 3 m -3 , while the microporosity varied from 41.98 to 49.05 m 3 m -3 and presented a reduction of the values with the increase of the depth, this occurs as a function of the density, which also increases, decreasing the macros to micropores. Thus by the texture the soil was measured with medium texture and from the porosity it can be concluded that these have a good drainage of water.

(2266 - 3034) Pore Size Distribution Frequency of Intensively Cultivated Oxidic Ferralsols.

Thaís Nascimento Pessoa[1]; Igor Rodrigues de Assis[2]; Teogenes Senna de Oliveira[2]
University of São Paulo, "Luiz de Queiroz" College of Agriculture, Pádua Dias Avenue, 11, 13418-900, Piracicaba, São Paulo, Brazil (thaisnpessoa@usp.br)[1]; Federal University of Viçosa, Peter Henry Rolfs Avenue, 36570-000, Viçosa, MG, Brazil[2]

Oxidic Ferralsols are characterized by physical properties that are favorable to agricultural mechanization due to their high resistance and resilience to the structural degradation process. Vegetable production cropping systems (generally irrigated) are intensively used and consist of a larger number of crops per year. The large number of operations using machines and implements, along the cropping period intensifies even more the soil use with these systems. The purpose of

this study was to evaluate changes in the frequency and the frequency distribution curves of soil pore size, after different times of soil use in areas of intensive cultivation with vegetable cropping systems. Undisturbed soil samples were collected from the layers 0-0.10; 0.10-0.30; 0.30-0.40; 0.40-0.70 and 0.70-1.00 m in areas of commercial farms and native Savanna (CE), both located in the region of Rio Paranaíba, Minas Gerais, Brazil. In these farm areas are vegetable cropping cultivated in succession with cereals and grasses, during different times of agricultural uses: 15 (HT_{15}), 20 (HT_{20}) and 30 (HT_{30}) years. It was evaluated the macroporosity (MA), mesoporosity (ME), microporosity (MI) from the curves of frequency distribution of soil pore diameter per unit of soil tension. These curves showed that, for the native area (CE), there was a higher frequency of pores with larger diameters in all layers, indicating more heterogeneity. For the areas with agricultural uses (AU), prevailed frequency of pores with smaller diameter and greater homogeneity. The comparison between CE and AU showed significant difference in MA and MI. With respect to ME, however, values were practically the same. There was a tendency of higher MA and ME in CE and in HT_{20} compared to other areas (HT_{15} and HT_{30}). For MI, there was a significant increase in all cultivated areas and in most of the layers, being significantly higher in HT_{30}. Thus, the soil use systems with intensive vegetable cropping modified the distribution of the pores in the evaluated Ferralsols. The level of alteration was not proportional to the time of agricultural use, since in the intermediate use (HT_{20}) higher values were obtained for MA and ME that are the most influenced by the impacts on the soil structure. This behaviour in the HT_{20} use can be attributed to the high resilience of the oxidic Ferralsols, which can recover from impacts on the structure in the short term.

(5778 - 283) Porosity of an Ultisol cultivated with soybean in integration system for livestock farming

Melissa Alexandre Santos[1]; Carolina dos Santos Batista Bonini[1]; Guilherme Constantino Meirelles[1]; Juliana Megumi Kanashiro de Oliveira[1]; Ronaldo Cintra Lima[1]
FCAT/UNESP DRACENA[1]

Large areas used for agricultural production have been increasingly exploited resulting in degraded soils and consequently reflecting lower productivity since their physical attributes can be negatively influenced by poor soil use. The objective of this study was to evaluate the effect of intercropping between soybean and tropical forages on the changes in the physical properties of a Ultisols in a no - tillage system by means of physical attributes evaluation. The experiment was carried out at the Faculty of Agrarian and Technological Sciences - UNESP / FCAT, in the city of Dracena / SP, since 2016. The experimental design was a randomized complete block design with fourteen replications, four SPD levels, consisting of four treatments: 1 - Witness with conventional soybean planting; 2 - Direct planting of soybean with forage of *Uroclhoa Ruziziensis*; 3 - Direct planting of soybean with forage of *Uroclhoa Brizantha* cv. Paiaguás; 4 - Direct planting of soybean with forage of *Uroclhoa Brizantha* cv. Piatã. The evaluations were physical soil attributes (macroporosity, microporosity, total porosity and soil density). Soil analyzes were done on three depths of soil, 0.00-0.10; 0.10-0.20 and 0.20-0.40 m. The results were analyzed by performing analysis of variance and Tukey's test at 5% probability for the comparison of means. In the 0.00-0.10 m depth macroporosity values were higher with conventional soil preparation. The microporosity values were not influenced by the treatments. The soil density was in increasing order with conventional preparation Uroclhoa Brizantha cv. Piatã. as cover plant got the highest macroporosity and lower soil density.

(4551 - 417) Porous spaces of soil in area under cultivation of guarana (*Paullinia cupana*) in South of Amazonas

Anderson Vieria Rodrigues[1]; Elyenayra Nogueira Pinheiro[1]; Carlos Henrique Gima Relvas[1]; José Maurício da Cunha[1]; Elilson Gomes de Brito Filho[1]; Milton César Costa Campos[1]; José Igor Silva Praça[1]; Sabrina Isabela da Silva Fernandes[1]; Francisca Xavier Quintino Neta[1]; Ludmilla Colares Rodrigues[1]
Federal University of Amazonas[1]

The southern region of Amazonas is characterized by natural environments and cultivated areas where, in addition to natural variability, anthropogenic sources of heterogeneity are added to the soil. Knowledge of soil asset variability has been characterized as an important step for proper management, as well as its use and limitations. Thus, there is a need to know if there are results and knowledge related to the evaluation of the spatial variability in Guaraná cultivated area, under Amazonian conditions, and with this, improvements in the sustainable use of soil, good efficiency in production and less degradation make the soil. The objective of this work was to verify the soil porous spaces under guaraná management, with no São Francisco settlement project in the south of Amazonas. The study was carried out in the Canutama municipality of Amazonas, Brazil, in an area under cultivation of Guarana. A mesh of 80 points, with a size of 90x70 m and a regular spacing of 10 m between samples were established, where undisturbed samples were collected at depths of 0.00-0.05 m; 0.05-0.10 m and 0.10-0.20 m. As samples in volumetric rings were saturated by means of gradual elevation, up to two thirds of the ring height. After saturation, as samples of heavy and brought to the tension table and subjected to a pressure of -0.006 MPa, a water column 60 mm high. By the descriptive analysis of the data, it was possible to verify the normality of the data by the test of Komogorov-Smirnova 5% probability. The data tend to symmetry with average and near median, as evidenced by the coefficients of asymmetry and kurtosis close to zero, and coefficients of variation for the classification of Warrick and Nielson in medium and low variability. Observed the porosity increased in depth, with a layer of 0.00-0.05 presenting the lowest values of porosities, justified by exposure layer of soil subjected to anthropic action, and its porous spaces decreased. The amount of micropores was higher than that of macropores, so these soils tend to make up most of the clay particles, and consequently a good retention of water without soil. Thus, the soil presented good characteristics regarding its porous spaces, which contributes to its other attributes and, consequently, to the management of the crop.

(4382 - 768) Productivity of Linseed genotypes under edaphoclimatic conditions in Dourados City- MS

Kaliana Gottschalk de Freitas[1]; Carla Eloize Carducci[1]; Eloise Mello Viana de Moraes[1]; Joyce Castro Xavier[1]; João Claudio Teodoro Turtt[1]; Leonardo de Assis Lopes[1]; Rafael Costa Ferreira[1]
Universidade Federal da Grande Dourados- UFGD[1]

The suthern region of central-west shows edaphoclimatic potential for linseed cultivation, however characterization studies of linseed performance in that region are very scarce. The aimed of this work were to evaluate the relationship between linseed genotypes fenometria and the edaphoclimatic conditions from Dourados-MS. The experiment were conducted in the experimental area of FCA/UFGD in acrustox, under Cwa climate. The experimental design

was in randomized blocks with three genotypes: M1= Caburé Argentina, M2= Aguará Argentina and M3= UFSC, all are brown seeds, in triplicate. The soil was prepared with plowing and manual sowing. Cover fertilization (8 g m^{-2} NPK (8-20-20)) was performed. Soil samples disturbed were collected in the plating line at 0-0.16 and 0.16-0.30 m depth, which refer to soil stratification found through visual analysis of the soil structure. It were determined: the particle size by the pipette method and the phenometric characteristics: plant height, capsules number, seeds per plant and productivity (kg ha^{-1}). The M1 genotype had a significant interaction ($R^2 \geq 0.50$) for clay and silt with seeds and capsules. The M2 negative linear interaction for silt (R^2= 0.57) with the phenometry and M3 differed from M1 genotype only in the clay interaction with the capsules number. It should be emphasized that the Oxisol particle size with clayey texture positively influeced the production capsules and seeds. The clay electrical charge gave it good nutrient adsorption and water retention, while the silt retained water with less retention force in the soil profile, both contributing to the seeds formation. When occurrence of water stress in the initial phase of linseed development, there wew a decrease in the capsules number. In this phase there were a Indian summer seriod in our region (± 60 days), which injured the capsules formation and seeds per capsule. M1, M2 and M3 genotypes showed the following yields of 122, 135 and 186 kg ha^{-1}, respectively, values considered average for the first harvest, besides being influenced by the variations of the climatic conditions to the region and by the soil-plant interaction, that were, with the increase of the clay content the increase of seeds number occurs, due to greater availability of soil electrical charhe. The genotype M3= UFSC were more adaptable to the regions conditions o: very clayey soil and Cwa climate, with Indian summer in winter.

(1889 - 2126) Red Latosol physical attributes under degraded pastures in Dourados-MS, Brazil

João Claudio Teodoro Turtt[1]; Kaliana Gottschalk de Freitas[1]; Maximiliano Kawahata Pagliarini[1]; Kamila de Almeida Monaco[1]; Carla Eloize Carducci[1]; Joyce Castro Xavier[1]; Leonardo de Assis Lopes[1]
Federal University of Grande Dourados[1]

Degraded pastures are the result of an evolutionary process of forage loss vigor and productivity, without natural recovery possibilities, which affects animal production and its performance culminating with soil and natural resources degradation due to inadequate management. The aim of this work was to evaluate the relationship between pastures degradation and Oxisoil physical properties changes in Dourados-MS, Brazil. The samples were collected at UFGD experimental farm inside four different areas with some forage degradation level : 1- fallow land (FL), 2- *Brachiaria* spp. Syn Urochloa without grazing (BWG), 3- *Brachiaria* spp. Syn Urochloa with ovine grazing (BOG), 4- inverted soil / restore pasture (IS/RP). Soil samples were collected in undisturbed and disturbed structure in two layers: 0-0.05 and 0.05-0.10 m depth, with three replications in a completely randomized design plot. The particle size distribution and water dispersed clay (ADA) were analyzed by the pipette method. Furthermore, it was analyzed flocculation index (FI), clay aggregate (CA), soil bulk density (BD) and pore distribution (>145, 145-73, 73 - 49, 49-29, 29-2.9, <2.9µm). There was difference among evaluated areas and depth where the best soil aggregates stability according to the FI> 50% and CA> 40% was found in the BWG. However, better distribution of drainage pores (0.20; 0.11, 0.07 cm3 cm-3 to >145, 145-73 and 73-49µm, respectively), lower BD (<1.30 g cm-3) and medium values of retention pores (<2.9 µm = 0.26 cm3 cm-3) was verified in BOG area at 0.05-0.10 m depth, favoring good supply of soil water to forage plant. On the other hand, the most degraded area was IS/RP where had had an intense soil inverting promoting high clay dispersion (AF and FI = <10%), which reflected significant micropores increase responsible to high energy to water retention (<2.9µm = 0.45cm^3 / cm^3).

(1058 - 2070) Resistance to penetration in Latosol cultivated under different species of green manure

Ivne Franco Pires[1]; Juan Ricardo Rocha[1]; Hugo Callegari Bonini[1]; João Victor Fiorot Cescon[1]; Yan Vinturini Vieira Dantas[1]; João Vitor Furlan[1]; Allan Mendes de Araújo Lima[1]; Ivoney Gontijo[1]
Universidade Federal do Espírito Santo[1]

The Coastal Flat Lands, a geological formation occurring predominantly in the north of Espírito Santo state, have a cohesive subsurface horizon. These horizons affect the processes and physical phenomena of the soil as well as the monoculture systems in the region, which contribute to the destructuring with effect on the compaction along the profile and the formation of surface sealing layer, which hinders the emergence of seedlings, reducing the stand of crops. Due to its ability to improve soil quality, the use of green manure has been shown to be efficient in achieving sustainability in the agricultural system. The objective of this research was to study the potential of different species used as cover crops in *Piper nigrum* cultivation in the soil and climate conditions of the northern region of Espírito Santo state. The study was carried out in a commercial crop with drip irrigation regime on a dystrophic Yellow Latosol with a clay-loamy texture and particle density of 2.65 g cm^{-3}. The experimental design was a randomized block design with four species of cover plants (*Crotalaria spectabilis, Cajanus cajan, Pennisetum glaucum* and *Brachiaria*) and one control (without cover plants), totaling four blocks. After 45 days of the cutting of the plants that were in full flowering stage, the undisturbed soil samples were taken at two depths (0-0.10 and 0.10-0.20 meters), and the physical test penetration resistance through a bench penetrograph where the samples were maintained in the condition of field capacity aiming at the standardization of the humidity. Data were submitted to analysis of variance by the GENES software. It was found that there was no significant statistical difference between the different species of cover plants used and also between the two depths of soil sampling. These results may be related to the short duration of the experiment, not enough time for the accumulation of organic matter necessary to promote the physical improvements of the soil. The continuation of the experiment for a few more cycles would be crucial to obtain more satisfactory results.

(6871 - 975) Resistance values to penetration in red argisol with different doses of limestone with and without superficial agricultural plaster.

Everton Luís Santos[1]; Luanda Torquato Feba[1]; Mais Sérgio Lopes da Silva[1]; Aline Saraiva Viudes[1]; Carlos Sérgio Tiritan[1]; Henrique Debiasi[2]
Universidade do Oeste Paulista[1]; Embrapa Soja[2]

In soils with high penetration resistance, the structure changes and, consequently, the loss of porosity, macroporosity, availability of water and nutrients and the diffusion of gases in the soil. The objective of this work was to evaluate the dynamics of resistance to penetration in different doses of superficial limestone combined with and without gypsum. The experiment was conducted at the Experimental Farm of University West of São Paulo (Unoeste) in Presidente Bernardes-SP at 22º17'27 "S, 51º40'51" W and 385 m

altitude. The soil of the experimental area is classified as Dystrophic Red Argisol, with smooth undulating relief. The area was carried out in bands with subdivided plot, in a 4x2 factorial scheme, with three replications. The plots were composed of the following limestone doses (0, 2, 4 and 8 t ha-1) and the plots with and without agricultural plaster (0 and 4 t ha-1), resistance to penetration (0 to 60 cm) and moisture analysis (from 0-10, 10-20, 20-30 and 30- 40 cm). The penetration resistance analysis was performed with a penetrometer (Falker PLG 1020), the points were defined by a transect of 1,92 m, composed of 16 points of 12 cm of distance between them. According to the results, there is a significant interaction between levels of compaction, liming and soil plaster, so this indicates that these three variables should be considered in the application of limestone and gypsum. However, it was generally concluded that the increase in penetration resistance was due to lower average soil moisture. Also the value of the resistance to penetration, when compared between the treatments, which contained limestone, obtained a higher value than the one without limestone.

(9914 - 992) Soil aggregate stability cultivated with organic strawberry under management systems

Daiane de Fatima da Silva Haubert[1]; Osvaldo Guedes Filho[1]; Lucas de Oliveira Neves[1]; Camila Pereira Cagna[1]; Nádia da Silva Salatta[1]
Universidade Federal do Paraná[1]

Organic production is based in the use of organic sources of nutrients and no addition of chemical fertilizers. It is a sustainable agricultural practice that coupled with a conservation management as no-tillage system may be improve the soil physical quality. Aggregate stability is one of the soil physical indicators that have been used to evaluate the alteration on soil physical condition throughout of weight mean diameter and geometric mean diameter. The objective was to evaluate the soil aggregate stability cultivated with organic strawberry under no-tillage and conventional tillage system. The experimental area has been cultivated by 17-years with strawberry organic production under conventional tillage. For experiment implantation the area was split in two parts: conventional tillage and no-tillage system. No-tillage area presents a triannual crop rotation system and integral soil cover. For the planting of the strawberry seedlings were made holes of 10-centimeter soil depth. A year after the experiment installation it was collected ten soil blocks in each management system at 0.0 to 0.10 and 0.10 to 0.20 m soil depth. The aggregates size used in the aggregate stability determination was 4 to 2 mm diameter. It was used the humid method with size sieves of 2; 1; 0.5; 0.25; 0.106 mm. It was obtained the following aggregates parameters: weight mean diameter (WMD), geometric mean diameter (GMD) and aggregate stability index (ASI). The WMD, GMD and ASI were statistically higher in no-tillage system compared with conventional tillage for 0 to 0.10 m soil depth. At 0.10 to 0.20 m soil depth there were no significant differences among management systems for WMD, GMD and ASI. No-tillage system showed a better soil structural quality for the surface layer in the strawberry organic production.

(4713 - 1921) Soil aggregation evaluation in systems with cover crops using ultrasonic energy

Micael Stolben Mallmann[1]; Dalvan José Reinert[1]; Felipe D. Bertol[1]; William S. Foggiato[1]; Érika Andressa Silva[1]
UFSM[1]

The use of cover crops is essential for promoting the improvement of the structural quality of the soil. For the evaluation of the structural quality, mainly the stability of the aggregates, the use of ultrasonic energy has been a useful tool, since with this technique it is possible to evaluate the energy necessary to promote the dispersion of the aggregates. We objected was to evaluate the aggregates stability in soil with several cover crops using ultrasonic energy. Six treatments were evaluated: 1. Bared soil (BS); 2. Spontaneous vegetation (EV); 3. Forage peanuts (Arachis pintoi) (FP); 4. Pensacola Grass (Paspalum notatum) (PG); 5. Black Oats (Avena strigosa) and radish (Raphanus sativus) -winter- and cowpea (Vigna unguiculata) -summer (ORB); 6. Black Oats (Avena strigosa) and vetch (Vicia sativa) -winter- and cowpea (Vigna unguiculata) -summer (OVB). The soil of the study area is a Hapludalf, with 85 g kg-1 of clay, 225 g kg-1 of silt and 690 g kg-1 of sand in A horizon. The soil was sampled 18 months after implantation. Aggregates from 4 to 8 mm collected from the 0 to 0.05 m depth layer were sonicated using seven times: 0, 21, 39, 74, 110, 150 and 200 s, equivalent to 0, 3, 6, 12, 18 , 24 and 32 J ml-1. The equipment operated with a power of 31.4 W. We determined the dispersion index (DI) and the normalized dispersion index (NDI). The treatments were compared by energy applied through the Tukey test with 5% alpha. Only at the energy levels of 24 and 32 J ml-1 treatments did not differ. At energy level 0, EV presented the lowest values of DI and NDI, differing from PG and ORB. With the application of 6 J ml-1, BS and EV presented the lowest DI values and were different from PG. NDI was higher for BS and EV, differing from PG. With increased energy to 12 J ml-1, EV, BS and OVB showed the lowest and PG the highest DI. The NID was lower in EV and BS and higher in PG. With 16 J mL-1, EV, OVB, BS and FP differed from PG. The use of BS and EV in soil management systems negatively affects the stability of aggregates, while the use of PG improves the stability of the aggregates, requiring greater energy for soil dispersion. The use of FP, ORB and OVB present intermediate results, with a tendency to improve aggregation with time.

(6796 - 1992) Soil aggregation in rhizosphere and in bulk soil of a Haplorthox soil in Paraná, Brazil.

Aline Martineli Batista[1]; Paulo Leonel Libardi[2]; Neyde Fabíola Balarezo Giarola[3]
University of São Paulo/Luiz de Queiroz College of Agriculture, Department of Soil Science, 11 Pádua Dias, Piracicaba, CEP 13418-900, Brazil (martineli.aline@gmail.com).[1]; University of São Paulo/Luiz de Queiroz College of Agriculture, Department of Soil Science, 11 Pádua Dias, Piracicaba, CEP 13418-900, Brazil.[2]; State University of Ponta Grossa, Department of Soil Science and Agricultural Engineering, Gal. Carlos Cavalcanti, Ponta Grossa, CEP 84030-900, Brazil.[3]

Soil aggregation is one of the main indicators of the soil structure state and its adequate maintenance is very important to avoid soil degradation. With respect to the root effect on soil, there are evidences that properties of rhizosphere differ from bulk soil leading to structural differences. The objective of this study was to investigate the rhizosphere soil aggregation. The experimental area was located in the state of Paraná, Brazil, in a Haplorthox soil. It was implanted in the winter of 2016 and the sampling was made in the summer of 2017 with other rotation crops. Then, the treatments consisted of differents winter/summer rotation crops: T1) wheat/soybean; T2) black oats + rye + vetch/buckwheat; T3) black oats + ryegrass/soybean; T4) blue lupine + black oats/maize, which were distributed in four blocks. The sampling was performed in the soil surface (0.00 - 0.05 m), considering as rhizosphere the soil adhered to the roots and, as bulk soil the soil not adhered to the roots and without plants in its proximity. The samples were prepared and the soil aggregation evaluated by the analyses: readily dispersible clay (RDC) and mechanically dispersible clay (MDC). The procedure for these analyses consists of the agitation of a small amount of soil in water inside a bottle followed by

measurement of clay in suspension with a turbidimeter. The agitation was done manually for RDC and mechanically for MDC. Data obtained were submitted to analysis of variance and, when significant to Tukey test ($P<0.05$). It was observed that MDC was more sensible than RDC to detect differences between rhizosphere and bulk soil, because RDC consisted of very small values that resulted in high variation, complicating to see the differences. Thus, the interaction between treatments and environments (rhizosphere or bulk soil) was significant only for MDC. MDC showed that for T1, T2 and T3 there was more dispersible clay in bulk soil than in rhizosphere. T4 did not present differences for both environments. This fact probably occurred because the aggregates removal from the maize rhizosphere was more difficult than the other treatments and the aggregates may had broken during this process. For both rhizosphere and bulk soil, T2 and T3 had smaller values of dispersible clay. As higher levels of dispersible clay indicates poor soil aggregation, then, these results showed that the root system affects the soil by improving its aggregation.

(1672 - 2452) Soil macroinvertebrate activity and pore size distribution: characterization by X ray CT and 3D image analysis.

Gilda Buscemi[1]; Laura Gargiulo[2]; Fabio Terribile[1]; Giacomo Mele[2]
University of Naples Federico II - Department of Agricultural Science[1]; National Research Council - Institute for Agriculture and Forestry in the Mediterranean[2]

Soil organisms play a role in soil structure dynamics mainly by their activities like burrowing and mixing of materials, which in turn influence water and matter fluxes. Since the beginning of the 90s non-invasive technologies such as X-ray CT have been applied to directly observe and quantify macroporosity and bioturbation induced by soil fauna. However, in comparison with earthworms, termites and ants, the direct quantification of the effects of the activities of other soil macroinvertebrates on soil pore system development remains largely unexplored. In this work we carried out a short-term microcosm experiment combined with tridimensional image analysis to identify and quantify separately the contribution of five different taxa of macroinvertebrates to the formation of the soil pore system. Biopore size distribution produced by earthworms, millipedes, centipedes, campodeiform and elateriform lavae has been calculated from X-ray CT images of repacked soil samples inoculated each with one individual and then incubated in the field where soil and invertebrates were collected. Pore system has then been analysed appling the "successive opening" algorithm. All taxa exhibited specific signs in term of shape of the pore size distribution: except for elateriform larvae and centipedes, all studied macroinvertebrates induced evident multimodality in the pore size spectrum, with negative skewness for the worms and strongly positive one for the Campodeiform larvae due, this latter, to the excavation of caves. Earthworms showed an individual burrowing ratio significantly lower than that of the other soil invertebrates, being such parameter inversely correlated with the size of the individuals for all the taxa. Overall, results confirm the need to properly consider the specific role of the different soil macroinvertebrates as ecosystem engineers, while the applied experimental approach has provided data suitable for modeling the contribution of macroinvertebrates in soil structure formation.

(6393 - 2092) Soil Physical Attributes and Productivity in Corn-Green Manure Intercropping

Wellington da Silva Toledo[1]; Marcelo Zaffalon Bobato[1]; Flávio Sergio Afferri[1]; Laíze Aparecida Ferreira Vilela[1]
Universidade Federal de São Carlos-UFSCar[1]

Nutrients loss and organic matter depletion are important factors related to reduction of the productive potential in tropical lands. Therefore, to promote the soil quality, some cultivation practices have stood out, especially to improve physical soil quality. In this sense, grain crops-green manure intercropping can be a promising strategy to conservation of agricultural soils, since it is an economically accessible practice, particularly for low-tech farmers. Thus, our research evaluated the agronomic performance of corn in single crop or corn-green manure intercropping, and its influence on soil physical attributes. This study was carried out in a *Latossolo Vermelho Distroférrico típico,* in experimental field of the Campus Lagoa do Sino, Federal University of São Carlos (CCN/UFSCar). The field trial includes 4 treatments with 5 replicates in a randomized block design: 1. Single corn; 2. Corn-*Crotalaria juncea* intercropping; 3. Corn-millet intercropping; 4. Negative control (uncultivated, with spontaneous vegetation). The evaluations included, in plants: weight and size of green maize ears, dry grains yield, 100 grain mass and biomass production of green manures; in soil: soil penetration resistance, average aggregate diameter, soil density, total porosity and moisture. Our results showed that only one year of intercropping, both green manure did not benefit the green maize productivity and 100 grain mass, because none of the species promoted greater yield than single maize. On the other hand, in the grain yield, corn-crotalaria intercropping was statistically similar to single maize in the first year of cultivation, suggesting the great potential of this practice to increase productivity in the medium and long term. In the plant biomass production, millet was better to crotalaria, producing 45% more dry mass than this legume. Most of the soil physical quality parameters were not improved in the first year, our treatments only influenced soil penetration resistance. The consortium using grasses (corn-millet) had the lowest penetration resistance indexes and similar results were also observed in the corn-crotalaria intercropping. Finally, there is a need to evaluate the benefits of green manure in soil physical parameters in long term, in order to verify efficiency of these consortium systems, collaborating for more sustainable management of agricultural soils and improvements in the agronomic performance of maize.

(1883 - 990) Soil physical attributes as a function of crop rotation and soil acidity amendment in a long term No till System (NTS) study.

Jayme Ferrari Neto[1]; Carlos Alexandre Costa Crusciol[2]; Alan Franzluebbers[3]; Katiuça Sueko Tanaka[2]; Letusa Momesso[2]
Dom Bosco Catholic University, Campo Grande, MS, Brazil[1]; Sao Paulo State University, Botucatu, SP, Brazil[2]; North Carolina State University, Raleigh, NC, USA[3]

The higher amount of plant residues in the soil profile in NTS, results in an increase in the soil organic matter content (SOM), which favors the formation of aggregates due to the cementing and agglutinating action that SOM exerts on the mineral particles of the soil. Soil acidity amendment may also have an indirect effect on the soil physical properties, as they favor the shoot and root development of the crops and increase the organic matter and microbial activity in the soil; factors that also help the formation of aggregates. Thus, the aim was to evaluate the bulk density, macro, micro and total soil porosity in the profile of a Rhodic Hapludox as a function of crop rotation system and superficial liming and calciumand calcium/magnesium silicate application on soil. This experiment was set up in October 2006 in Botucatu, SaoBotucatu, Sao Paulo, Brazil. A randomized block design consisted of four crop systems, varying by the type of crop during the offseason (forage crop, second crop, cover crops and fallow). The

main crop during the summer was either soybean, maize, rice, or common bean. Split-plots were two sources for soil acidity correction (dolomitic lime; calcium/magnesium silicate) and a control (no soil correction for a total of 12 treatments with four replications. Soil samples were collected in 2013 at depths of 0-5, 5-10, and 10-20 cm for evaluation bulk density, macro, micro and total soil porosity. In general, when there were two crops per agricultural year, there was a greater macroaggregation of the soil, which may also be related to the input of dry matter mass in these crop systems and the only production system that influencedthat influenced on soil microaggregates was the forage crop in the 0 to 5 cm layer of soil. Although no direct effect of the soil acidity correction on soil physical properties was observed, the benefits provided by them on the production of shoot dry matter during the seven agricultural years negated the possible deleterious effect of clay dispersion.

(7473 - 2096) Soil physical attributes in an integrated crop-livestock systems in southern Brazil

Douglas Rodrigo Kaiser[1]; Lucas Raimundo Rauber[1]; Flávio de Lara Lemes[1]
Universidade Federal da Fronteira Sul[1]

The integrated crop-livestock systems (ICLS), when well managed, generates benefits to the soil-animal-plant system, due to the synergism between its components. However, there is a concern about soil compaction by animal trampling in intensive systems, which may compromise soil structure. In this systems the reducing porosity and increasing soil bulk density may compromise water availability and plant root growth. This study evaluated the effect of rotational grazing and soil chiseling on an ICLS, where during the winter the area is destined to produce oats for grazing with dairy cows and in the summer the soybean and corn crops are grown. The experimental design was a randomized block design with three treatments and four replications: T1: Area with grazing in winter; T2: Area with winter grazing followed by soil chiseling and T3: Area without grazing in winter. The soil was a Oxisol. During the winter, the area underwent four cycles of grazing, and before each grazing the soil moisture was evaluated. Before and after each grazing cycle, the dry mass of oats was evaluated. At the end of the grazing cycles the bulk density and distribution of soil pores were evaluated in the layers 0-5, 5-10, 10-20 and 20-30 cm. After the end of the oat pasture cycle, soybean (Glycine max) was implanted and during its cycle were evaluated the soil moisture and the root distribution and grain yield. On days when grazing occurred the soil was in a friable state. The cows trampling increased the bulk density and decreased the porosity of the soil in the superficial layer (0-5 cm). The soil chiseling reducing the bulk density and increasing the porosity of the soil up to 15 cm, but it was unnecessary because it did not influence the root distribution and soybean yield. In addition, changes in soil surface structure due to grazing did not affect the retention and availability of water for the soybean crop. Therefore, in an integrated crop-livestock systems, with high stocking of dairy cows in the winter, if a rotation grazing and carried out under conditions of friable soil, soil degradation does not occur and not affecting root growth and yield of summer crops.

(4035 - 3140) Soil Physical Indicators in an Agroforestry System in the Cerrado-Amazonian Maranhense Forest

Diego Freire Almeida[1]; Wilson Araújo da Silva[1]; Alinne da Silva[1]; Cristiane Matos da Silva[1]; Willian Araújo Cardins[1]
UEMASUL[1]

The study is carried out in the city of São Francisco do Brejão in the state of Maranhão, farm Monalisa. The property has an area of 740 hectares in its extension and is located in the ecotone Cerrado-Amazon forest. On the site the existence of two types of management for pasture, conventional pasture and another with a silvopastoral system, a type of agroforestry system. The objective of this work is to evaluate soil physical characteristics as a function of land use change in the ecotone Cerrado-Amazonian forest of Maranhão. The collection of undisturbed samples for the evaluation of soil density and particle density was performed in two areas, in two random points, with 3 replicates, and 3 depths of 0 to 10 cm, 10 to 20 cm and 20 to 30 cm, using Kopeck's rings. For the analysis of soil density and particle density, a factorial experiment was used, evaluating the effects of grassland pasture and conventional pasture on the soil. As for the average of the treatments of the parameters were submitted to analysis of variance and compared by the test of Tukey to 5% of probability using the software ASSISTAT 7.7. The rings were weighed on a scale, obtaining the wet weight and, after that, they were conditioned in an oven with a temperature of 110 ° C for 24 hours, then they were weighed, determining the mass of dry soil for calculations of densities. The compaction index was determined on site using an impact penetrometer, at two random points in each area, at each point with three replicates. Regarding the soil density results, there were no significant differences between the evaluated depths for both evaluated areas. In the particle density there was a significant difference, where in the conventional pasture area in comparison with the wooded pasture presented higher density of particles. As a result, the compaction index values are higher for the conventional pasture area compared to the wooded pasture area. The conventional pasture area presented values of up to 20 dm^{-1} and the pasture was already up to 13 dm^{-1}. Considering the results obtained in the project, the wooded pasture the degree of compaction is smaller because of the intercropping of trees with the pastures, because it presented greater protection to the soil and that the lowest value also occurred in the density of particles, concluding that the area of conventional pasture is more compacted than the wooded pasture area.

(1498 - 2221) Soil precompression stress related to water meniscus forces

Paulo Ivonir Gubiani[1]
Universidade Federal de Santa Maria, 1000 Camobi, Santa Maria, 97105900, Brazil[1]

The soil precompression stress (σ_p) has been used as an estimator of the soil load bearing capacity, mainly indicating the maximum previous load applied on sol. The part of σ_p resulting from forces other than the external load applied on soil is little studied. The objective of this study was quantify the increase in σ_p caused by water meniscus forces. Samples of a Rhodic Hapludox (RH1: 14, 24, 62), a Rhodic Hapludox (RH2: 45, 20, 35) and a Typic Paleudults (TP: 64, 26, 10) were used (numbers in parentheses are the percentage of sand, silt and clay, respectively). The air-dried samples were milled with a porcelain pistil inside a porcelain bowl, for breaking aggregates as much as possible to remove mechanical resistance stored inside the aggregates. A set of ten samples for each soil were built just spilling the milled soil fraction into metal rings. All samples were water saturated by capillary rise during 48 h. From the ten saturated samples for each soil, two other sets with five samples each one was randomly prepared. In one of these two sets, it were applied three sequence of drying followed by saturation (D-S). Finally, all samples (set with and without D-S sequence) were transferred to a pressure plate extractor to standardize the matric suction at 33kPa. The uniaxial static compression test was performed applying successively loads (σ) of

12.5, 25, 50, 100, 200, 400, 800 and 1600 kPa, and σ_p was determined according to Casagrande procedure. The σ_p of samples without D-S was 35, 50 and 46 kPa for RH1, RH2 and TP, respectively. These values reflect mainly the mechanical resistance stored inside the aggregates. The sequence of D-S increased σ_p up to 75, 92 and 60 kP for RH1, RH2 and TP, respectively. Thus, water meniscus forces increased from 14 to 42 kPa the σ_p, indicating that a large part of σ_p can be a result of forces other than the external load applied on soil.

(7477 - 1670) Soil resistance to penetration in sugarcane area as a function of different soil tillage

Tiara Moraes Guimarães[1]; Ciro Pozzi Garcia[1]; Ariani Garcia[1]; Jorge Martinelli Martello[1]; Erilene Romeiro[1]; Juliano Carlos Calonego[1]; Carlos Alexandre Costa Crusciol[1]
Universidade Estadual Paulista[1]

The increasing adoption of mechanical harvesting of sugarcane and an inadequate traffic of the machines, through the mechanized operation in the field, has significantly increased soil compaction. However, a recent technique of management of agricultural mechanization, called traffic control, represents an interesting alternative for the cultivation of sugarcane, since it separates the traffic zones from areas where there is plant growth, concentrating the passage of tires in delimited lines, substantially decreasing the soil compaction at the plant site, with consequent increase of productivity and longevity of the sugarcane. The objective of this experiment was to evaluate the soil compaction as a function of soil tillage system. The experiment was installed in April, 2015 in a clay soil at Macatuba, SP, Brazil. The experimental design was a randomized complet blocks with four replications. The treatments were constituted by two systems of soil tillage: conventional soil preparation (CSP) - standard / control and deep soil tillage (DST). The CSP system was characterized by the tillage with disk harrow, chiseling and disk harrow again. In the DST was used deep tillage with rod up to 0.80 m and rotating hoe. The plant growth zone are 1.20 m wide, with the two planting grooves 0.9 m apart, located in the center of the revolved area. After planting and immediately after the first harvest, the soil resistence to penetration was measured by means of the impact penetrometer, Stolf model. The samples were taken based on a perpendicular transept of 1.20 m, between the center of the plant growth zone and the center of the traffic zone. In this transept, 9 points distanced in 0.15 m of each other were evaluated. With this, results were obtained both in the non-traffic area and in the traffic area. A compaction was observed mainly in the traffic zones of machines for both system of soil tillage with a more significant value in the layer of 20 to 60 cm depth. The DST presented values lower than the CSP in the region of the plant growth zone (0 to 45 cm), the most evident differences being located mainly in the intermediate depths (between 20 to 50 cm of depth). Inside the plant growth zone, the contrasts between resistance to penetration values were three times higher in CSP than DST, with values above 2.5 MPa, values that are restrictive to the root development of the crop.

(6884 - 2737) Soil resistance to penetration of an Plintossolo Argilúvico under different management systems

Gustavo Cassiano da Silva[1]; Otavio Silveira Gravina[1]; Rafael Almeida Ferreira[1]; Lucas Pergentino Brandão[1]; Djavan Pinheiro Santos[1]; Thiago Pereira de Souza[1]; Angélica Pires Batista Martins[1]; Fillipe de Paula Almeida[1]; Vladia Correchel[1]; Glenio Guimarães Santos[1]
Federal University of Goiás[1]

The intensification of agricultural production systems has led to one of the main problems faced by farmers, soil compaction, since the use of increasingly large and heavy machinery can lead to changes in the structure, density, porosity, and infiltration of water content in the soil. Among the physical attributes of the soil that best portray the compaction is resistance to penetration (RP), as it has a direct relationship with soil density and plant growth. This study was carried out in the Araguaia Valley, in Luiz Alves city, state of Goiás, the soil was classified as Plintossolo Argilúvico, in the following systems: rice cultivated two years ago, without water blade (A2); rice for five years, with 27 cm of water blade (A5); rice for ten years, with 21 cm of water (A10); rice for fourteen years, with 5 cm of water blade (A14); kills with a 5 cm blade of water (M5). The resistance to soil penetration was determined using the Impact Penetrometer Model IAA / Planalsucar - Stolf, from the soil surface to the depth of 0.60 m. The initial evaluation of the data was done by means of descriptive statistics of the values obtained in the 30 points sampled, as well as the coefficient of variation and the 95% confidence interval. The intensification of the systems of cultivation A2 showed higher values of resistance to penetration at depth 0-0.20 m, in this system, there was no water slide, evidencing that the resistance to penetration can be influenced by soil moisture, that is, the lower the humidity, the greater the soil resistance to penetration. At the depth of 0.20-0.40 m, both A2 and A14 obtained higher values of resistance to penetration between the evaluated systems, which indicates that with the passage of the time of handling, even areas with water slides the resistance of the only tends to increase. At depth 0.40-0.60 indicated lower soil resistance to penetration at M5, and the other systems at these depths were not statistically different. The systems of rice cultivated two years ago without a water slide and rice fourteen years ago, with 5 cm of water blade, have higher values of resistance to penetration in the 0-0.20 and 0.20-0.40 layers of the ground.

(2102 - 1412) Soil structural state in continuous cropping systems

De León Gastón[1]; Pérez Bidegain Mario[2]; Terra José[3]; Ernst Oswaldo[2]
Universidad de la República. Centro Universitario Región Este[1]; Universidad de la República. Facultad de Agronomía[2]; Instituto Nacional de Investigación Agropecuaria[3]

Soil compaction in no tillage systems is a degrading process that reduces crop productivity and soil quality. However, methodologies to analyze soil compaction at field scale are scarce. The “Profile Cultural” (PC) methodology is based on visually identifying structures with varying compaction status. In this study, we used the PC to evaluate soil structure of a Uruguayan Typic Argiudoll after 14 years of continuous cropping. Two different continuous cropping systems (treatments) were analyzed; soybean (SB) and sorghum (S). In each pit (n=2) we quantified the proportion of the surface occupied by PC structures: Δ, Φ, Γ and P. On each of those structures we measured soil strength (SS), soil bulk density (BD), soil total porosity (TP), soil structural porosity (SP), and soil textural porosity (TexP). Additionally, root frequency (RF) was evaluated on a grid on each pit. Field work was done in May-June 2015, after crop harvest. Treatment effect on the proportion of PC structures was analyzed using the X^2 test (α=0.05). Within treatments, we compared SS, BD, TP, SP, TexP values of the structures (Δ, Φ, Γ, P) using one-way ANOVA (α=0.05). Among treatments, we compared total SS, BD, TP, SP, TexP, those means were calculated as the weighted average of the values on each structure. We did not found treatment effect on the proportion of structures; 63% the Φ structures, 19% of Δ, and 18% of P. The type Φ structures are characterized by the development of porosity caused by alternation of wetting and drying cycles. The Δ are compact structures

related to traffic. The P are surface structures which have horizontal porosity. Interestingly, in this systems of continuous agriculture in clay loamy soils the presence of P structures was verified. The SS showed significant differences in the structures being the compact zones (Δ) more resistant to the shear stress. SS value in Δ zones it was 179, 1 KPa and 179. 3 KPa for SB and S, respectively. SS value in Φ zone it was 74.2 KPa and 137.1 KPa for SB and S respectively. Soil BD was not affected by treatments (1.36 $Mg.m^{-3}$ and 1.42 $Mg.m^{-3}$ for SB and S, respectively). TexP was constant within the soil profile (38.1 % and 35.5 % for SB and S, respectively). Treatments did not affect RF. Applying the PC we found evidence of compact structures, regardless of the crop used. Therefore, continuous cropping systems may compromise soil long term sustainability, and other management options, besides no tillage, must be included.

(1225 - 1460) Soil tillage effects on some soil physical properties in a lowland soybean cropping system

Vinícius Pedron[1]; Robson Giacomeli[1]; Leonardo Chechi[1]; Reimar Carlesso[1]; Mirta Petry[1]; Bernardo Dalmolin[1]; Diego Londero[1]; Jéssica Maiara Iensen[1]; Felipe Sarmento[1]
UFSM[1]

The lowlands located in the Rio Grande do Sul State Southern region correspond to nearly 4.4 million ha, usually cropped with sole rice and presenting a compacted layer between 10-20 cm deep and textural B horizon, that when not well managed leads to poor aeration, low hydraulic conductivity and low water holding capacity. Crop rotation appears as an excellent soil management alternative to improve soil physical quality and to diversify the soil biota. However, to grow dryland crops in these soils, it is necessary to study alternatives to reduce the environment stress to plants caused by poor soil conditions. In this way, the present study aimed to study the effect of different tillage practices on some soil physical properties in a lowland cropped with soybean. The study area is located at the Federal University of Pampa, Campus Itaqui. The experiment was carried out in the 2016/17 growing season, applying a randomized block design, with three replications. The treatments were composed by: no-tillage, where no soil disturbance was applied after a soil chiseling realized in August, 2016, intending to begin a no-till system; conventional tillage performed by two times disking at 10 cm depth, plus soil leveling 15 days before sowing; no-tillage with raised seedbed (built in the winter of the first year, with a 0.15 m height in relation to the soil level, and 1.0 m wide); and conventional tillage with raised seedbed, built after the tillage, 15 days before sowing. After the soil chiseling in early August, a cover crop was implanted, and on November 8th, 2016 soybean was sown. Soil physical properties were monitored two months after soybean sown in the 0-5, 5-10 and 10-20 cm depth layers. The properties measured were: bulk density, total porosity, macroporosity, microporosity and penetration resistance, using 71.2749 cm3 soil core samples and applying -100kpa soil matric potential. The results showed that no-till with raised seedbed obtained the least total porosity and greatest macroporosity of 43.59 and 16.56%, respectively at 5-10 cm depth layer while the microporosity was greater for both conventional tillage, with and without raised seedbed. The penetration resistance was greater for conventional tillage at 0-5 and 5-10 cm depth layers, and the conventional tillage with raised seedbed treatment at 10-20 cm depth layer. No-tillage with and without seedbed raised promoted improvements in soil physical properties compared to conventional tillage treatments.

(6986 - 1751) Soil water storage and water available in irrigated wheat crop in the cerrado

William Fenner[1]; Tonny José Araújo da Silva[1]; Edna Maria Bonfim-Silva[1]; Thiago Franco Duarte[1]; Thiago Henrique Ferreira Matos Castañon[1]; Vinícius Melo da Silva[1]
UFMT[1]

Given the current dynamics of irrigated agriculture associated with meteorological instabilities during the cropping, the monitoring soil moisture and storing water are essential for productive stability and rationalization of water and monetary resources. Thus, the objective was to determine the water storage in irrigated wheat cultivation (*Triticum aestivum* L.), BRS 254 variety in Cerrado Oxisol. To this end, 12 access tubes were installed at a depth of 0.6 m to read the water content of soil using a capacitance probe model Diviner 2000. The access tubes were installed after sowing the wheat, in the central line of each plot and the readings were performed daily between 8:00 am and 9:00 am. For the storage, the effective depth of the root system of wheat (0.3 m) was considered. Using the soil water retention characteristic curve, were obtained the values of moisture equivalent to the field capacity and the permanent wilting point and, sequentially, the water available for the wheat crop was determined. The amount of water available for the crop is 43.08 mm for the considered depth. The average storage until maturation of the culture was 63.69 mm.

(7102 – 2127) Space correlation of soil texture in archaeological black land area under different uses in south of amazonas

Luana Celestino Calista[1]; Milton César Costa Campos[1]; Elilson Gomes de Brito Filho[1]; Wildson Benedito Mendes Brito[1]; Thalita Silva Martins[1]; Lucas Eduardo Realto da Silva[1]; José Maurício da Cunha[1]; Marcelo Dayron Rogrigues Soares[1]; Francisca Xavier Quintino Neta[1]; Ludimila Souza Oliveira[1]
Federal University of Amazonas[1]

The Amazon region has mostly low fertility soils, but with soils called black archeological lands (TPA), usually presenting the sand fraction as dominant, besides, these soils present high natural fertility and physical potential in relation to the adjacent soils. a study of its texture is of great importance to obtain information and to relate its characteristics. The objective of this work was to evaluate the spatial variability of texture in black archeological areas under different uses in the southern region of Amazonas. The study was carried out in the city of Apuí, where a sample grid of 88x64 m was established in the study area and the soils were sampled at the crossing points of the mesh, with regular intervals of 8 m, totalizing 88 sample points. Soil samples were collected at a depth of 0.0-0.5 m. The granulometric analysis was performed by the pipette method. Data were submitted to descriptive and geostatistical statistics. When the average of the textured attributes was evaluated, it was possible to observe the domain of the silt fraction, in the areas of cocoa and coffee, which corresponds to more than half of the granulometric composition justified by the by the high degree of weathering of these soils. In the pasture area, dominance of the sand fraction was observed, this soil tending the sandy texturewhere, the greater concentration of sand between the granulometric fractions is a common characteristic of the TPA's that can be attributed to the formation of stable organic - material size equivalent to sand, it is clear lycombining the practice of the use of fire and depositing organic material by Native Americans occupying these sites. Regarding geostatistics, the models that best fit the data were exponential and spherical, according toCambardella et al. (1994) for the classification of the degree of spatial dependence

(GDE%) , it was observed that in the areas of cocoa and coffee all variables presented a strong degree of spatial dependence for sand, silt and clay, with values close to zero , the highest range values were found in the pasture area and the smaller ones in the area under coffee. By observ study or that cocoa areas, coffee and pasture respectively presented the average textures, sandy and clay and the area under pasture management, was the most differed with respect to cocoa and coffee areas with higher reach (a) and lesser degree of spatial dependence (GDE).

(3126 - 2185) Space variability of aggregate stability only in arqueological black land area (tpa) with cocoa cultivation in south of amazonas

Estefani de Souza Oliveira[1]; Anderson Vieira Rodrigues[1]; Milton César Costa Campos[1]; José Maurício da Cunha[1]; Elilson Gomes de Brito Filho[1]; José Igor Silva Praça[1]; Ludmilla Colares Rodrigues[1]; Carlos Henrique Gima Relvas[1]; Sabrina Isabela da Silva Fernandes[1]; Elyenayra Nogueira Pinheiro[1]

Federal University of Amazonas[1]

The soils of Amazonas are considered as little fertile soils presenting high levels of aluminum and low CTC (cation exchange capacity), presenting good physical fitness for handling . On the other hand, in Amazonas there are soil patches where by the anthropic action of the pre-Columbian peoples who used them for their daily use, they modified these areas and made these soils with fertile potential higher than adjacent soils . The objective of this work was to verify the spatial variability of soil aggregate stability in archeological black earth (TPA) area with cocoa management in southern Amazonas. TPA area with cocoa cultivation is localized in Apuí in the Amazon's ul state, a sampling this mesh 80 x 56 m and regular spacing of 8 m where soil samples were collected at depths was established 0,00- 0.05; 0.05-0.1% ;0.10-0.20 and 0.20-0.30, making 352 samples with each point being georeferenced with GPS. After drying and dewatering, the stability analysis of aggregates was performed and the results were calculated the Geometric Mean Diameter (DMG) and the Weighted Mean Diameter (WMD). After obtaining the data, these were analyzed through descriptive statistics and geostatistics . By the descriptive statistics it was observed that the values of DMG varied between 2.50 and 2.67 mm and there was reduction according to the depth increase. The DMP varied from 2.50 to 3.12mm for the 0.10-0.20m layer and 0.00-0.05m respectively. The values of aggregates in the class> 2mm ranged from 72.94 to 88.84% and the values also decreased according to the depth increase. However, the values of aggregates in the class <2mm ranged from 11.15 to 27.06% and, unlike DMG and class> 2mm, increased values according to depth increase. By the normality test, all variables were significant at 5% probability. In relation to geoesthetics, the model that best fit the data was the exponential for all attributes at all depths, according to the classification of Cambardella et al. (1994) for the degree of spatial dependence (GDE%) of attributes in strong, moderate and low, the attributes varied all around zero except for the unanimous class of aggregates in the layer of 0.20-0.30m that presented value of 15.33% , in terms of the range this presented different values among the attributes, being around 11.00 and 53.10m . Thus by GDE% the attributes had strong spatial dependence and by the low reach spatial variability

Soils are indispensable to life, as they have fundamental chemical, physical and biological properties for agricultural sustainability, as well as providing environmental and ecosystem services. Thus, the physical and chemical attributes of Red Oxisols were obtained and spatialized by geostatistical, remote sensing and geoprocessing techniques. For this, 18 samples of deformed and undeformed soil were collected from 0.0 to 0.2m depth to evaluate the land use capacity for agricultural activities in the Caçús basin river in southern Minas Gerais, Brazil. The climate of the region is Tropical Mesothermic with mean precipitation of 1,500 mm/year. The region is characterized by the transition between Atlantic Forest and Savanna biomes but with only 10% of native forest remnants. The geological substrate is dating from Proterozoic with gneissic and granulitic rocks, and have relief slightly undulated to undulated where slopes between 2 to 20% prevail and Red Oxisols dominate. The distribution of the attributes of soil pH, aluminum toxicity, organic matter, cation exchange capacity effective and potential, soil texture, clay flocculation, geometric mean diameter and soil permeability to water were used to evaluate the hydrosedimentological flow. It was identified out high concentrations of organic matter associated with fragments of native forest. In general, the basin presents low base saturation, due to the low natural fertility of the tropical soils. The results point the pastures and crops with tillage are poor in organic matter and have difficulty in maintenance of capacity of cation exchange when they do not were previously fertilized. In these areas when they are close to streams and in high slopes, they should be destined to the reconstitution of the native forests, to protect the soils against water erosion. In the downstream area, the acid pH, increase of cation exchange capacities, and increment small grains, result of deposition the particles by hydric erosion and are regions susceptible the contamination. Thus, this work detected priority areas for to improve agricultural management practices and for recovery of degraded areas. Alternatives such as integrated crop, no till, pasture rotation, and sustainable forestry systems should be used to combine production and conservation of natural resources. Thus, the geostatistics and geoprocessing techniques were efficient for a sustainable evaluation of soils and management practices.

(5796 - 2055) Spatial variability of hydraulic properties in two contrasting soils under maize monoculture

Oscar Seguel[1]; Nicolás Riveras[2]; Carla Silva[3]; Osvaldo Salazar[3]

Universidad de Chile, Fac. de Ciencias Agronómicas. Santa Rosa 11315, casilla 1004, Santiago, Chile (oseguel@uchile.cl)[1]; Universidad de Chile, Escuela de Postgrado. Santa Rosa 11315, casilla 1004, Santiago, Chile.[2]; Universidad de Chile, Fac. de Ciencias Agronómicas. Santa Rosa 11315, casilla 1004, Santiago, Chile[3]

Soil compaction changes its porosity and structure, which affect the hydraulic conductivity (K) as a highly variable property; nevertheless, in soils under tillage, a dependence of K due to traffic is expected. In the present work, it was considered that the tillage is a homogenization factor of K. To verify this, a previous characterization of penetration resistance (PR) was carried out in two soils (corn fields) with contrasting textures (San Luis, sandy loam Entisol, and Caleuche, clay Alfisol), identifying zones of high PR (close to 2.0 MPa at 0-10 cm) and low PR (<1.0 MPa at 0-10 cm). In each case, in-track and out-track positions were identified and the bulk density (Db) and the hydraulic conductivity (K) were measured, both on surface and in depth (20 cm). The Db did not show sensibility to the spatial components, except in the low PR site of the clay soil, with significant higher values in depth. The sandy loam soil showed an increase of K in depth in the PR site (4.47 cm h^{-1} at surface and 8.89 cm h^{-1} at 20 cm depth), due to the persistence of the porosity because of the structure was not altered with the tillage; in the clay soil was identified a low stability at surface and a plough-pan distributed heterogeneously throughout the field, with low K values in all cases (<2.0 cm h^{-1}), which leads to unfavorable conditions for the crops. Based on the results it is concluded that the conventional tillage affects the soil structure, homogenizing the porous system. Thus, there is a strong spatial dependence in depth, but not in relation to the wheel-track, of properties such as penetration resistance, bulk density and hydraulic conductivity.

(7391 - 2177) Spatial variability of stability of soil aggregates in archaeological black land area (tpa) with coffee cultivation in south of amazonas

Francisca Xavier Quintino Neta[1]; Milton César Costa Campos[1]; José Maurício da Cunha[1]; Elilson Gomes de Brito Filho[1]; Elyenayra Nogueira Pinheiro[1]; Carlos Henrique Gima Relvas[1]; Ludmilla Colares Rodrigues[1]; Sabrina Isabela da Silva Fernandes[1]; José Igor Silva Praça[1]; Luana Celestino Calista[1]

Federal University of Amazonas[1]

The Black Indian Lands are soils that exhibit dark coloration, anthropic horizon with presence of lithic and / or ceramic artifacts besides high fertility. Several studies indicate that the TPAs are of anthropic origin from pre-Columbian peoples; that is, it would be the result of old indigenous settlements. The evidences of the passage of the human being through these areas are the very elements that were part of the daily life of the indigenous peoples of the Amazon. Therefore, the objective of this work was to verify the spatial variability of the stability of aggregate stability in black archeological land area with cocoa cultivation in southern Amazonas. The study area is located in the region of Manicoré, in the South of Amazonas, where an area with Archaeological Black Terra (TPI) was established, with coffee cultivation , with a sample mesh of 80 x 56 m and regular spacing of 8 m where samples were taken at depths of 0.00-0.05; 0.05-0.10 and 0.10-0.20 m, making 264 samples with each point being georeferenced with GPS.After drying and destorroadas performed to aggregate stability analysis and the results obtained were calculated the average diameter Ge and knitting the m (DMG) and weighted mean diameter (SMD). After obtaining the data, these were analyzed through descriptive statistics and geostatistics. By the descriptive statistics the values of DMG and DMP varied between 2 and 3, and DMP presented values greater than DMG for all depths, this is probably because the DMG presents an estimate of the class of aggregates of greater occurrence, whereas the DMP increases as the percentage of large aggregates increases. The coefficient of variation (CV%) according to Warrick and Nielson (1980) classification for variability of the soil variables showed that the attributes presented low variability for WMD except for the last depth, moderate variability for DMG, low and moderate variability for class> 2mm and, high variability for class <2mm. By geostatistics, there was predominance of the exponential model, by the evaluation of the degree of spatial dependence (GDE%) all variables presented a strong degree of spatial dependence with. The range varied between 11.80 m and 28.50 m being larger than the spacing between sample points, and smaller than the maximum length limited by geostatistical analysis, thus justifying its degree of spatial dependence. Thus, due to low range values and strong GDE%, the variables presented low spatial variability.

(8425 - 2649) Specific surface area for the development of pedotransfer functions and their use in the estimation of water retention and availability in soils of the State of Santa Catarina.

Diego Bortolini[1]; Jackson Adriano Albuquerque[1]; Luana da Silva[1]; Juliano Silva Teles[1]

UDESC[1]

The specific surface area of the soil (SSA) is directly related to the retention of water, nutrients and other molecules. Therefore, this property has potential to be used in pedotransfer functions to estimate retention and availability of water in soils. The objective of this work was to determine the specific surface area of soils of the State of Santa Catarina and to use it as a predictor variable of the field capacity (FC), permanent wilting point (PWP) and available water (AW) in the soil. The samples of the horizons of 37 soil profiles of the State of Santa Catarina were used. The database is composed of the following properties: total clay (0-0.002 mm), silt (0.002-0.053 mm), very fine sand (0.053-0.106 mm), fine sand (0.106-0.25 mm), average sand (0.25-0.5 mm), coarse sand (0.5-1.0 mm), very coarse sand (1.0-2.0 mm), water retention curve in the soil (points: total porosity, 1, 6, 10, 33, 100, 500 and 1,500 kPa), available water, total organic carbon content, SSA, FC, PWP and AW. The analyzed variables were submitted to normality analysis by Kolmogorov-Smirnov, indicating that they didn’t present normal by performing Spearman correlation analysis. The FC, PWP and AW were estimated by two models; Model 1: clay, silt, organic carbon and specific surface área; Model 2: five classes of sand, silt, organic carbon and specific surface área, through multiple linear regressions, artificial neural networks (ANN) and regression trees (RT). Pearson's coefficient of determination (R2) and root mean square error (RMSE) were used as statistical indicators to evaluate the predictive capacity of the models. The use of ASE to develop pedotransfer functions generated estimates with high predictive capacity, mainly for ANN and RT for the soils of the State of Santa Catarina. The use of five grades of sand has similar results in the estimation of water retention and availability compared to the use of clay contente. In general, the estimation has better statistical indicators in the surface horizons, for model 1 (clay, silt, organic carbon and specific surface area) and regression trees, for estimating the field capacity, permanent wilting point and water available.

Keywords: available water, artificial neural networks, Specific surface área.

(8338 - 1323) Susceptibility to erosion of soils in the Planalto Serrano Catarinense under forest cultivation.

Leonardo de Assis Lopes[1]; João Cláudio Teodoro Turtt[1]; Carla Eloize Carducci[1]; Kaliana Gottschalk de Freitas[1]; Joyce Castro Xavier[1]; Felipe Ceccon[1]; Luiz Antonio Assis Lima[1]

Universidade Federal da Grande Dourados[1]

The erodibility is a complex attribute and intrinsic to each soil which expresses the greater or lesser susceptibility of the soil to erosive process. Represents the integrated effect of processes that govern the dynamics of water and soil resistance to breakdown and transport of particles. The objective of this work was to evaluate the erodibility of two classes of soils under experimental forest plantations in the Planalto Serrano, State of Santa Catarina UFSC/Curitibanos, SC. Deformed soil samples were collected in the horizons (Hz) A and B of 14 sampling points distributed in the third strand (upper, middle and lower), referring to the Oxisols and Alfisols cultivated with pinus, eucalyptus, Araucaria, Bamboo and Liquidambar (± 4 to 6 years). Were determined the particle size distribution and water dispersible clay (ADA) by the method of the pipette, made up of clay (AF), silt/clay ratio, textural relationship (RTHzB/A), and the estimators of soil erodibility index of Boyoucous (IB) and flocculation index (IE), in triplicate. The experiment was carried out in a completely randomized design and evaluated the interactions between the attributes. All soils were classified as clayey and very clayey with average clay content LVAd, LVd, LBd and SXd (580, 425, 545, 450 g kg-1 in Hz A, respectively). The soils present in the region of the Planalto Serrano have recently genesis (RT > 1.2) even the Oxisols (RR 0.99). The Dystrophic Red-Yellow Latosol (LVAd) B horizon although young presented higher IE, AF and ADA (78%, 50% and 66%, respectively). The soil more susceptible to erosion in accordance with the IB was the Red-Yellow Latosol (LBd) on the horizon A, presenting 13% IF AND IB 0.41% and location in a bustling relief more and more resistant the dystrophic Red Latosol (LVd) in Hz A with IB of 1.35%, inserted in a relief softened with effective depth high and high content of clay, organic matter (37.24 g kg-1) and textural relationship of 1.28. The Sxe (Alfisols) presented high concentration of clay B horizon (> 550 g kg-1), located in continuous areas and flat, which reduces the incidence of erosion. Therefore, since the areas are used with forests of Pinus plants in the LVAd and LBd, araucaria, eucalyptus and liquidambar in the LVAd and bamboo in SXd low resistance to erosion of the LBd and SXd are compensated by the protection of residual plant material left on the soil with the performance of the forests and increase in organic carbon in the soil.

(5052 - 278) Tensile strength and friability of soil aggregates cultivated with organic strawberry under no-tillage

Nádia da Silva Salatta[1]; Osvaldo Guedes Filho[1]; Camila Pereira Cagna[1]; Lucas de Oliveira Neves[1]; Daiane de Fátima da Silva Haubert[1]

Universidade Federal do Paraná[1]

Organic agriculture is an alternative to more sustainable agricultural production. No-tillage system is a soil management option to maintain its quality in organic production systems. The soil physical quality is commonly measured through the evaluation of properties related to shape and structural stability. The tensile strength of the aggregates is an indicator of the effects of management on the soil structural quality. The objective was to evaluate the tensile strength and friability of the aggregates of an Oxisol cultivated with organic strawberry under no-tillage. The study area has been cultivated with organic strawberry in the conventional tillage over 17-years. The organic production area was split in two parts for the experiment installation. An area in conventional tillage with shallow plowing of 0.15 m soil depth and another with no-tillage, which has soil cover and triannual crop rotation. The planting of strawberry seedlings was performed with a cutting tool for the hole opening. A year after the experiment installation it was collected ten soil blocks in each management system at 0.0 to 0.10 and 0.10 to 0.20 m soil depth. The aggregates size used in the tensile strength determination was 12.5 to 19 mm diameter. Tensile strength of the aggregates was measured through the penetrometer with penetration needle adapted. In each collected sample five replications were performed with 10 aggregates each. Soil friability was estimated by the variation coefficient of the tensile strength values. Tensile strength in the no-tillage system was significantly higher than in conventional tillage at 0.0 to 0.10 m soil depth. Soil friability in the conventional tillage was significantly higher than in no-tillage system at 0.0 to 0.10 m soil depth. For the 0.10 to 0.20 m soil depth there was no significant difference between the management systems for tensile strength and friability. By the analysis of the tensile strength and friability, the no-tillage system proved to be a good option for improvement and maintenance of soil physical quality in the organic production system.

(1121 - 3098) Tensiometer with reading systems in the estimation of soil hydraulic parameters

Alcione Guimarães Freire[1]; Thiago Leite de Alencar[2]; Raimundo Nonato de Assis Júnior[3]; Jaedson Cláudio Anunciato Mota[3]; Francisco Ítalo Fernandes de Oliveira[1]

Federal Rural University of Pernambuco[1]; Federal Institute of Education, Science and Technology of Piauí[2]; Federal University of Ceará[3]

The tensiometer presents itself as an excellent instrument to monitor soil solution drainage, for measuring soil water energy in situ. However, measuring this variable requires a tensiometer reading system sensitive enough to accurately record the matric potential. Hence, an instantaneous profile-type experiment was conducted in the field, to measure the potentials within a moisture range from saturation to field capacity. After that, matric potential, soil moisture, total potential gradient, flow density and hydraulic conductivity were calculated and van Genuchten equation parameters were estimated through inverse modeling. This study aimed to test two alternative systems to the mercury manometer to quantify the soil water matric potential and observe their implications in the estimates of soil moisture, soil water flow density and hydraulic conductivity as a function of soil moisture. In addition, the study also aimed to evaluate soil hydraulic parameters, obtained by inverse modeling, based on the matric potentials from each reading system. Bourdon pressure gauge replaces the Hg manometer in the measurement of soil water matric potential within the moisture range from saturation to field capacity; alternative systems led to underestimation of flow density and hydraulic conductivity as a function of soil moisture and overestimation of hydraulic gradient and, therefore, are not recommended for the estimation of these hydraulic parameters; tensiometer reading systems converged in the estimation of hydraulic parameters by inverse modeling.

(2727 - 2729) The change of kaolinite's physical properties after cultivation of Bacillus sp.

Bykova Galina[1]; Shein Evgeny[1]; Milanovskiy Evgeny[1]; Verkhovtseva Nadezda[1]; Pashkevich Elena[1]; Khaydapova Dolgor[1]

Lomonosov Moscow State University[1]

The influence of microorganisms on the soil properties is hard to

underestimate. They affect the soil's solid, liquid and gas phase, cause the destruction and transformation of minerals, formation and preservation of the organic matter, changes of the pore solution. They are able to participate in the formation of soil structure via gluing of the soil particles by their metabolic products. The adsorption of microorganisms and their metabolic products on the surface of mineral particles can change their wettability. The aim of this work is the studying of the microbiological modification of the one of the main soil primary mineral - the modification of the surface of the kaolinite clay by the pure culture of bacteria (Bacillus velezensis), which can remove silicon and potassium from the minerals. Within two months microorganisms was cultivated in liquid culture medium the following composition: sucrose - 0, 75 g/l; $(NH_4)_2SO_4$ - 0.15 g/l; Na_2HPO_4 - 0,30 g/l; $MgSO_4$ - 0,075 g/l; $FeCl_3$ – traces; clay mineral - 5 g/l. In this breading ground the clay mineral was the only source of potassium. After incubation, the mineral was separated from the liquid medium and dried. Properties of the mineral were determined after 10, 20, 30, 40, 50 and 60 days of cultivation. Assessment of the rheological characteristics was performed in the mineral suspension with the modular compact MCR rheometer (Anton Paar, Austria). Microaggregate composition of the clay mineral and its particle size distribution was investigated by laser diffraction method (Microtrac Bluewave SDC, United States). To assess the wetability of the surface the sessile-drop contact angle was determined (DSA-100, Krüss, Germany). After two months of culturing the bacteria in a clay medium, where the clay minerals were the source of potassium, the surfaces properties (the contact angle), the microaggregate composition and the rheological characteristics of clay mineral were changed. Obtained data have shown an increasing of viscosity of suspension during the cultivation in comparison with the control sample and the pure mineral. There was the increasing of the content of microaggregates with diameter greater than 50 µm during the incubation. The influence of Bacillus sp. on the wettability of the mineral surface was determined.

(4587 - 3094) The role of biopores to reduce the mechanical impedance to soybean root elongation

Nayara Caroline Majewski Ulbrich[1]; Moacir Tuzzin de Moraes[2]; Rafael Soriani[3]; Julio Cezar Franchini[3]; Henrique Debiasi[3]
University of Parana[1]; University of Sao Paulo[2]; Embrapa Soja[3]

The presence of biopores and cracks in structured soil layers under no-tillage may reduce the soil strength to soybean root penetration. We aim to determine the root elongation rate in structured and packed soil sample to quantify the biopores effect to soybean root growth. Soil compaction levels of a Rhodic Eutrudox were simulated at the field (structured soil) and in the laboratory (packed soils). Undisturbed soil cores were sampled from topsoil (0-10 cm) in four soil compaction levels (chiselled soil; no-tillage; and both compacted with 10 tractor passes), with nine replicates. Additionally, six compaction levels (0.8; 0.9; 1.0; 1.1; 1.2; 1.3; and 1.4 Mg m^{-3}) were produced compacting disturbed soil samples into cores (10 cm height and 5 cm diameter), with six replicates. Soil bulk density, macroporosity and penetration resistance were measured using these samples. Soybean seeds (BRS 1010-PRO) were incubated at 25^{o}C for 72h in a germination chamber. Resulting soybean seedlings were transplanted into both structured and packed soil cores, previously saturated and equilibrated at a matric potential of -6 kPa, and then maintained at 25^{o}C for 96h in the germination chamber. Length of tap root was measured with a digital pachymeter. Biopore effects on soybean root growth were analysed taking into account the relation of root elongation rate obtained in undisturbed or remoulded soil samples vs physical properties. Penetration resistance was higher in packed soil at the same bulk density or macroporosity. However, in the same water contents, penetration resistance was higher in structured samples. For similar values of bulk density, macro- and total porosity, soybean root elongation rate was larger in structured than remoulded samples, proving the key role played by soil structure and pore quality on root growth. The relationship between root elongation rate and soil penetration resistance was described by an exponential negative function regardless of soil structure. Undisturbed cores taken from chiselled or trafficked plots yielded similar soybean root elongations rates compared do remoulded cores with similar bulk densities. In contrast, soybean root elongation rate was increased 58% in undisturbed soil samples collected from no-tillage plots compared to remoulded cores with the same degree of compaction. The presence of biopores and continuous pores in no-tillage increases soybean root elongation rate due to reduction of mechanical stress to root growth.

Luiz de Camões, 2090, Conta dinheiro, Lages, Santa Catarina, 88520000. Brasil (alvaro.mafra@udesc.br)[7]

The State of Santa Catarina is the largest national producer of onion, where cultivation is still carried out, through the conventional tillage system (CTS), which is characterized by excessive soil disturbance, resulting in physical, chemical and biological soil degradation. One way to alleviate this problem caused by CTS can be obtained using the no-tillage system (NTS). The objective of this work was to quantify total organic carbon (TOC) and total nitrogen (TN), soil aggregation index and mass distribution of the aggregates of a Humic Distrudept under onion culture systems in succession or crop rotation. The experiment was implemented in 2011 and the treatments used were: T1 - onion/corn succession in NTS; T2 - commercial rotation with winter cover and biennial onion in NTS; T3 - corn/winter grasses rotation and annual onion in NTS; T4 - legume succession of summer and annual onion in NTS; T5 – grasses rotation of summer/winter and annual onion in NTS; T6 - legume summer/winter grassy succession and annual onion in NTS; T7 – onion/corn succession in CTS; T8 - consortium of summer covers plants and annual onion in NTS. In August 2016, the soil was collected and the soil aggregation indexes were determined: weighted average diameter (WMD) and geometric average diameter (GAD) of the aggregates, respectively; distribution of macro, meso and microaggregates masses; as well as the TOC and

TN contents in the layers of 0-5, 5-10 and 10-20 cm. The treatments T1 and T7 presented lower TOC (0-5 cm), lower WMD and GAD (0-5 cm) and lower NT (10-20 cm) contents compared to the other onion culture systems. The treatment T8 favors the formation of stable macroaggregates, with higher values of WMD and GAD in depth (10-20 cm). The use of cover crops in winter or summer in the treatments T2, T3, T4, T5, T6 and T8 favors the formation of stable macroaggregates in comparison to treatments T1 and T7, which do not use cover crops in winter and summer.

(1404 - 2061) Ultrasonic energy in the stability of the aggregates of oxidic Oxisols with intensive cultivation and irrigation

Marcel Thomas Job Pereira[1]; Raphael Bragança Alves Fernandes[1]; Maurício Paulo Ferreira Fontes[1]; Teógenes Senna de Oliveira[1]

Federal University of Viçosa[1]

Soil, when subjected to conventional intensive crops, tends to lose its original structure. The objective of this study was to evaluate the stability of aggregates of Red-Yellow Oxisols submitted to long periods of intensive cultivation and irrigation, from the mesoregion of Rio Paranaíba, Minas Gerais, Brazil. Samples of 0.1 to 0.2 m were collected in areas under native vegetation and with horticulture cultivation in different times of use, characterized by the intensive use of machines and implements, inorganic fertilizers, and center-pivot irrigation. The data were analysed using a completely randomized experimental design, arranged in factorial scheme (7x7), corresponding to the times of use (1; 17; 22, 28, 32 and 43 years) + native vegetation (Cerrado) and times of sonication (0; 15; 30; 60; 120; 240; and 480 seconds) with three replicates. First, samples of 5 g of 2-4 mm aggregates were pre-wetted (sprayed) with deionized water and allowed to stand for 2 hours. Subsequently, the samples were transferred to a beaker of 250 mL, completing the beaker with 200 mL of deionized water (soil:water ratio of 1:40). They were then sonicated with ultrasonic probe (Sonics Vibracell, model Ultrasonic processor 750 Watt operating at 20 kHz), applying the calculated energy of 0,0; 3.5; 7.0; 14.0; 28.0 56.0; and 112.0 J mL^{-1}, at the amplitude of 60% and calibrated power of 46.67 W. Finally, the dispersion indices were normalized, and from the relationship between the parameters of the regression equation (b/a) the disaggregation index was calculated. The results were submitted to analysis of variance, with the comparisons between the intensive use by the Scott-Knott test and the sonication times by regression, both at 5% probability. The depletion of the significant interaction indicated that, at each applied energy level, the lowest rates of soil disaggregation were observed under native vegetation (0.13), while in those with only one year of cultivation the highest index was observed (0.33). Meanwhile, cultures of 43, 32 and 28 years presented higher disintegration rates (0.30, 0.27, and 0.28, respectively) when compared to the use times of 17 and 22 years of cultivation (0.19 and 0.24, respectively). The results observed for the first year of cultivation led to the hypothesis that, with a time of use, there is a process of selection of aggregates by the stability, but the results indicated that soil aggregation is being compromised with the time of soil use.

UFPE[1]; UFRPE[2]; EMBRAPA[3]

Physical, chemical and mineralogical characteristics of tropical soils influence their hydro-physical behavior, which is different from that of soils of temperate climates. The mineralogy of tropical soils, mainly that of the clay fraction, makes soil texture the dominant factor to define their water retention properties. Çlay type is directly related to the specific surface of clay particles, their arrangement and pore distribution. Pernambuco State, located in Northeast region of Brazil, is the study area. In this State, there are many soil profiles that lack information related to field capacity. The objective of this study is to develop pedotransfer function (PTF) to estimate field capacity using physical and chemical analyzes of representative soil profiles from Pernambuco State. Data from 81 profiles comprising 285 horizons were used. PTF were developed by multiple regression techniques, using a forward stepwise procedure to select the best predictor from the proportions of sand (S, g.kg-1), silt (Si, g.kg-1) and clay (C, g.kg-1). The evaluation of adequacy of the PTF was based on the correlation coefficient (r) and Willmott index (d). The obtained PTF was FC (%) = 22.7625030 - 0.02136242S + 0.020114636C. The obtained PTF with r = 0.89 and d = 0.96 indicate its suitability to estimate field capacity using only soil texture. Results also showed that silt content has little influence in water retention of tropical soils, chiefly because of its low values.

Keywords: Soil texture, PTF, tropical soils.

(5383 - 2302) Are shallow impermeable layers beneficial for vegetation function in the semi-arid zone?

Alexandre Tadeu Brunello[1]; Carlos Alberto Nobre Quesada[2]; Tomas Ferreira Domingues[3]; Jonathan James Lloyd[4]

Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto (FFCLRP), Universidade de São Paulo (USP), 3900 Bandeirantes Avenue, Ribeirão Preto, 14040-901, Brazil, brunelloflorestal@gmail.com[1]; Instituto Nacional de Pesquisas da Amazônia, 2932 André Araújo Avenue, Manaus, 69060-001, Brazil, quesada.beto@gmail.com;[2]; Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto (FFCLRP), Universidade de São Paulo (USP), 3900 Bandeirantes Avenue, Ribeirão Preto, 14040-901, Brazil, tdomingu@gmail.com;[3]; Department of Life Sciences, Imperial College London, Silwood Park Campus, Buckhurst Road, Ascot, Berkshire SL5 7PY, England, UK, jonathan.lloyd@imperial.ac.uk[4]

This work develops upon the idea that - not only should root systems in precipitation limited ecosystems have shallower optimal rooting depths than vegetation types growing where water is more abundant – but also, due to reduced drainage losses, that shallow soils with an impermeable layer should actually be beneficial for vegetation function in water limited situations. Finding support for this hypothesis, we show that, - sampling over 20 sites across the Brazilian Caatinga (a semi-arid dry deciduous forest/shrubland vegetation type) - that sites with shallow impermeable layers (usually 0.5 to 1.0 m deep) typically support much higher vegetation biomass amounts than is found under the same climatic conditions but with no such impermeable layer present. This result is found to be consistent with predictions of ecosystem water use as obtained from a simple plant carbon-investment/water uptake trade-off approach and we would like to suggest, contrary to common assumption, that potentially deeper rooting zones are not always beneficial for

ecosystem function.

(1116 - 1599) Artificial neural networks to estimate soil moisture content under corn in integrated crop-livestock-forest system

Vinicius Marchioro[1]; Renan Francisco Rimoldi Tavanti[2]; Hugo Miranda Faria[1]; Daniel Dalvan do Nascimento[1]; Henildo de Sousa Pereira[1]; José Eduardo Corá[1]; Antônio Sergio Ferraudo[1]; Glauco de Souza Rolim[1]
Unesp Jaboticabal[1]; Unesp Ilha Solteira[2]

The soil water availability is one of the main factors that influence crop yield, and it is affected by climatological agents and soil management. Complex agricultural systems such as integrated crop-livestock-forest (ICLF), may contribute to increase the spatial variability of soil attributes and, consequently, affect soil water availability for plants. The objective of the present work was to test artificial neural networks to estimate soil moisture at different positions related to the forest component of an ICLF system. The study was developed at the Teaching, Research and Extension Farm of the UNESP campus of Jaboticabal (FCAV-UNESP). The forest components of the ICLF were composed by Urograndis I144 (*Eucalyptus grandis* (MAIDEN) W. Hill x *Eucalyptus urophylla* (MAIDEN) W. Hill) and the *Corymbia citriodora*, planted in double rows, at 20 m apart. An intercropped corn/brachiaria grass was planted between rows of the forest component, during the winter time. Soil moisture was monitored by tensiometers, installed at 0.2 m depth, every 3 meters, between the corn rows. Tension data obtained by the tensiometers were transformed into soil moisture content, using the van Genutchen model. Perceptron Multi-layered Artificial Neural Network was used to estimate soil moisture content, using average, minimum and maximum temperature, rainfall and number of days without rainfall. The neural network was composed of two hidden layers with ten neurons in each. Therefore, the neural network architecture was described as 5-10-10-1, using hyperbolic tangent activation function. The results showed that soil moisture content was accurately estimated using artificial neural networks (R = 0.98). Soil moisture content varied differently for soil water measuring positions and for the two forest component species. Dryer soil was observed closer to the forest component, independently of the specie, which resulted in lower corn yield. However, soil water content values were higher close (27.9%) or far (29.9%) from the plants of the *Corymbia citriodora,* compared to those soil water content values observed close (19.4%) or far (27.1%) from the plants of the Urograndis I144, probably due to the higher water uptake of the Urogradis specie, compared to those from the plants of the *Corymbia citriodora*.

(9210 - 1916) Characterization of soil physical attributes in degraded slope for revegetation purposes

Fábio Ribeiro Pires[1]; Ana Carolina Roos Pinheiro[1]; Henrique Capucho Justiniano dos Santos[1]; Larissa Pinto Seiberti[1]; Felipe Gabriel Cardoso Pires[1]; Paulo Roberto da Rocha Junior[2]; Amanda Duim Ferreira[1]; Adriano Alves Fernandes[1]; André Luiz Ribeiro Azevedo[1]
Universidade Federal do Espirito Santo[1]; Fazenda da Toca[2]

Extraction of clay as a substrate for roads and buildings results in degradation due to the removal of local vegetation and the exposure of the subsoil in the deposits, besides promoting changes in the physical attributes of the soil, triggering accelerated erosive processes. In this sense, the slopes wake up great concern for exhibiting great structural fragility. Revegetation is the main practice to recover vegetation cover and soil physical attributes are fundamental in determining the vegetation used and management technique adopted. Therefore, this work aimed to characterize the slope area regarding the physical attributes in order to plan the best form of revegetation. The soil characterization was performed in a field at region of São Mateus/ES, an area used for clay loan. The slope was divided into four horizons: A, AB, B and C. Deformed and undisturbed samples were collected in this horizons for the determination of particles density (PD), soil texture, soil density (SD), total porosity (TP), macro and microporosity (Ma, Mi) and geometric mean diameter (GMD). To determine the resistance to soil penetration (RSP), an impact penetrometer was used, as well as sample collection to determine the present moisture. The average clay, silt and sand content in the four horizons evaluated was 505.3 g kg^{-1}, 63.1 g kg^{-1} and 431.6 g kg^{-1}, respectively, which characterizes the soil as clay texture according to the Soil Survey Manual. The soil presented a mean SD of 2.13 g cm^{-3}, classified as high for its textural class. The PD was also high, on average equal to 2.95 g cm^{-3}, indicating the presence of iron oxides, common in these soils of tropical regions. The structural quality of the soil can be characterized as low due to the low values of GMD, that varied from 0.68 to 1 mm. Higher moisture content and resistance to penetration were observed in the B horizon, in relation to horizon A. Despite the high retention capacity of water in this soil depth, the RSP greater than 15 MPa in the firsts 0.1m of the soil could be a serious limitation to the root development of the species. High total porosity was observed in the B horizon, due to the higher number of micropores, as a result of to the higher clay content in this horizon. The attributes indicate high degree of compaction and soil degradation and management practices are necessary before the introduction of vegetation.

(6055 - 997) Climate change impact on groundwater quantity under different land management systems in Central Sand Area of Wisconsin, USA.

Birl Lowery[1]; Amber M. Radatz[1]
University of Wisconsin-Madison[1]

Groundwater quantity and quality is a vital resource worldwide, but it is especially critical for Wisconsin Central Sand Plain (WCSP) and other areas where sand plains are used in irrigated agricultural production. Thus, an understanding of the linkage between various land uses, including conservation practices, and groundwater usage with respect to climate change are important to understanding the breadth of potential solutions to water shortage. We investigated water table changes over time and the interface between groundwater resources under several management systems as they are impacted by climate change. While total precipitation has either increased or remained the same over time, the water table elevation assessed by monitoring wells in WCSP declined over many years, and those near Hancock, Wisconsin dropped about two meters over the period from 2002 to 2011. This water table decline was also reflected in lake levels as several lakes in WCSP suffered from low water levels. The objective of this research was to quantify interactions between vegetation (irrigated agricultural crops, prairie, and forest) and groundwater recharge in WCSP over extended time under changing climate conditions. Groundwater monitoring data were obtained from the US Geological Survey and specific water monitoring equipment was installed at eight sites to assess water table elevation, soil water content, and precipitation at 15-minute intervals under different vegetations. Data showed that the water table responded to

precipitation events differently based on the position in the groundwatershed and depth to the water table. Monitoring sites in the groundwatershed's discharge area responded quickly to precipitation events and the amount of rise of the water table increased linearly with precipitation. Interception of precipitation by plant canopy and decaying vegetative material on the soil surface in forest and prairie environments of the discharge area decreased groundwater rise as it responded to precipitation relative to agricultural fields. While agricultural crops used groundwater through irrigation, natural vegetation relied on water stored in the sandy soils and the shallow water table (1.5 to 3 m) for daily transpiration needs. Where groundwater was further from the surface, responses to precipitation events were buffered by the greater depth (5 to 7 m) of soil above the water table.

(8819 - 204) Cover plants on the control of soil water content in sugar cane areas

Ingrid Nehmi De Oliveira[1]; Camila Viana Vieira Farhate[1]; Lenon Henrique Lovera[1]; Zigomar Menezes De Souza[1]; Juliana Aparecida Fracarolli[1]; Diego Alexander Aguilera Esteban[1]; Elizeu De Souza Lima[1]; Euriana Maria Guimarães[1]; Renato Lopez Noronha[1]; Camila De Souza Gabriel[1]
State University of Campinas (Unicamp), Agricultural Engineering (Feagri)[1]

The use of cover crops in sugarcane cultivation generates higher levels of water in the soil, reflecting on crop development and productivity. The objective of this study was to monitor soil water content in sugarcane areas where millet and peanut were used as cover crops. We carried out the study along two agricultural years at Santa Fe Mill, in an experimental area in Ibitinga county, São Paulo, cane plant and first ratoon. Experimental design was performed in randomized blocks with three replicates. The experiment started in December 2014 with soil collection for physical and chemical characterization of the area. The cover plants were sown in December 2014 and conducted until April 2015 and managed (desiccation) at the point of maximum flowering . Sugarcane planting occurred in April 2016, upon the use of minimum tillage system (subsoiling at 0.40 m and sulcation) and sugarcane variety CTC 4. Water content monitoring was performed between August 2015 and January 2017 using a FDR (Frequency Domain Reflectometry) probe, model Diviner 2000. The readings were performed monthly, up to 1.0 m depth. In general, applying the treatment sown with millet as cover plant lead to higher water contents in the soil on surface layers (0.00 to 0.50 m) compared to peanuts (a difference of 26%). Such behavior probably occurred due to the higher amount of straw produced by the millet (10 Mg ha^{-1}), which guarantees a lower solar incidence, low evaporation, and higher water content in the soil. In contrast, for the subsurface layers (0.50 to 1.00 m), soil water contents were very similar between the treatments, demonstrating that the straw from the cover plants were determinant at controlling soil water content only on surface layers. Such results can lead to the conclusion that millet provides higher soil water content in relation to peanuts, an effect which is more pronounced on soil surface layers.

(7373 - 2617) Data assimilation techniques for retrieving soil moisture in root-zone by using a combination of satellites.

Uvarov M.V.[1]; Martyniuk P.M.[1]; Gnatushenko V.V.[1]; Panchii N.I.[1]
EOS Data Analytics[1]

Soil moisture can be retrieved from in-situ observation, hydro-meteorological models and remote-sensing inverse problems. But only remote sensing observation provides acceptable spatial coverage and resolution of retrievals value. The modern Data Assimilation techniques, such as Optimal Interpolation, Kalman filtering techniques or variational assimilation (4D-Var), provides an effective way to combine hydro-meteorological simulations and remote sensing observations to obtain acceptable accuracy of soil moisture retrievals. Thus, for Data Assimilation system it is very important to develop a hydro-meteorological model for soil moisture dynamics modelling. For this purpose, the mathematical model of soil moisture transfer were built including the impact of the soil heat and taking into account the terrain topography. To describe the movement of water in soil we are using Richards' equation [1]. For efficient numerical solution of the soil moisture equation, it is convenient to describe the soil hydraulic properties using analytical relationship. The following models were used: BC (R.H. Brooks & A.T.Corey model [1]), VGM (Van Genuchten - Mualem model [1]). The corresponding one-dimensional boundary value problem was solved by finite element method. For retrieving states and parameters controlling the soil water dynamics in the root zone (~100cm) by assimilating near-surface state observation, we develop a dual Kalman filter technique using a model based on the Richards equation with Lü et al. (2011) approach, by combining the EKF to update the state variables, with an optimization algorithm for retrieving parameters of soil hydraulic functions defined according to the BC/VGM relations and BG/VGM parameters by using a particle filter algorithm. In order to provide topsoil (3–5 cm) moisture maps with a good spatial resolution ~100x100m we developed a multi-sensor approach, which combined data from different satellites. The coarse scale satellite data SMOS/SMAP, MODIS(LST&NDVI data utilized to take vegetation into account by trapezoid technique), and high-resolution Sentinel data (S1,S2,S3). To combine active/passive soil moisture product we are develop DISPATCH (DISaggregation based on Physical And Theoretical scale Change) method. 1. P. M. Martyniuk, et al. Mathematical model of nonisothermal moisture transference in the form of water and vapor in soils. //(FJMS) © 2017 Pushpa Publishing House, Allahabad, India. (3787 - 1263) Effect of Afforestation of Marginal Lands on Infiltration and Penetration Resistance

Thomas J. Sauer[1]; Eric C. Brevik[2]
USDA[1]; Dickinson State University[2]

Food security can be reduced when agricultural lands are converted from crop to bioenergy feedstock production. Targeting marginal lands for woody feedstock production avoids some of the competition for food production and may improve soil health and the local microclimate and provide additional ecosystem services. The objective of this study was to evaluate the effect of eastern red cedar (*Juniperus virginiana* L.) windbreaks on soil quality in the U.S. Great Plains. Eastern red cedar has great potential for bioenergy production due to its adaptability to a wide range of soil and climate conditions and the physical and chemical characteristics of its biomass. Nine sites were selected from latitudes 41-47 deg N and longitudes 94-103 deg W with MAP from 425 to 970 mm and MAT from 4.9 to 9.9 deg C. Tree age varied from 22 to 59 years. Ponded infiltration (twin ring technique) and penetration resistance at 2.5 cm increments to 30 cm (digital static cone penetrometer) were measured at 9 locations under the trees and in adjacent fields (crop, pasture, or hay) at each site. Soil samples were collected for bulk density, pH, carbon, and nutrient analyses from the same locations. Infiltration rates averaged 163 mm/h (55%) greater and penetration resistance averaged 228 kPa lower under tree cover. These results suggest that precipitation was more likely to infiltrate and be available for root uptake under the

trees. Additional hydraulic properties (saturated hydraulic conductivity and sorptivity will be determined from the twin ring infiltration measurements. Improvements in soil physical and chemical quality following tree planting for bioenergy feedstock production may allow some marginal lands to be converted back to crop or forage production at a higher level of productivity.

(7589 - 841) Effect the runoff harvesting collection area shape on the efficiency of the water conservation in the soil profile

Pedro Berliner[1]; Gennady Carmi[1]; Solomon Leake[1]
Ben-Gurion University of the Negev[1]

Water is a primary limiting factor to agricultural development in many arid and semi-arid regions. In these regions, much of the annual rainfall occurs as a result of a few intensive convective storms. Only a small fraction of the rain is absorbed by the soil, does not penetrate deeply into the soil profile and is mostly lost by direct evaporation into the atmosphere shortly after the rain event. Runoff harvesting technique may be used for food, fuel production, flood and erosion control, as well as for landscape development. Microcatchments are one of the primary techniques used for collecting, storing and conserving local surface runoff for growing trees/shrubs. In this system, runoff water is collected close-by the area in which it was generated, and trees/shrubs may utilize the water during the next dry season. The main objective of the present research was to estimate the effect the shape of the micro-catchment collection area (shallow basin and deep trench) has on the efficiency of the water conservation in the soil profile. The study was carried out using regular micro-catchments (three replicates) with a surface area of 9 m^2 (3 x 3 m) and a depth of 0.1 m and trenches (three replicates) with a surface area of 12 m^2 (12 x 1 m) and 1 m depth. One and three olive trees were planted inside the trenches and micro-catchments, respectively. Access tubes for neutron probe were installed in micro-catchments and trenches (four and seven, respectively) to depths of 3 m. Soil water content in the soil profile was monitored. Sap flow in trees was measured by PS-TDP8 Granier sap flow system every 0.5 hour and fluxes computed for the time intervals that correspond to the soil water measurements. The study included flooding trenches and regular micro-catchments with the same amount of water (1 m^3), monitoring the water balance components and estimation of evaporation losses and water use efficiency by olive trees. Evaporation from trenches and regular micro-catchments was estimated as the difference between evapotranspiration obtained by soil water content monitoring and transpiration estimated by sap flow measurements. The results clearly show that the evaporation from the regular micro-catchments was significantly larger than that of trenches during the entire duration of the experiment. The fractional loss due to evaporation for the entire experimental period was 53 and 22% for micro-catchments and trenches, respectively.

(2501 - 324) Effects of solute type and mineralization on soil salt ions during the release water process

Quanen Guo[1]; Yiquan Wang[2]; Zongxian Che[1]; Lili Nan[3]; Shiyu Cao[1]; Jiancheng Wang[1]
Soil Fertilizer and Water-Saving Institute, Gansu Academy of Agricultural Sciences[1]; College of Resources and Environmental, Northwest A & F University[2]; Pratacultural College, Gansu Agricultural University[3]

Water resource shortage has become an important limiting factor for the agricultural production in arid areas in Northwest China. The efficient utilization of brackish water resources is of great importance significance for food safety in irrigated areas. However, the influence of irrigation with different salt ion compositions on soil salt ions during the release water process is unknown. In the study, the soil samples were collected from orchard calcareous soil in Qin'an County of Gansu Province. The content of soil organic matter is 10.52 g/kg and pH is 8.54. Soil electrical conductivity is 0.43 mS/cm. The influences of two sodium salts (NaCl, Na_2SO_4) with different mineralization degrees (0, 1, 3, 5, 10 g/L) on salt ion composition (HCO_3^-, Cl^-, SO_4^{2-}, K^+, Na^+,Ca^{2+},Mg^{2+}) in soil solution were explored with the dehydration centrifugal method under different water suction conditions (*pF* 1.0, 1.49, 2.01, 2.71, 3.49, and 4.09). The influences of NaCl and Na_2SO_4 on salt ions in soil solution were different. When soil water tension (*pF*) was more than 2.0, Cl^- and SO_4^{2-} in irrigation water inhibited the dissociation of Cl^- in soil solution and Cl^- in irrigation water inhibited the dissociation of SO_4^{2-} in soil solution. When soil water tension (*pF*) was less than 2.0, the NaCl solution with the degree of mineralization more than 3 g/L promoted the dissociation of the Ca^{2+} in soil solution and the promoting effects of dissociation increased with the increase of salinity. When soil water tension (*pF*) was more than 2.0, NaCl solution (the degree of mineralization of was 1 g/L) inhibited the dissociation of Ca^{2+} in soil solution. NaCl and Na_2SO_4 in irrigation water promoted the dissociation of Mg^{2+} in soil solution. The study could provide the basis for restraining soil salts in brackish water irrigation in arid regions.

(7794 - 658) Establishment of critical soil water potential tresholds for water stress deficit in *Carica Papaya*

Róger Armando Fallas Corrales[1]; Bryan Alemán Montes[1]; Gabriel Garbanzo León[1]; Carlos Henríquez Henríquez[1]
University of Costa Rica[1]

Carica papaya is a tropical crop with a very high potential yield (if well fertilized and irrigated can achieve more than 200.000 kg fresh fruit ha^{-1}). In order to define the soil water potential in which *Carica papaya* begins to suffer from water stress deficit (a necessary parameter for the proper management of irrigation), it were developed pot experiments with variation in soil moisture. It was measured the soil water potential, its plant canopy temperature and the spectral signature in the most recent completely expanded leaf for each plant in different evaluations. A good Spearman´s correlation rank (rho=0,71, p-value<0,0001) was observed between the relative increase of the plant canopy temperature and soil water potential. Using the graphical data of the relative increase of leaf temperature, it was possible to define the critical soil water potential that generates water stress deficit to *Carica papaya* plants. There were high variations in the spectral signatures of plants submitted to similar soil water potential, which difficult to correlate plant measurements with the respective soil water potentials.

(7827 - 2429) Estimation of surface runoff using the stable infiltration rate determined by different methods

Felipe Dalla-zen Bertol[1]; Dalvan José Reinert[1]; Micael Stolben Mallmann[1]; Willian Saidelles Foggiato[1]
Universidade Federal de Santa Maria - RS[1]

The infiltration rate of water in the soil is one of the main factors that regulates and determines the volume of the surface runoff, responsible for the soil erosive process. For determination of infiltration rate, different methods are used, seeking better to represent an infiltration in rainfall events. Among the methods are the Double Rings and Cornell Sprinkle Infiltrometers. We objective to estimate the runoff using Steady Infiltration Rate (SIR) values determined by three different methods. The study was carried out in the experimental area of the Department of Soil in Federal University of Santa Maria, Santa Maria, Brazil, in a Hapludalf. The SIR was determined with the Double Rings and Cornell Sprinkler Infiltrometer and using a Natural Rain runoff measuring in three treatments: 1. Bare soil (BS); 2. Black oats (Avena strigosa) and vetch (Vicia sativa) – winter - and cowpea (Vigna unguiculata) - summer (OVB); 3. Pensacola Grass (Paspalum notatum) (PG). The plots with dimensions of 3 x 14.5 m, are delimited by metal sheets and in the lower part of the plot a frame collect runoff and direct the volume to a reservoir of 1 m³, where were volume readings are made at intervals of 1 min. The SIR with Natural Rain event was determined in a rain event that occurred a few days after the measuring infiltration with the other methods, and calculated by integrating the difference between a precipitation and the surface runoff for 1 min time intervals. The runoff estimation was performed for 1 min intervals, using a difference between precipitation rate and SIR, and time-integrated values. The three methods were compared by evaluation of Nash-Sutcliffe efficiency coefficient (NSE) and the standard deviation of observations (RSR). The runoff estimation using the SIR determined with Natural Rain was more efficient instead of using the SIR by double ring and Cornell methods, with NSE between 0.87 and 0.96 and RSR between 0.21 and 0.36. Using a SIR determined by Double Ring and Cornell methods, the estimate of the runoff showed NSE between -0.22 and -1.17 for double ring and -0.06 and 0.1 for the Cornell. The surface runoff is underestimated when using the SIR determined by Double Ring and Cornell methods, being better estimated, for plot scale, when use SIR determined with natural rain.

(6249 - 2234) Evaluation of a low-cost sensor to implement a wireless soil moisture sensor networks

Pedro Vieira CRUZ[1]; Marcos Bacis CEDDIA[1]
UFRRJ[1]

The monitoring of the spatial variability of soil moisture is very important in order to improve the efficiency of water use in agriculture. However, the implementation of a monitoring system demands the combination of technology (soil moisture sensors, methods of data transmission and processing) and low-cost. In recent years, wireless soil moisture sensor networks (WSMN) have emerged. Basically, it encompasses the soil sensor, a wireless communication technology like ZigBee/XBee, Bluetooth, Wibree and WiFi and hardware platforms (like Arduino). In this work, we present an evaluation of a low-cost soil sensor to be implemented in a WSMN which will be used to characterize the spatial variability of soil moisture in an agroecological production system. The soil sensor evaluated was the model Analog Capacitive Soil Moisture Sensor-Corrosion Resistant. In order to evaluate the accuracy of soil sensor, a laboratory experiment was performed to compare the estimation of soil moisture using the sensor with the soil moisture measurement using the thermogravimetric method. The evaluation tested the sensor under different soil moisture (six levels - from hygroscopic to saturated soil moisture) soil texture (sandy, loamy and clayed soil). Considering the soil moisture level (6), soil texture (3) and the repetitions (4), the soil sensors were installed in 72 PVC soil recipients (11.3 cm of high, 3.6 cm of radius, 460 cm^3). From 72 PVC soil recipients, 48 (75%) were used to develop the prediction equation, while 24 PVC (25%) were used to validation. The index RMSE and MAE and R^2 were used to evaluate if a unique equation could be used for all soil texture or if the accuracy is significantly improved adopting specific equation for each soil texture. The results show that both the MAE and RMSE were lower (higher accuracy) in sandy soil. The accuracy reduced as the clay content increase and the use of a unique equation cause a significant loss of accuracy (MAE of 1.7, 2.3, 4.1 and 5.4; RMSE of 2.1, 2.9, 4.1 and 5.4, for sandy, loamy, clayed and all soil texture respectively). The results show that the accuracy of the soil sensor is acceptable and the soil sensor can be used in a WSMN, however, the topology of the network has to be implemented including different equations according to the soil texture of the position where the sensor is inserted along the field.

(8976 - 3230) Evaluation of the hydraulic conductivity of the soil under different uses and sun-exposed faces

Lopes, Vanessa Schiavon[1]; Fernandes, Osmar Rosa[1]; Zeferino, Leiliane Bozzi[1]; Cardoso, Irene Maria[1]; Simas, Felipe Nogueira Bello[1]
Universidade Federal de Viçosa[1]

Understanding the hydraulic conductivity of soil (Ks) in different types of soil cover and faces of exposure to the sun helps the acquisition of new knowledge on the behavior of soil hydraulic properties. The change of land cover has great influence on K s, many studies have shown that the conversion of degraded pastures into forest increases the K s, but there is little knowledge about the Ks of areas in the regeneration process to the native vegetation as well as the influence of the different faces of exposure to the sun on the soil. The objective of this study was to evaluate the relationship between the type of land use and cover, pastures and areas under regeneration, and the two faces of exposure to the sun, east and west, on Ks. The study was carried out at the headwaters of the São Bartolomeu River, responsible for part of the water supply of the city of Viçosa, MG. Fifteen soil samples were collected at depths of 0.0-0.15 m in regeneration and pasture areas on the east and west faces of exposure to the sun, with a total of 60 samplings. For the purpose of comparison, the slope and the type of soil were standardized. Undisturbed soil samples were collected to measure the Ks with the help of auger type-Uhland. The samples were saturated (from the bottom up to expel the air bubbles) with water for 24 hours. Then a tube of the same diameter and height was fixed by means of waterproof adhesive tape to act as a reservoir and Mariotte bottle were used to maintain a constant load. Finally, the volume of water in the sample cylinder was measured after the flow stabilization, with each sample showing reproducibility in five successive determinations. The results showed that Ks was significantly higher ($P < 0.05$) in the regenerated area compared to the pasture area. The area under regeneration with the soil facing the east presented higher ($P < 0.05$) Ks than the area in regeneration with facing the west exposure to the sun. The Ks decreased in the order of regeneration area with east exposure face, regeneration area with west exposure face, pasture with east facing face and pasture with face of west exposure, corresponding to the degree of vegetation degradation. The west face of exposure to the sun is affected by increased sunlight that favor the greatest number of wetting and drying cycles, greater degradation of organic matter in influencing different physical soil

properties such as hydraulic conductivity.

(1000 - 745) Evapotranspiration: model versus measurements

Sascha Reth[1]; Christian Heerdt[1]
UGT GmbH[1]

Evapotranspiration is one of the most needed information in environmental research, and one of the most discussed. The calculation of the evapotranspiration using climate data measured by a (standard) climate station is stand of the art. Calculations normally used the equations of Penman-Monteith, Haude or Turc, with all the known limitations of each method. Further on eddy covariance is a common method. Often the calculated rates are not in line with the real scenarios at the place, because of the requirements postulated by the different methods – e.g. homogeneous surface structure- are not given. Real measurements of the evapotranspiration need the use of large lysimeters which are time and money consuming. The new Ready-to-go Lysimeter is a small lysimeter station for soil columns with an area of up to 0.5 m² and a length of up to 1 m. The Ready-to-go lysimeter is suitable both for disturbed soil (filled by hand) and for undisturbed soil monoliths when using the patented UGT excavation technology. The Ready-to-go Lysimeter is the ideal supplement to an existing weather/climate station for directly calculating evaporation and the recalibration of the mentioned above calculation methods for the exanimate area.

(5746 - 2018) Filtration of *Phytophthora* and *Pythium* Zoospores in Recycled Irrigation Water to Control Plant Disease Outbreaks in Greenhouse

Sangho Jeon[1]; Charles S. Krasnow[2]; Mary K. Hausbeck[2]; Yeon-Kyu Sonn[1]; Byung-Keun Hyun[1]; Sun-Gang Yun[1]; Wei Zhang[2]
National Institute of Agricultural Science in Korea[1]; Michigan State University[2]

Pythium and *Phytophthora*, also known as “water molds”, cause enormous economic losses on crop species worldwide, which include seedling damping-off, stunting, and stem, crown, and root rot diseases in both floriculture and vegetable crops as well as environmental damage in natural ecosystems. It is challenging to control these pathogens because plants are infected and do not show symptoms until the disease is too advanced to respond to treatment, and easily develop resistance to effective fungicides. In this regard, our study investigated the transport and retention of *Phytophthora. capsici* zoospores in saturated columns packed with iron oxide coated sand (IOCS) or uncoated sand in Na^+ or Ca^{2+} background solution at pH 7.2 or 4.4, in combination with zeta-potential and microscopic visualizations. The findings suggest that the transport of the plant pathogen *Phytophthora. capsici* zoospores in porous media was collectively controlled by surface properties of zoospores and porous media, solution chemistry, and pore straining. Greenhouse experiment was investigated to demonstrate a proof-of-concept of using fast-flow filtration system to control *Pythium* disease of poinsettias grown with ebb-and-flow and flood floor irrigation systems in greenhouses. This study showed that *Pythium aphanidermatum* could be effectively removed by the sand and AC filters during fast-flow filtration with low water pressure. The rapid sand filter had the best performance because no decrease in the poinsettia quality was observed when compared to the non-inoculated control plants. Additional greenhouse experiment was carried out to investigate the effectiveness of fast-flow filtration to control *Phytophthora* diseases in the greenhouse vegetable production. This study found that the IOCM filter could effectively protect the squash plants from *Phytophthora capsici*, but caused the nutrient deficiency in the squash. The sand filter could not prevent, but only slow the disease development in the squash. Thus, it is clear that the IOCM filter has the potential to be used in treating irrigation water in the greenhouse vegetable production. Overall my results suggested that physical removal of pathogens using fast-flow filtration can overcome many limitations of fungicide application, and may be a promising alternative for disease management in the greenhouses.

(2411 - 2981) Geophysical investigation of soil moisture content for agricultural purposes

Ruan Ainslie[1]; Jaco Koch[1]
North-West University[1]

Water scarcity is on the rise and is rapidly becoming an international problem. This has enormous effects on agriculture and water management systems. The causes of water scarcity is mainly due to the large continuous increase in population, urbanisation and the continued improvement of living standards. This greatly increases the pressure on water supplies, due to the increasing demand for food production and industrial activities. Draught is seen as a common and recurring phenomena globally. Such severe climatic events can have an enormous effect on crop production and livestock, which occurs in agricultural regions worldwide. This study aims at correlating geophysical techniques applicable to soil moisture estimation, as to ensure that soil moisture content is managed correctly and efficiently. Thereby saving time and decreasing expenses by minimising water and electricity usage on pivots, and maximising crop yields. Furthermore, this study is also aimed at determining the best and most efficient method (of the methods used in this study) for soil moisture investigation aimed at decreasing time and cost of data collection for soil moisture. Previous studies usually concentrates on only one or two of the methods used. This study compares three geophysical techniques and is correlated with the gravimetric water content of the soils. With the correlation of the three different techniques, it would be able to establish the most accurate, quick and easy method for continues soil moisture monitoring. In this study, the CMD Explorer, the CMD Mini-Explorer, the CPN 501DR Depthprobe and the Diviner 2000 will be used throughout the planting season, on a farm near Potchefstroom, South Africa, to measure and monitor soil moisture content. This data will be monitored over a period of six months, to ensure accurate short term data for ground water management. The preliminary assumption is that the Diviner 2000 would be the method of choice. This is mostly due to the mobility, cost and ease at which the apparatus is used, given that this apparatus correlates with the other, more known and trusted, methods of geophysical investigation with regard to soil moisture content.

(2412 - 1644) Hydrological characteristics of four Soilless Substrates for Potting Cultivation

Daniel Fonseca de Carvalho[1]; Eleandro Silva da Cruz[1]; Clodoaldo Spadeto Ambrozim[1]; Wendel Lucas de Sousa[1]
Universidade Federal Rural do Rio de Janeiro[1]

In the last years the soilless potting cultivation has increased considerably in face of traditional technics. The materials adopted as substrate in these systems must present favorable physical characteristics to the development of the plants, highlighting those directly related to the capacity of water retention. This study was

developed at Federal Rural University of Rio de Janeiro, Rio de Janeiro State – Brazil, and intend to generate water retention curves of four soilless medium. The evaluated materials were: S1 –coconut fiber crushed with vermicompost produced from bovine manure (3:1 vol. by vol.); S2 – sewage sludge provided by the State Water and Sewerage Company of Rio de Janeiro (CEDAE); S3 - substrate S1 plus granite powder, a residue of stone cutting and polishing resulting from its preparation for ornamental use (3:1 vol. by vol.); and S4 - substrate S2 plus granite powder (3:1 vol. by vol.). The sample was obtained from the hidraulic campactation process, that consists in to put the substrates on a plastic pipe (diameter: 15 cm, height: 65 cm), and fill it loosely up to 5 cm below the upper edge. After water must be added at the surface until water left at the bottom of the pipe, and than the pipe must be placed for 2 days in a pan with a 3 cm water level. After this time, the tension at the surface layer its about 50 hPa. The substrate material of the upper 5 cm layer of the pipe was taken, mixed and used to loosely fill 250 cm^3 HYPROP steel cylinders.The samples were then homogenized and conditioned again in the steel cylinders. They were then saturated and subsequently placed in the HYPROP system (UMS) to begin the readings. The observed dry bulk densities observed were 0.12; 0.44; 0.69 and 0.58 $g.cm^{-3}$, respectively, for S1, S2, S3 and S4. The Van Guenuchten model was adjusted to the water retention data, whose soil residual water content (θr), soil saturated water content (θs), scale parameter (α) and shape parameter (n) values were respectively: 0.261, 0.970, 0.1102 and 2.657 (S1); 0.277, 0.707, 0.0781 and 1.945 (S2); 0.272, 0.806, 0.1162 and 1.489 (S3) and 0.339, 0.781, 0.0941 and 1.714 (S4). The root mean square error values of the adjustments were 0.0431 (S1), 0.0086 (S2), 0.0145 (S3) and 0.0111 (S4). The results show that the water retention capacity is altered according to the soilless medium adopted, and it is necessary to be properly characterized before being used as agricultural substrates.

(3631 - 284) Infiltration of water in a Oxisol in organic corn crop using different cover crops

Juliana Megumi Kanashiro de Oliveira[1]; Carolina dos Santos Batista Bonini[1]; Melissa Alexandre Santos[1]; Neli Cristina Belmiro dos Santos[2]; Guilherme Constantino Meirelles[1]

FCAT/UNESP DRACENA[1]; Agência Paulista de Tecnologia dos Agronegócios - Pólo Regional de Andradina[2]

The quality of the physical aspects of the soil, as a consequence of the use and management, is given by the indices of different physical properties related to the structural stability and soil form. The changes in the physical properties are many, we can mention the decrease of the rate of infiltration of the soil, which is influenced by the reduction of the macropores, leading to the reduction in the cross-sectional area for the water flow. The use of other species for the production of biomass as ground cover, prevents leaching of nutrients, allowing for more efficient use of nutrients in solo. To ensure good root development and water infiltration capacity of the soil, it is necessary that the internal physical conditions are suitable for infiltration occurs. Once the structural quality is good, the pore size distribution favors the factors mentioned above. The infiltration rate is a good parameter for the internal physical condition of the soil. The field experiment is being developed for the agricultural year 2016-17, the Technological Development of Regional Center of West Far Agribusiness, Andradina-SP. The soil is classified as Oxisol dystrophic. The experimental design was a randomized block with four replications. Seven treatments were evaluated consisting of green manures described below: *Canavalia ensiformis*, *Mucuna cinereum*, *Mucuna pruriens*, crotalária (*Crotalaria juncea*), *Dolichos lablab, Canavalia ensiformis* + *Mucuna pruriens and witness (fallow).* Evaluating the constant rate of water infiltration into the soil was carried out using the Mini Disk infiltrometer, at the time of green manure (October / 2016) and green maize (April / 2017). The statistical test used for analysis was the Scott-Knott test at 5% probability. Statistically analyzing the treatments were not influenced by different green manures used. This result agrees with that 6 soils with sandy texture have average infiltration ranging from 38.1 to 111.8 mm/h. And second the adopted handling systems have great effect on the rate of infiltration into the soil. The homogeneity of the constant rate of infiltration all close to 100 mm / hr due to the fact that all species tested belonging to the legume family that has a root system which beneficially influences the physical properties of the soil. Therefore, it was concluded that the treatments used did not influence the water infiltration rate in the soil.

(4605 - 2616) Influence of soil layers with canal bed with different water cuttings on frost heaving of lining structure

Xiangdong Shen[1]

IMAU[1]

Freezing tests were carried out on canal bed soil, foundation soil and lining composite structures with water content of 10%, 15% and 20%, respectively. The frost heaving volume, freezing thickness and freezing time of various soils were measured. The relationship between the three factors is analyzed, and the influence of soil with different water content on the frost heaving failure of the lining structure is analyzed. The influence of the freezing and thawing of the soil with different water content on the frost heaving failure of the lining structure is obtained. With the increase of soil water content, the scope and depth of deformation and failure in the structure increase. The failure mode changes mainly from the local slump of the interface to that of the whole slump. The greater the moisture content, the more severe the freezing and destruction. Using Leica Z16APOA super-depth of field to observe the change of the interface during the freezing process, the variation of the frost heaving failure on the interface was obtained.

(8238 - 277) Measuring near-wilting soil hydraulic properties and their application in crop water availability modeling

Quirijn de Jong van Lier[1]; Everton Alves Rodrigues Pinheiro[1]

CENA/USP[1]

Water availability to crops depends on dynamic processes in the soil, however, predictions of characteristic water contents like field capacity or permanent wilting point are commonly based on a fixed pressure head value alone. Mesoscopic root water uptake models show that crop water availability and the characterizing conditions largely depend on soil hydraulic properties, especially those for the dry soil close to wilting point. On its turn, agricultural management affects the hydraulic properties, hence the evaluation of changes in crop water availability should include their determination. We verified the changes in water availability limits in some Brazilian soils with different management histories and, based on obtained values, made predictions of the available water fraction and how it is affected by soil management. We performed evaporation experiments measuring soil water content by gamma-ray attenuation readings. Undisturbed soil samples were taken from some soils from São Paulo State, Brazil. Samples were saturated by capillarity, closed at the bottom and then submitted to natural evaporation from their upper surface. Evaporation rate was determined by weighing. Measurements of attenuation of a collimated gamma ray, produced by a ^{137}Cs source

were performed at several times and depths below the sample surface, during some weeks after the onset of evaporation, until samples reached a very low (quasi air-dry) water content. Samples were finally oven dried and one last reading was performed to determine the attenuated reading of the dry sample. Water contents corresponding to attenuated readings were calculated using Beer´s law. From these measurements, hydraulic properties (retention and conductivity) were obtained as a function of pressure head using Richards equation-based inverse modeling. The obtained hydraulic properties allowed to determine field capacity by a flux density criterion at the lower soil boundary. Critical and wilting point conditions could be estimated by a matric flux potential approach. Determined values for field capacity and critical and wilting point conditions were evaluated by comparison to values obtained by the common practice using fixed pressure heads. The set of information allowed to discuss the validity of the common (fixed pressure head) method, suggest improvements for its interpretation and limitations to its use. Impact of agricultural management on crop water availability will be discussed in this context.

(3996 - 2613) Modernizing surface irrigation and land levelling in Hetao with application of the DSS SADREG

Haibin Shi[1]; Qingfeng Miao[1]; José M. Gonçalves[2]; Luis S. Pereira[3]

IMAU[1]; CEER - Biosystems Engineering, Institute of Agronomy, University of Lisbon[2]; Polytechnic Institute of Coimbra, College of Agriculture[3]

Water resources allocated to the agricultural sector in the Yellow River basin are being reduced due to severe water scarcity and an increasing demand by the non-agricultural sectors, which imply surface irrigation modernization and the adopting water-saving technologies. The Hetao irrigation district has 0,570 Mha of irrigated land; traditional basin irrigation is the most common irrigation method. Its general conditions are adequate for surface irrigation due to the high charge of sediments on irrigation water and, among other factors, due to its appropriateness to leach salts. The new technologies of surface irrigation, including the modernized furrowed and flat basin irrigation systems, require the adoption of effective precise land levelling to reach the best performance standards. In this context, the development of high quality land levelling operation is a main condition for irrigation modernization. The laser land levelling technology provides for high land leveling quality, with significant benefits on water saving, salinity control and crop productivity. The irrigation modernization also requires adopting adequate irrigation scheduling, control of inflow discharges and of related application times. The DSS methodology may contribute to improved design and management. The DSS SADREG aims to support design and selection of farm surface irrigation alternatives; it ranks those alternatives relative to irrigation performance and environmental and economic impacts using multicriteria analysis. The DSS application bases on three years field work to evaluate the traditional practices and for the parameterization of design models from field irrigation systems evaluation. This paper presents the following SADREG application results: (i) evaluation of land levelling operation based on field observations and the comparison between laser and common practices; (ii) SADREG base models parameterization, including crop irrigation scheduling, infiltration, SIRMOD hydraulic simulation and economics.

(6149 - 2950) Physical attributes of a dystrophic Yellow Latosol submitted to different mulchings in 'Ateira' (*Annona squamosa* L.) plantation

João Vitor Garcia de Lima[1]; Matheus Gonçalves Paulichi[1]; Augusto César Rodrigues Santos[1]; Patrícia dos Santos Mendes[1]; Wellington Farias de Araújo[1]; Pollyana Cardoso Chagas[1]; Marcus Vinicius Cardoso Trento[2]; Carlos Abanto Rodriguez[1]; João Luiz Lopes Monteiro Neto[1]; Raphael Henrique da Silva Siqueira[3]

Federal University of Roraima (UFRR)[1]; Federal University of Lavras (UFLA)[2]; Federal University of Amazonas (UFAM)[3]

The control of soil moisture and temperature can interfere in the dynamics of physical, chemical, and biological attributes in their different uses and management. The use of mulching is a practice that has been disseminated to improve the characteristics of water retention in the soil and to leverage the development of the crops in the field. Therefore, the objective of this research was to evaluate possible physical changes caused by different mulchings in a Yellow Latosol cultivated with 'Ateira' (*Annona squamosa* L.). The experimental design was a randomized block with 5 treatments (SC-no cover (control group); CA – *in-natura* rice hulls; PB – white plastic; CAC – carbonized rice hulls; and PP-black plastic) and 2 layers (0-0.15 and 0.15-0.30 m), with 4 repetitions. The different types of mulching were applied in the line of the 'ateira' trees, after having been made a heap in the dimensions of the plot (1 meter wide x 12 meters long), respecting the growth area of the plant. Soil samples were collected with Kopech rings and analyzed according to EMBRAPA (1997). The variables analyzed were: soil density (Ds), total pore volume (VTP), macroporosity (Macro), and microporosity (Micro). Soil density and total pore volume did not vary between layers and treatments, presenting mean values of 1.64 Mg m^{-3} and 36.46%, respectively. Macro and microporosity demonstrated interaction effect between layers and treatments. For the macroporosity, in the 0-0.15 m layer, the CAC treatment presented greater macroporosity in relation to the other treatments, presenting 30.22% of macropores. The microporosity was higher in the treatments CA, PP, and SC in comparison to the other treatments in the first layer, whereas for the layer 0.15-0.30 m it did not present differences between treatments. Variation in the pore dynamics occurs with the different types of mulching in the Latosol cultivated with 'ateira'. The 0-0.15 m layer is most influenced by the mulchings.

(2550 - 2990) Physical soil quality indicators under cassava harvesting systems (*Manihot esculenta Crantz*)

Ronilson de Souza Santos[1]; Sandra Andréa Santos da Silva[1]; Maria Helena Morais[2]; Kléber Pereira Lanças[2]

Universidade Federal do Pará/Campus de Altamira[1]; Universidade Estadual Paulista/Campus Botucatu[2]

The cassava originally from the Brazilian Amazon, has a worldwide production of 275 million tons and feeds approximately 500 million people. In Brazil, the crop has average yield of 14 $t.ha^{-1}$. The objective this work was to evaluate some physical soil indicators, considering the management actions maked during cassava harvesting process. The experiment was conducted in commercial cassava field, and was composed of three treatments called of Manual harvesting system (S1), that was composed of manual pruning of the aerial part plant, manual roots pulling, roots separation following of roots boarding into mobile wagon unit that doesn't traffic by inter row planting; Semi-

mechanized harvesting system (S2), that was composed of mechanized pruning of the aerial part plant, soil detachment, manual roots pulling, root separation following of boarding into mobile wagon unit that got traffic by inter row planting and Mechanized harvesting system (S3), that was composed of mechanized pruning of the aerial part plant, soil detachment, mechanized picking and machanized boarding roots into mobile wagon unit that doesn't traffic by inter row planting. The experimental design used was in strip, measuring 23.4 x 100 meters, composed of 15 pair of rows per system. Randomly, among row pair, was chosen six pair of inter rows planting, and was make penetrometry action to six radom places per inter row. The measure was done using the transept that had five measuring places with 0,18 meter between them, positioned transversely to the traffic line maked by farm workers and wheel agricultural machines, during harvesting operation. Also was collected at the center of the inter row undisturbed sample, distanced perpendicularly to 0.50 m of the transept line, being for both quality indicators, the data collect happened from 0 to 0,30 meter of depth. From the data obtained, was calculated the cone index and the soil density. The averages results obtained for cone index at the transept were 0.77, 1.20, 1.44, 1.52, 1.27 MPa; 1.40, 1.83, 2.09, 2.05, 1.86 MPa and 1.28, 1.93, 2.22, 1.91, 2.06 MPa, S1, S2 and S3 systems, respectively. The superior results to S2 and S3 treatments could be associated to located traffic from the whell agricultural machines, condition observed mainly to central samples. This behavior was repeated to results of soil density that were to 1.53, 1.57 and 1.59 $Mg.m^{-3}$; S1, S3 and S2 systems, respectively.

(5893 - 1522) Physico-empirical approach to predict soil water retention

Rodrigo Pivoto Mulazzani[1]; Paulo Ivonir Gubiani[1]
Federal University of Santa Maria[1]

Soil water content is physically linked to its pressure head (ψ), resulting in a relation known as soil water retention curve (SWRC). As SWRC obtainment is time-consuming, scientists try to access it by using pedotransfer functions (PTF). Currently, most of PTFs are empirical, therefore, restricted in application. Thus, efforts must be made to produce PTFs based on mechanistic processes or elementary relationship of physical soil characteristics. From this approach, we have proposed a model to predict SWRC based on soil specific surface (SS – textural component) and bulk density (ρ_b – structural component). The model describes gravimetric water (W) as the product of free SS (SS_f – particle specific surface that is not in contact with surrounding particles) by factor 'fa', which represents water mass by unit of surface. Free SS depends on particles characteristics (shape, size distribution), estimated by total SS (SS_t), and degree of packing, represented by ρ_b. Factor 'fa' was related to ψ by Van Genuchten's (1980) sigmoidal model, and the effects of SS and ρ_b on 'fa' were incorporated to the model parameters. Overall, the model can be described as $W = [SS_f = f(SS_t, \rho_b)] \times [fa = f(\psi, SSt, \rho_b)]$. Samples from 13 soils with different textures were used to draw up two sample sets. One set of disturbed soil samples was artificially set up in metal cylinders to obtain controlled ρ_b (artificial set); the other set was constituted of undisturbed soil samples (undisturbed set). A part of the artificial set was used for model calibration and another part of the artificial set and the whole undisturbed set was used for model validation. Results of the calibration process show that the model can describe physically consistent variations of SS (texture) and ρ_b (structure) on soil water retention. The model validation shows values of Nash–Sutcliffe efficiency index of 0.73 to 0.99 (mean 0.93) to artificial set and values of 0.27 to 0.90 (mean 0.65) to undisturbed set samples. Results evidence that the proposed model has potential to be used to estimate water retention, because it was able to predict SWRCs with good accuracy in both sample sets (0.99 and 0.90). On the other hand, a few undisturbed samples did not show good estimative (0.27). Thus, it is reasonable to conclude that either water retention at undisturbed samples is still too complex to be modeled or the proposed model needs improvements to ensure its applicability to broader soil conditions.

(7360 - 897) Retention and availability of water from a soil treated with biochar

Maria Maiara Cazotti[1]; Hélio Alves Pereira Filho[1]; Leiliane Bozzi Zeferino[1]; Luís Paulo Patente Tanure[2]; Liovando Marciano da Costa[1]
Universidade Federal de Viçosa[1]; Produquímica[2]

The agricultural sector is responsible for the production of food, fiber, and energy. However, it has been largely responsible for water consumption as well as the extensive areas of degraded soils, which increasingly constrains gains in agricultural production and threatens food security. In this sense, the application of biochar has been proposed as an excellent alternative for improving the chemical, physical and biological quality of agricultural systems. Although many studies have shown positive effects of the application of biochar, some aspects need to be further studied, especially those related to the soil physicohydric properties. The objective of this work was to improve the knowledge about biochar of forest residues, in the retention and availability of water when applied in an Oxisol. The biochar used in the test was produced by the slow pyrolysis process at 350 ºC, using *Eucalyptus* spp. as feedstock. The pyrolysis was performed with an average heating rate of 4 min and a residence time of 60 min. To conduct the test, the biochar was milled to obtain the particle size less than 0.5 mm. Oxisol B horizon samples, with 35% sand, 3% silt and 62% clay, were passed in a 2 mm sieve and then added three doses biochar (0, 20 and 40 g kg^{-1}). Three deformed samples of each treatment and a treatment with only biochar were used to generate the water retention curve in the soil from the tensions (6; 10; 30; 50; 100; 300; 1500 kPa). The available water content (AWC) was calculated by means of difference of humidity between the 30 and 1500 kPa tensions. The analysis of variance was performed and the means compared by the Tukey Test. It was observed that the water retention capacity of the pure biochar is large, that at 6 kPa the material retains water mass greater than its own mass (1.40 kg kg-1). The increment of the doses increased the retained moisture in the different potentials in compared to the control (dose of biochar 0 g kg^{-1}). The AWC was statistically higher in the only biochar, equal between the treatments of 20 and 40 g kg^{-1} of biochar and lower in the treatment with 0 g kg^{-1} of biochar. Characteristics such as, high specific surface area and high porosity may be responsible for increasing retention and water availability of soils treated with biochar. The results show that at the lower dose applied the biochar could be used to improve the retention and availability of water in the soil.

(4005 - 2527) Seasonal Plant Water Status in Native Shrubs and Trees, northeastern Mexico

Humberto González Rodríguez[1]; Haydee Alejandra Dueñas Tijerina[1]; Israel Cantú Silva[1]; Roque Gonzalo Ramírez Lozano[1]; Marco Vinicio Gómez Meza[1]
Universidad Autónoma de Nuevo León[1]

Since plant internal water potentials (Ψ) are a consequence of the soil-plant atmospheric continuum, measuring the actual internal plant water potential and soil water status directly in the field gives us reliable information about the water stress plants may suffer. Hence, it is important to measure water potential in order to identify the plant's capacity and strategy to cope with drought. According to the above mentioned, this study deals with the physiological adaptation of native trees and shrubs to drought stress in the semiarid ecosystems of northeastern Mexico. The present study has the objective to relate the soil water content with xylem water potential in native woody species such as *Condalia hookeri* (Rhamnaceae), *Cordia boissieri* (Boraginaceae), *Prosopis laevigata* (Fabaceae), and *Celtis pallida*. Seasonal xylem predawn (06:00 hrs) and midday (12:00 hrs) water potentials were determined at 15 day-intervals. Maximum and minimum seasonal predawn values ranged from –0.67 MPa (*C. pallida*) to –2.92 MPa (*C. hookeri*). At midday, xylem water potential varied from –1.07 MPa (*C. pallida*) to –3.10 MPa (*C. hookeri*). Predawn water potential values were highly and positively correlated with midday ones (r values varied from 0.900, *C. boissieri*, to .867 in *C. pallida*) and rainfall (r values ranged from .894, *C. hookeri*, to .697 in *C. pallida*). Correlation analysis between soil water content at different soil layers with predawn water potential values was weak. During the course of the study, native plant species faced mild to severe drought periods, being the species *P. laevigata* and *C. pallida* the ones that achieved higher predawn and midday water potential values. Thus, these species, could be considered as drought tolerant species while, *C. hookeri* and *C. boissieri* showed lower water potentials and could be in a physiological disadvantage under soil water stress. In conclusion, the study shows that the ability of species to control its water status may depends on the response capacity to absorb water and to control the loss of water during the day.

(8748 - 2648) Simulation of planting date on the yield of vegetable soybean and irrgation strategy in southern Taiwan by GLYCIM model

Chu-Chung Chen[1]; Chi-Chieh Hu[2]; Suh-Jen Lin[1]; Chi-Ling Chen[1]

Taiwan Agricultural Research Institute[1]; Kaohsiung District Agricultural Research and Extension Station[2]

The purpose of this study was to use the soybean simulation model on analyzing the climate and planting date effect of vegetable soybean in Taiwan. The variety parameter was calibrated from field experiment conducted in 2017. Two vegetable soybean variety Kaohsiung 9 and Kaohsiung 11 were planted in in three experiment sites one located in central and two located in southern Taiwan to acquire crop response data from different climate and soil properties. The vegetable soybean was grown in two planting date, spring crop and autumn crop, in southern experimental sites and one planting date, spring crop, in central experimental site. The validation results indicated that high consistence between simulated and observed results of phenostage, leaf area, leaf dry matter, stem dry matter, stem height and yield. Simulation of planting date effect in spring crop and autumn crop on yield was carried out by using historical climate data and major soil properties of vegetable soybean growing sites in southern Taiwan. The simulation results indicated that more irrigation required in early spring crop and late autumn crop to overcome the yield gap. Higher frequency requirement of irrigation in the sandy loam soil than the loam soil especially in spring crop.

(8527 - 2153) Soil and crop management strategies under drought conditions in the semiarid north of Chile

Ricardo Quintana[1]; Oscar Seguel[1]; Claudio Pastenes[1]; Charlotte Hardy[2]; Francisco Alfaro[2]; Nicolás Franck[1]

Universidad de Chile[1]; Centro de Estudios de Zonas Áridas[2]

In the north semiarid region of Chile, with an average precipitation of 100 mm year^{-1}, water scarcity is a normal constraint in crop production. In the present study, we have assessed the resistance and capacity to recover to transient drought of grapevines (*Vitis vinifera*) cv. Chardonnay, submitted to water deficit, by means of soil organic amendments and pruning severity, evaluating both: soil physical properties and plant physiology. In a 6 years old vine orchard, cultivated on a clay soil, four levels of soil amendments (E) were established: Control (EO), humic substances (EA), N-fixing bacteria (EB) and humic substances with N-fixing bacteria (EAB). Also, three levels of pruning (P) were established: no pruning (PO), 50% pruning (P5) and 80% pruning (P8). Finally, the combined effects of soil amendments and pruning were assessed, evaluating the treatments of no pruning and no amendments (POEO) and 50% pruning and humic substances (P5EA). After 60% of veraison, water irrigation was withheld. Soil amendments were effective in decreasing the bulk density of the soil, increasing water availability, mainly when humic substances were combined with microorganisms (EAB). Pruning resulted in reductions of total transpiration, with significant reductions of the stem water potential levels, but with no enhanced performance upon humic amendments. After the first rain, the different soil and pruning treatments showed a better recovery than the control, similar to the well-watered plants. At present, we continue assessing the cumulative effects of drought on grapevines, and also, olives, seeking for sustainable crop practices in arid and semi arid agricultural zones in Chile.

(3863 - 592) Soil moisture movement and spatial distribution on sand dune at a cold desert in the central Eurasian, China

Hongfei ZHOU[1]; Lanhai LI[1]; Hao LIU[1]; Xiang LIU[1]

Xinjiang Institute of Ecology and Geography, Chinese Academy of Sciences[1]

Water is the main driving forces for the vegetation succession in a desert ecosystem. We established a rainfall and snowmelt water infiltration and migration observation experiment site (44°22′ N, 87°55′ E) at a sand dune in the Gurbantunggut Desert. The artificial rainfall and brilliant blue FCF traced experiment were arranged. The soil water content and meteorological parameters were observed. By analyzing the monitoring data, it is recognized that the soil water movement and spatial variability at sand dune in the Gurbantunggut Desert is complex. (1) Soil moisture migration along the slope direction is existed under the rainfall and snowmelt water infiltration condition. When the accumulation of snow water equivalent is 40 mm, the soil water at the foot of sand dune derived from snowmelt lateral flow was 43.29%. When rainfall intensity is 0.52 mm/min and rainfall amount is 20.9 mm, the soil water at the foot of sand dune derived from rain infiltration lateral flow is 32.63%. (2) The soil moisture has the same variation tendency at different sites of the sand dune in different season. But the changing trend of soil moisture is different in the upper soil layers (0-100cm) and subsoil layers (100-200cm). Soil moisture is top > hill >foot in upper soil layers and foot > hill > top in the subsoil layers. (3) There are obvious seasonally and soil layering changing law for the soil moisture. The spring is the richest and fastest changes season of the soil moisture. The CV of the soil moisture in 0~40cm, 40~140cm and 140~200cm soil layers are 13.56%, 5.35% and 0.8% respectively. This is correspondence with the

surface layer, shrub root distribution layer and the deep layer. In conclusion, after the snowmelt water and rainfall infiltration, the soil lateral flow takes an important role on spatial redistribution of soil moisture. There exists a water enrichment zone at the foot of the sand dune.

(6074 - 295) Soil penetration resistance and water content of a Oxisol cultivated with degraded pasture in recovery with estilosants

Beatriz Santos Bisi[1]; Carolina dos Santos Batista Bonini[2]; Reges Heinrichs[2]; Alfredo Bonini Neto[3]; Cleiton Alexandre Silveira do Nascimento[2]; Aline Magalhães[2]

São Paulo State University (UNESP/Tupã). R. Domingos da Costa Lopes 780 , Tupã, 17602-496, Brazil. beatriz_bisi@hotmail.com[1]; São Paulo State University (UNESP/Dracena). Rodovia SP 294, km 651, Dracena, 179000-000, Brazil.[2]; São Paulo State University (UNESP/Tupã). R. Domingos da Costa Lopes 780 , Tupã, 17602-496, Brazil.[3]

Agricultural systems associated with the use of inadequate soil preparation equipment result in rapid soil degradation. This condition also occurs in pastures under extensive management regime. The use of more rustic forages, such as those of the Brachiaria genus, has alleviated the problem of degradation, but over time, not even these forages have managed to develop well in these soils. The need for recovery of degraded pasture areas is evident. Thus, the objective of this work was to evaluate the mechanical resistance to penetration and the water content of a degraded Urochloa decumbens (Brachiaria decumbens) pasture in recovery since 2012, with different forms of introduction of Estilosants cv. Campo Grande (Stylosanthes capitata and S. macrocephala). The experiment was carried out in Andradina-SP, with Oxisol. The experimental design was a randomized block design with four replicates composed of seven strategies in no-tillage of the legume (estilosantes - E) in the pasture: Brachiaria grass (B); B + E with partial desiccation with 1.5 L ha^{-1} glyphosate; B + E with total desiccation with 3.0 L ha^{-1} glyphosate; B + E with no-tillage; B + E with soil scarification, B + E with rome and B + E with plowing + harrowing. Samples were collected for the determination of the water content, obtained by the classical weighing method, and mechanical resistance to soil penetration, using penetroLOG, model Falker automatic. Soil analyzes were performed in three soil depths, from 0.00-0.10; 0.10-0.20 and 0.20-0.40 m, from the years 2015 and 2016. For the soil resistance to penetration (SRP) , only one depth of 0.20-0.40 m presented a significant difference between the treatments, where the treatment harrow + plow showed lower SRP, while no-tillage with soil scarification presented the higher SRP. In the studied years, it was observed that the studied layers can be classified as low resistance to penetration, since the values found are below the average resistance class (2.0-5.0 MPa). In the evaluation of soil water content, in all the studied layers, did not present the significant difference between the treatments. It is concluded with the experiment that as a soil management strategy for sowing of the legume influenced in the mechanical resistance a penetration, in which the treatment harrow + plow showed lower SRP. It is concluded that the values obtained in the treatments studied did not limit root growth.

(3788 - 3071) Soil physical properties affected by different land uses in the Cauquenes catchment, central Chile.

Eduardo Vega[1]; Mauricio Galleguillos[2]; Oscar Seguel[1]; Cristobal Puelma[1]

Universidad de Chile[1]; Center of Climate Research and Resilience[2]

The soils of the coastal range of Chile show a critical state by the water regime (high precipitations during winter, with dry summer), the parent material (erodible granitic soils) and the relief condition (steeply lands), factors that lead the soil degradation enlarged by the soil use change. The original native forest has been replaced by other uses, affecting the water dynamic of the watersheds. The purpose of this work is to characterize the physical properties of soil under different land uses and its effects on basin hydrology. In the Cauquenes watershed (central south of the rainfeed coastal Chile), five land uses were selected (native forest, pine forest plantations, meadows, vineyards, shrublands) with five replicates each ones. The morphologic profile description and the soil physical properties by genetic horizons were assessed to understand its effects on soil hydrology behavior. Besides, the water dynamic was characterized in a catena of a vineyard. The undisturbed original condition (native forest) ensures the best soil physical properties, due to the highest organic matter contents, the lowest bulk density and the higher aggregate stability. The meadows and the shrublands sites showed variable results depending on the magnitude of stocking rate, and pine industrial plantations shows the most affected soil properties, as result of forest harvest with heavy machinery. The long term soil use with vineyards explains a good soil physical condition, with an expected water dynamic during season; in this sense, the physiographical condition better explains the water content in the soil profile than the local soil properties, but future studies have to be done to understand the water dynamic in a watershed scale.

Keywords: Soil use change, soil degradation, water movement, soil catena.

(7108 - 2432) Soil-use changes: effect on the water dynamic in soils

Tania Soledad Rey Montoya[1]; Ditmar Kurtz[1]; Cristina Sanabria[1]; Carolina Fernandez Lopez[1]; Alicia Fabrizzio de Iorio[2]; Juan Fernando Gallardo Lancho[3]

INTA Corrientes[1]; FAUBA[2]; IRNASa[3]

The objective of the study was to assess the effects of the change of land use (measuring edaphic-climatic variables) after replacement natural grasslands by conifers in these sandy soils. The evaluated sites were a) natural grasslands (T), b) forested land by *Pinus* sp. after 5 yr (F). Province of Corrientes (Argentina) has a subtropical climate, i.e., wet weather, frequent water surplus during autumn and spring. The climatic classification indicates that average precipitation corresponds to 1,100 mm yr^{-1}, with the average annual temperature ranging between 20-22 °C. Soils are classified as *Psammaquents*, with limited evolution and dominate by the sandy fraction in all horizons (except relic underlying); that produces a fluctuating phreatic layer. This study includes 5 months (November 2016-March 2017). Soil moisture and groundwater dynamic study were measure and carried out in two soil profiles (one in each site); the clay horizon was found at -80 cm soil depth in both sites. Two portable automatic meteorological stations were placed in each site, including a sensor of soil moisture, with measurements every 10 cm to the soil depth of -1.2 m, with variable adjustment to field conditions. Temperature sensors was also included, permitting monitoring this variable. Data of temperature, rainfall and soil moisture were analyzed using the INFOSTAT software. The groundwater level was found at -55 and -65 cm soil depth in T and F, respectively. The average monthly temperature was similar in both sites, varying between 27 and 31 °C, registering the maximum average value in January (2017). The order of the monthly accumulated rainfall recorded was: December (2016) > January (2017) > March >

February > November, registering a greater value in T (645 mm) that in F (572 mm); the different found should be attributed to the canopy interception (and later evaporation). Soil moisture (SM) changed differently in the two sites from -55 cm soil depth, from November and January; in F, SM increased significantly from 18,7 ±0.17 mm to 32 ±1.1 mm; but in T, the value of SM did not change (26 ±1.1). For the months of December, February, and March the quantity of soil water retained at each site also varied; however, F retains more quantity of water just below to -65 cm soil depth. The data measured allow to infer that the soil water, perched above the clay horizon, varies between -55 and -75 cm soil depth and it is regulated by the water consumption of the trees.

(9492 - 824) Spatiotemporal Heterogeneity of Soil Water Content at Different Size of Gaps of *Pinus koraiensis*-Dominated Broadleaved Mixed Forest

wenbiao duan[1]; feng jing[1]; lixin chen[1]
School of Forestry, Northeast Forestry University[1]

Sampling plots were established by the method of grids in a forest gap and closed forest of *Pinus koraiensis*-dominated broadleaved mixed forests in Xiaoxing'anling Mountains, the volumetric soil water content (SWC) in I-III soil layers in medium and small gaps was measured by using time domain reflectometry 200 (TDR 200) during the period of July and September, 2010. The basic characteristics of SWC in each soil layer and the difference in SWC among various sampling locations in the same gap were analyzed by traditional statistics and geo-statistical methods, Kriging interpolating was performed and the spatial distribution maps of SWC were drawn by using surfer 8.0 software, the spatiotemporal heterogeneity of SWC in the gaps was analyzed. The aim of this study was to provide the theoretical basis and data support for further studies on soil physical properties, gap regeneration and sustainable management of *Pinus koraiensis*-dominated broadleaved mixed forest. The results showed that SWC in I-III soil layers in medium and small gaps fell into moderate variability. With increased soil depth, the SWC and patchy connection degree increased. The maximum SWC occurred in the area in and around gap center, and this area expanded and approached to the gap center with increased soil depth. However, the minimum SWC appeared within the expanded gaps and closed forest. For medium and small gaps, the difference in SWC in layer II among respective gap center and its edge was larger than that in layer I and layer III. Between July and September, the mean SWC exhibited single-peak variation, larger in medium gap than in small gap, the maximum appeared in August. The SWC in layer I and II in September decreased substantially than that in August, but there was slightly variation in layer III in September as compared with that in August.

(2693 - 2266) The influence of thin soil fractions in the attenuation of groundwater contamination

Francisco Afonso Cavalcanti-Junior[1]; Déborah de Oliveira[2]
University of São Paulo, Departamentnt of Geography, CP 72042, São Paulo, Brazil (cavalcantijunior@usp.br)[1]; University of São Paulo, Departamentnt of Geography, CP 72042, São Paulo, Brazil (debolive@usp.br)[2]

The physical characteristics of the soil are very important for their understanding, as well as to understand the natural and induced processes, such as the contamination frames. The main objective of this work is to bring notes on the relation of the physical properties of the soil in the attenuation of the contamination of groundwater by domestic effluents in the urban perimeter of the city of Turiaçu/Maranhão/Brazil. The area of study is located in the coastal region of the Legal Amazon, with predominance of plinthosols and characterized by average annual temperature of 27 º C and average precipitation of 2169mm. The collection of 37 samples was carried out in 8 points spread in the features top, strand and base, the collection of the samples complied with the morphological variations observed in the profiles. For the determination of the silt and clay fractions the Method of the Pipette was used and for sand the agitator with mesh sieves of 1, 00mm, was used; 0, 50mm; 0, 25mm; 0,125mm, and 0,66mm. In the tops, the profiles present a predominantly red-yellow coloration, and in the strands, there is predominance of the yellow color in the deeper horizons, in the two features the most striking characteristic is the presence concretions iron, from the surface, and Reaching more than 200 cm deep independent of the presence of gley horizon and pale colours. The first results point to an augmentation of thinner sediments (clay and silt) both downstream of the interfluves and in depth of the profiles, with a high concentration of clay at the base of the strands, characterized by paler coloring profiles and outcrop of the water table. The predominance of smaller particles exerts a strong influence on the quantity of soil porosity, in the case in question, and may make it less porous and hinder the drainage of water and other fluids. The reduced size of the fine particles increases the specific surface area (SSA) in this way, increasing the adsorption process, thus retaining atoms, molecules and hydrocarbon ions in these fractions. As assumptions, we believe that the attenuation of groundwater contamination is linked to the deviations of fluxes caused by geomorphological influence; To the concentration of fine particles, such as clay; And the high cationic exchange Capacity (CEC). However, the study still needs chemical and micromorphological analyses for better results.

(2422 - 3236) The role of cover crop in improving rainwater and nutrient use efficiency for a no-tilled dryland corn and soybean rotation system

Gary Feng[1]; Wei Yang[2]; Dennis Reginelli[3]
USDA-ARS, Genetics and Sustainable Agricultural Research Unit[1]; Department of Soil and Water Sciences, China Agricultural University[2]; Mississippi State University[3]

Integrating cover crops into a crop production system should be considered a long-term investment for conserving soil, nutrient and water resources. However, the E×M impact of this practice has not been well investigated under long-term various weather conditions. We conducted 4-yr field study (2014-2017) in the Mississippi Blackland Prairie of the United States and measured soil water content, nitrate, and organic carbon as well as cover crop, corn and soybean N uptake, height, cover, leaf area index, aboveground biomass, and grain yield. Then those data were used to calibrate and validate RZWQM2 model. We applied the calibrated agroecosystem model to conduct 80-yr (1938-2017) simulation study and determine the long-term impacts of a wheat cover crop from October to April on water balance, nitrogen and water use efficiency in a rainfed and no-tilled corn and soybean cropping system. Long-term simulation demonstrated that average annual percolation under the wheat cover crop system was decreased by 9%, 11%, and 12% in wet, normal, and dry years over 8 decades as compared with the plots without cover crop. Evaporation during crop vegetative growth period under cover crop plots was 25% less than under no cover crop plots over 8 decades. Crop evapotranspiration under cover crop was increased by 6% during corn growth period and by 3% during soybean growth

period. Corn and soybean yields were increased by 5% and 4% in the cover crop-based cropping system. Compared to the plots with no cover crop, the WUE for soybean and corn were respectively improved by 12% and by 9% for the plots with cover crop, due primarily to the decrease in soil evaporation. Growing a winter wheat cover crop between harvest and planting of corn and soybean reduced the NO_3-N loss by 16% and improved soil organic carbon by 15%. This study suggests that incorporating wheat cover crop between summer crops rotation is a promising practice to reduce deep percolation, restrict soil evaporation, and improve crop water and nitrogen use efficiency in the dryland system.

(3594 - 2049) Validation of a hydrological model to simulate water transport in a volcanic ash soil of southern Chile

Tihare Hermosilla[1]; José Dörner[2]; Dorota Dec[2]; Susana Valle[2]
Magíster en Ciencias del Suelo, Escuela de Graduados, Facultad de Ciencias Agrarias, Universidad Austral de Chile, Valdivia, Chile[1]; Instituto de Ingeniería Agraria y Suelos, Facultad de Ciencias Agrarias, Universidad Austral de Chile, Valdivia, Chile[2]

Climate change caused variations in water supplies in the soil, affecting agriculture and food security. This, emphasis the importance of exact estimation of soil water content in the forestry and agricultural sector. The latter, can be done by the estimation of soil water balance with lysimeters which are high precision instruments. The information generate by them, however, refers to a certain area. The extrapolation of data is possible through modeling, with its respective validation. Andisoles soils are characterized by low bulk density, high water storage capacity, water conduction and contraction. The objective of this study is to validate a hydrological model that allows simulating the potential effects of global climate change on the availability of water in a volcanic ash soil. The water transport was modeled for Andisol (Duric Hapludand) using the HYDRUS-1D. During lysimeter installation undisturbed soils samples were collected to determine the hydraulic properties of the soils. Sensors to measure volumetric water content were installed at 10, 20, 60 cm. and the registered information will be used to validate the model comparing them with the modeled data. The simulation considers evaluating the variations in the moisture content of a Duric Hapludand soil, assuming reduction scenarios in rainfall by 15% and 20%. It is expected that the HYDRUS-1D allows modeling the water transport in a Duric Hapludand soil, and obtain a high level of adjustment with respect to the values actually measured. Thereafter, the simulate of different scenario whicho quantify the potential effects of global climate change on the availability of water in the soil for plants. Based on the expected results, information can be generated that allows a more efficient use of water resources, solving problems related to irrigation water needs, environmental considerations and determination of water surpluses and / or projections of water supply.

(8326 - 360) Variability of soil hydraulic properties and its impact on predictions of an agro-hydrological model

Thalita Campos Oliveira[1]; Quirijn de Jong van Lier[1]
Center for Nuclear Energy in Agriculture/University os São Paulo[1]

Soil hydraulic properties may show a high spatial variability both vertically and horizontally. The strong non-linearity of soil hydraulic properties relationships (ϑ-h-K) disqualifies conventional statistics for the purpose of describing this variability. In an agro-hydrological modeling context, soil hydraulic properties are key input parameter and their variability may affect prediction of water balance components and, ultimately, crop yield. The aim of this study is to investigate the impact of within-field variability of soil hydraulic properties on transpiration and crop yield predictions for different scenarios using the SWAP model, and to evaluate the sensitivity of SWAP predictions to soil hydraulic parameters through a stochastic procedure. A soil hydraulic property dataset (Van Genuchten-Mualem ϑ_s, ϑ_r, α n, K_{sat} and λ) obtained by inverse modeling of field water content data measured in a small agricultural field in Piracicaba, Brazil was used. The climate scenarios comprised meteorological records from the past 30 years. Simulated cropping systems included an annual (maize) and a perennial (pasture) crop. Results about model sensitivity to the soil hydraulic properties and the consequent impact of the within-field variability on the model predictions will be presented and discussed.

(6198 - 794) Water retention properties of stony soils.

Balin Robertson[1]; Peter Almond[1]; Sam Carrick[2]; Henry Chau[1]; Carol Smith[1]
Lincoln University, Lincoln, New Zealand[1]; Landcare Research, Lincoln, New Zealand[2]

New Zealand is currently in a period of land-use intensification including expansion of irrigated grazed-pasture systems, particularly in the Canterbury region, where two-thirds of irrigated land is on stony soils. Environmental models consistently predict stony soils as being vulnerable to nutrient leaching because of their low water storage and high hydraulic conductivity. However, leaching predictions are based on limited experimental research, and rely mostly on estimated soil water attributes because of the limitations of small-core based techniques for measuring soil water retention in stony soils. Nutrient leaching models that New Zealand uses for nutrient discharge regulation are strongly sensitive to soil attribute data, particularly water holding capacity and field capacity. In New Zealand, field capacity is taken as the water content at 10 kPa tension, which is applied to all soils, but on stony soils our preliminary research indicates that this tension may not be appropriate. This paper presents results from a project aimed at determining the appropriate water tension for field capacity, and key drivers of its variation, in stony soils. Multiple locations with soils of varying stone content were chosen for field sampling across the Canterbury region. All sites were under pastoral dairy grazing. At each site, two sampling locations were selected, one site on an area of land that has been irrigated for > 3 years, the other on an area of land that has never been irrigated. Field work was conducted in winter to early spring, to ensure the antecedent soil moisture was near field capacity. At each site, an initial infiltration experiment was conducted to thoroughly wet the soil. After two days drainage (~field capacity), a 30 x 30 cm soil pit was excavated in 10 cm increments to 60 cm depth. In each increment, water tension was measured with tensiometer probes, and samples collected for measurements of particle size distribution, rock fragment volume and size, carbon content, specific surface area and soil water content. Results from our study will show the variation in field capacity tension that can occur down a soil profile, among different stony soils, and between dryland and irrigated practices. Preliminary results indicate field capacity may occur at tensions less than 10 kPa, implying that changes in nutrient discharge predictions and management strategies for Canterbury stony soils may be necessary.

(4047 - 1882) Adsorption kinetics of dissolve organic matter at the water-air interface

Gilboa Arye[1]
French Associates Institute for Agriculture and Biotechnology of Drylands, The Jacob Blaustein Institutes for Desert Research, Ben-Gurion University of the Negev, Israel[1]

The surface active nature of humic substances and naturally occurring dissolved organic matter (DOM), has been confirmed by a growing number of studies. The main quantity from which the surface activity has been deduced obtained from measurements of surface-tension (ST, mN m^{-1}) at the water/air interface. All studies demonstrated the decay in the ST of water (72.5 mN m^{-1} at 25°C) with increased aqueous concentrations of dissolved organic carbon (DOC). The ST values reported for DOM should be defined as equilibrium ST, when the adsorption and orientation of the amphipathic molecule at the water/air interface have reached equilibrium state. However, for any amphipathic molecule the adsorption kinetics at the water/air interface is not reached instantaneously and may range from seconds up to several hours. The time depended ST started from the time where a new water/air interface is formed. Thereafter, amphipathic molecules need first to diffuse from the bulk solution to the interface, subsequently adsorb and simultaneously achieving the correct orientation at the interface. The consequence of this process will be expressed in a decay of the ST as a function of time until it will reach the equilibrium surface tension. The main objective of this study was to quantify the rate and extent of DOM adsorption kinetics at the water-air interface through dynamic surface tension measurement, using the pendant drop method. The applicability of a diffusion-only model to describe the results will be presented and discussed.

(9825 - 1186) An advanced wet oxidation methods of soil organic carbon determination

sanjib kar[1]
University of calcutta[1]

An advanced wet oxidation methods of soil organic carbon determination Sanjib Kar Department of Agricultural Chemistry & Soil Science, Institute of Agricultural Science, University of Calcutta ; 35, B.C.Road; Kolkata-700019, India. E-mail: sanjib_@yahoo.co.iun Abstract: Several methods exists for determining soil organic carbon, and each one has its own advantages and limitations. Dry combustion method is an accurate method to measure total soil carbon, it is rather expensive. Therefore, wet oxidation is widely used. This study aimed for an advanced wet oxidation method for the determination of soil organic carbon and their relationship with soil mineralogy and texture. In the proposed method soil organic carbon is determined using nitric-sulphuric- potassium per chlorate digestion. For this study five tropical soil sample from 0-15 cm. depth were collected from different regions of India. The highest estimate of soil organic carbon was established in this new method in comparison with Walkley Black, Modified Walkley Black, Mebius, Schollenberges, Tube digestion and Tyurin methods. The data obtained using the proposed method co-rrelate strongly (r= 0.96-99 , p≤0.05) with the data obtained from other methods. Soil mineralogy interfered with the determination of soil organic carbon. Key word: Soil organic carbon determination, wet oxidation, dry combustion, Walkley-Black.

(7712 - 272) Benefits of biochar application to tropical soils: greenhouse gas emissions, soil improvement and crop yield

Carlos Eduardo P Cerri[1]; Tatiana F Rittl[1]; Thalita F Abbruzzini[1]; Mariana D O Zenero[1]; Sarah V Novais[1]; Rafaela F Conz[1]; Sara J Duarte[1]
University of São Paulo, Luiz de Queiroz College of Agriculture (ESALQ/USP)[1]

Researchers are pointing out the importance of greenhouse gas (GHG) emission reduction and increase carbon sequestration in the soil. Biochar, the solid product of pyrolysis, has been proposed as part of agronomic and environmental management to simultaneously improve soil properties and address climate mitigation. Although research on biochar has now accumulated an appreciable volume of data regarding effect of biochar in GHG emissions, soil properties and crop yields specially in temperate conditions, much less has been done for addressing these questions in tropical conditions. This study evaluated the benefits of applying biochar to soils under i) laboratory incubations under controlled conditions, ii) greenhouse pot experiments and iii) cultivation of sugarcane in field conditions in a sandy tropical soil. We used biochar produced from different organic materials (poultry litter, sugarcane straw, rice hull, sawdust and *Miscanthus*) pyrolysed at final temperatures of 350˚C, 450˚C, 550˚C and 650˚C. The effect of temperature and feedstock type on the variability of physicochemical properties of biochars was evaluated through measurements of pH, electrical conductivity, cation exchange capacity, macronutrient content, proximate and elemental analyses, Fourier transform infrared spectroscopy, thermogravimetric analyses, GHG emissions and biological analyses. We assess not only aspects related to the mitigation of GHG emissions to the atmosphere, but also changes in soil chemical, physical and biological attributes and crop productivity. The main findings of this research, indicate that the application of biochar can improve soil conditions and therefore help to enhance agricultural production system, reconciling high energy efficiency and contribute to the mitigation of GHG emissions to the atmosphere.

(9084 - 1330) Carbon stock losses and decomposition in riparian and well- drained areas under lowland rainforest transformation systems on Sumatra, Indonesia

Nina Hennings[1]; Thomas Guillaume[2]; Michaela Dippold[3]; Yakov Kuzyakov[1]
Soil Science of Temperate Ecosystem Science, University of Göttingen[1]; 2École Polytechnique Fédérale de Lausanne[2]; Biogeochemistry of Agroecosystems, University of Göttingen[3]

Tropical deforestation for agricultural land use changes soil organic carbon (SOC) dynamics. Indonesia´s forest ranked among the three largest rainforests areas worldwide experiences a severe forest loss since the 1970s, which alters an old and large carbon pool. Carbon stocks in soils of riparian zones are strongly affected by forest conversion that lead to changes in water regime and water level drops. We investigated the effects of rainforest transformations in riparian and well-drained areas of Sumatra, on soil C content, stocks and decomposability. C losses after conversion of rainforests to rubber and oil palm plantations in riparian areas were compared to that in plantations in well-drained mineral soils. C content in Ah-horizons of well-drained soils under oil palm and rubber plantations

decreased for 70% and 62% after forest conversion. In riparian soils, C content decreased between 25% and 66% after land use change. There, soil C content is not only dependent on vegetation inputs, but also on a complex riparian soil pedogenesis. Carbon stocks in well-drained soils decreased by conversion from forest to oil palm plantations for about 42% and in rubber plantation for about 40%. In riparian soils carbon stocks decreased from 269 Mg C ha^{-1} to 46 Mg C ha^{-1} (68%) in oil palm and 43 Mg C ha^{-1} (71%) in rubber plantations. $\delta^{13}C$ signature in riparian soils shows an inhomogeneous depth profile ranging from -26 to -31‰, whereas well-drained soils show a homogenous picture with more enriched $\delta^{13}C$ signature with increasing depth. This inhomogeneous depth profile in riparian soils indicates that erosion and deposition dynamics overlie the decomposition effects on the SOC isotopy.

I-type granites are originated from melting of igneous source rocks, whereas S-type granites result from melting of sedimentar sources. This gives rise to differences in mineralogical and geochemical characteristics of the rocks. The objective of this study was to address the effect of petrology and mineralogy of I- and S-type granites on total organic carbon stocks across a climosequence. The study area lies in the Borborema Province (Pernambuco State), northeastern Brazil. Three soil profiles and the underlying rocks (from both I- and S-type granites) were sampled under native vegetation in the three climatic zones. The total organic carbon stocks were calculated using the equation: TOC stocks = total organic carbon (%) x bulk density (g cm^{-3}) x sampling depth (m). The type of parent material governed the rates of carbon accumulation in soils. The mean TOC contents were always higher in soil profiles developed on I-type granites. These soil profiles showed mean TOC values of 17.2, 12.0, 13,4 g kg^{-1} for humid, sub-humid and dry zones. On the other hand, the mean TOC values for S-type granite soils were only 10.2, 2.6, 2.8 g kg^{-1}. As a result, TOC stocks in the I- and S-granite soils showed a clear climatic zonation with increasing values from the dry zone to the humid zone. It is important to highlight that, regardless climate, the highest TOC stocks were recorded in soil profiles developed from I-type granite soils (46 to 207 Mg ha^{-1}); S-type granite soils presented TOC stocks ranging from 23 to 150 Mg ha^{-1}. This finding demonstrates that the parent material rather than the climate plays the most significant role on determining the soil carbon stocks. This outcome can result from both the natural higher soil fertility that allows biomass increasing and the higher clay contents in I-type soils.

(5975 - 1494) Characteristics of Biochar produced from water hyacinth in different pyrolysis temperatures

Luana Bottezini[1]; Deborah Pinheiro Dick[2]; Daniel Hanke[3]; Alberto Wiesniewski Junior[4]; Heike Knicker[5]; Ingred Suellen Carvalho Carregosa[4]; Fernanda Carolina de Santana Oliveira Apolônio[4]
Federal University of Rio Grande do Sul, 7712, Avenida Bento Gonçalves, Porto Alegre, 91540000, Rio Grande do Sul (luanabott@gmail.com)[1]; Federal University of Rio Grande do Sul, 7712, Avenida Bento Gonçalves, Porto Alegre, 91540000, Rio Grande do Sul[2]; Federal University of Pampa, Dom Pedrito, Rio Grande do Sul[3]; Federal University of Sergipe, Av. Marechal Rondon, São Cristóvão, 49100000, Sergipe[4]; Institute of Natural Resources and Agrobiology, 10, Av. Reina Mercedes, Sevilla, E-41012, Spain[5]

The production of Biochar (BC) from agroindustry wastes, with the goal to use it as soil conditioner, has grown in the last years. Water Hyacinth (WH) is a plague that, due to water eutrophication, occurs frequently in rivers and estuaries along the Brazilian Coast hampering port activities and navigation. WH may contain a significant phosphorus (P) concentration, and that makes it a potential source for soil P fertilization. Our work aimed to determine chemical and molecular composition of WH biochars (WHBC) produced in different temperatures in order to identify the adequate conditions for soil conditioners production. WH samples from Sergipe (BR) were air-dried and submitted to controlled pyrolysis under N_2 (5 L min^{-1}) at 400, 500 and 600°C. In WH biomass and in WHBC's, elemental composition was determined by EDX spectroscopy (EDX-720/800HS) and C and N content by dry combustion (Flash EA1112). Molecular composition was investigated by ^{13}C and ^{31}P NMR CP/MAS (Bruker DSX 200) and by FTIR (Shimadzu 8300 FTIR) spectroscopy. From 400 to 500°C both C and P content increased and then decreased for temperature of 600ºC. On the contrary, N content decreased steadily from 400 to 600°C, indicating a continuous N loss until 600ºC. The C/N ratio varied from 13 to 18, and the values are relatively low in comparison to that of high temperature BC's. From the ^{31}P NMR spectra, phosphate was identified in all WHBC's. The proportion of O/N-alkyl C group decreased from 15.8 ($WHBC_{400}$) to 6.4 % ($WHBC_{600}$) following the behavior of N content. Up to 500°C alkyl C increased from 31 to 38% and decreased to 20% at 600°C, while that of aromatic C gradually increased reaching 66% in $WHBC_{600}$. Carboxyl C decreased from 6.2% to 5.7 % with temperature rise, while carbonyl C increased slightly (1.8 to 2.3%). It seems that heating from 400 to 500°C carbohydrates are the main consumed structures while alkyl and aromatic structures get enriched. By further temperature rise, an increase of aromatic C occurs mainly at the expenses of alkyl C. In the WHBC's, the chemical form of P is absorbable by plants, but its real availability should be further tested with bioassays. Based on the P concentration, the sample most adequate for soil conditioner would be $WHBC_{500}$. However, by considering the C/N ratio and the proportion of Oxygen containing groups, $WHBC_{400}$ appears as a better choice. Incubation experiments with plants as bioindicators should be performed in order to elucidate this question.

(3869 - 2641) Characterization and bioactivity of humic acids from different origins in rice plants.

Tadeu Augusto van Tol de Castro[1]; Ricardo Luis Louro Berbara[1]; Orlando Carlos Huertas Tavares[1]; Marcos Gervasio Pereira[1]; Andrés Calderín García[1]

Universidade Federal Rural do Rio de Janeiro[1]

Humic substances are widely distributed over the Earth and are the major constituent of organic matter, being classified in: humic acids (HA), fulvic acids (FA) and humin. Biological activity of these supramolecules is directly associated with their origin, molecular size, composition, structure and concentration, therefore the characterization of humic substances is necessary to understand the different functions and properties of these compounds. In this work were characterized HA extracted from different sources of origin: histosol (HASOIL), vermicompost (HAVC) and sediment of Rio Negro-AM (HARN), and the effects on root system development and in the biomass of rice (*Oryza sativa* L.) of the BRS Esmeralda variety, cultivated in a growth chamber were evaluated. The HA was obtained following the International Society of Humic Substances extraction methodology and characterized by ^{13}C isotope nuclear magnetic resonance spectroscopy with cross polarization and magic angle spin (CP MAS ^{13}C NMR). Three experiments were carried out, occurring application of HA of different origins in the root system, using six treatments with different concentrations of this substance, equivalent to 0, 2, 5, 10, 30 and 50 mg $HA.L^{-1}$. Experimental design was a completely randomized design with five repetitions. After seven days of humic acids application was evaluated the length (mm) and quantity of roots. The results obtained on the structural characteristics of HA shows that HASOIL is more aromatic and hydrophobic than HARN and HAVC, presenting a high degree of recalcitrance. The HARN also has a high amount of recalcitrant structures, but with predominance of non-functionalized aliphatic carbons. The HAVC is the most polar, explained by the high functionalization of aliphatic and aromatic carbons. It has also been observed that HAVC has the greatest effects on the quantity of roots this may indicate that the root emission in rice plants responds to the effects of structures with higher polarity and lower hydrophobicity. On the other hand, root elongation appears to be more responsive to structures with more recalcitrant properties. Data also showed that higher polarity and lower hydrophobicity are not structural properties responsible for biomass production, whereas structures with a certain recalcitrance degree can stimulate the biomass production both in leaves or roots.

(6608 - 3047) Charcoal contribution to umbric epipedons of Ferralsols in Brazilian cerrado biome

Marina Justi[1]; Judith Schellekens[2]; Pablo Vidal-Torrado[2]
UFLA[1]; ESALQ/USP[2]

Ferralsols with humic properties (umbric Ferralsols) are characterised by a thick (≥100 cm), dark A horizon rich in organic matter (OM) and occur next to Ferralsols without humic characteristics. Our purpose was to contribute to the understanding of the stability of carbon in these soils. To this end we focussed on the Cerrado (Brazilian savanna) biome, which has a natural association with wildfires. Profiles were selected in Grão Mogol (Minas Gerais) and sampled according to pedogenic horizon, including two humic Ferralsols (HF1, HF2) and a nearby Ferralsol without humic characteristics, i.e., a reference profile (TF). Macroscopic charcoal fragments (> 2 mm) were quantified for all samples, while micromorphology was studied for samples of selected horizons to evaluate micro-charcoal and biological activity. The contribution from black carbon (BC) to other soil OM fractions was determined by analytical pyrolysis, and included the free (FLF) and occluded (OLF) light fractions, the NaOH extractable OM (EXT) and the remaining residue (RES). The light fractions represent relatively intact BC (i.e. charcoal), the EXT contains more decomposed material and the RES represents residual OM that is difficult to decompose. All profiles contained two visible charcoal layers with radiocarbon dates up to 8600 yr BP and reflecting past fire events. The macroscopic charcoal content was larger in HF1 and HF2 than in TF. Micromorphology showed that HF1 and HF2 also had more microscopic charcoal fragments than TF. In addition, intense bioturbation, charcoal fragmentation and incorporation in soil matrix were observed from thin sections of all three profiles. Analytical pyrolysis showed a larger contribution from BC in HF1 and HF2 than in TF in the FLF, while no such difference was observed in the other fractions (OLF, EXT, RES). Thus, it was concluded that BC plays a major role in the formation of umbric epipedons in the Brazilian Cerrado. The larger contribution from charcoal to the HF profiles may be due to differences in input (more woody plants) or in the degree of decomposition (less decomposed charcoal). All three profiles showed a similar relative increase of BC with depth in the RES, in agreement with the recalcitrance of BC in the soil environment and demonstrating no significant difference in decomposition between HF and TF. A larger contribution from woody plants in Cerrado may suggest that soil humidity controls local differences in vegetation composition.

(8407 - 430) Comparison of three methods to determine organic matter in alluvial soils cultivated with cocoa

Salomon Barrezueta-Unda[1]; Jenner Becerra-Leon[1]; Antonio Paz Gonzalez[2]
University Technique of Machala[1]; University of A Coruña[2]

The aim of the research was to compare the values obtained of soil organic matter (SOM) by dry combustion (DC) with Walkley Black methodology (WB) and weight loss by Ignition (LOI) by four temperatures (300°C, 350°C, 430°C and 600°C) in some soils with cocoa plantations. The starting point of this research was selecting randomly 30 cultivated plots with cocoa of alluvial soil origin, located in El Oro province, Ecuador. To determine SOM, the sample was dried and sifted by using a 2 mm sieve previously the use of the methods below: Dry combustion (DC), wet oxidation of Wlakley and Back (WB) and loss for ignition (LOI), which consisted of weighing 5 g of soil for sample that were placed on a heater to 105 ºC for 3 hours (h) to eliminate moisture; Then, the samples were cooled in a drying apparatus and its weight was registered. After they were placed in a muffle furnace which maintained 80 °C as initial temperature, then the muffle was programmed to maintain the temperature for 2 h, the proposed maximum status that were 300, 350, 430 and 600 °C. The following step was to transfer the muffle furnace to a dryer and the weight was registered again. The SOM was calculated by differentiating the weight at different temperatures. The linear regression analysis was carried out between the results DC as a dependent variable with the data of the average derivative from the method WB and the four temperatures of the LOI method as independent variables. The results of SOM statistical means were DC 3,19 g kg-1 ±1,75 >; WB 3,38 g kg-1±1.86 >; LOI300 3,51 g kg-1±1,55 >; LOI350 4,91 g kg-1±1,84 >; LOI430 4,99 g kg-1±2,07 >; LOI 8,47 g kg-1 ±3,33. With ranges of 0,84-8,29 g kg-1 for DC and 2,25-17,41 g kg-1 for LOI600. The Pearson matrix showed high DC correlation with the WB method (0,981 * *), followed by LOI300 (0,725 * *), LOI430 (0,698 * *), LOI350 (0,674 * *) and LOI600 (0,648 * *). The best R2 was between WB and DC with an 0,962. In the case of LOI, the adjustments were: LO300 R2=0,526; LOI350 R2=0,454; LOI430 R2=0,454; LOI600 R2 0,323. ANOVA among the methods was significant with a p≤0,000. Tukey's test grouped 5 subsets (DCa, WBab, LOI300ab, LOI350bc, LOI430c, LOI600d). To conclude, the methods DC and WB are recommended for alluvial soils cultivated with cocoa, although the method LOI is not discarded, being necessary to extend the study with lower temperature or diminish the ignition times, up to reaching a R2>

0,9.

(1464 - 2830) Contribution of roots and shoots from summer crops on physical fractions of soil organic matter in two lowland soils

Bruno Chaves[1]; Sandro José Giacomini[1]; Douglas Adams Weiler[1]; Mariana Ferneda Dossin[1]; Lethícia Rosa Neto[1]; Rafael Alexandre Bick[1]; Roberta Lago Giovelli[1]

Federal University of Santa Maria[1]

Sorghum (*Sorghum bicolor*) and soybean (*Glycine max*) are being cropedd in rotation with flooded rice (Oryza sativa) in Rio Grande do Sul state as an alternative to reduce weeds pressure and increase profits and land use efficiency. Little is known about the effects of these crop residues on soil carbon (C) stabilization in physical fractions of soil organic matter (FF-SOM) in lowland soils. The objective of this study was evaluate fate of C from sorghum, soybean and rice residues (roots and shoots) in FF-SOM in two Planosols (A – 9.9% clay, 15,5% silt and 74.6% sand; B – 17.3% clay, 28,7% and 54% sand). We incubated soil and crop residues ^{13}C labelled during 360 days: in the first 180 days, soil was kept moist through frequent irrigations; from 180 to 360 days soil was flooded to reproduce an irrigated rice system. Shoot residues were kept on soil surface while roots were incorporated to the soil. Soil was physically fractionated by size of >250 µm, 250-53 µm and < 53 µm at zero, 30, 180 and 360 days of incubation. There was a three-way interactive effect of soil, residue and physical fraction on soil C. In general, the fate of the majority of the residue-derived C in the soil in first 30 days of incubation was in the >250 and 250-53 µm fractions. The residue-derived C recovered at 30 days in these fractions range from 41.2 to 100% and from 63.9 to 82.9% of total C incorporated to the soil by shoots and roots, respectively. The contribution of <53 µm fraction to total soil carbon increased over the incubation. At 360 days, the residue-derived C recovered in <53 µm fraction range from 28.7 to 52.8% and from 10.6 to 53.5% of total C incorporated to the soil by shoots and roots, respectively. Rice shoot in Planosol B had the highest residue-derived C recovered (27.4%) at the end of incubation. The root-derived C in Planosol B was higher in soybean (48.3%) and sorghum (38.9%) than rice (21.2%) treatment, but there is no difference among the residues in Planosol A at 360 days. Physical fractionation showed higher shoot-derived C recovery in Planosol B than Planosol A, but root-derived C recovered was higher in Planosol B only for soybean residues. Our results showed that sorghum and soybean residues might contribute for C incorporation on lowland soils, especially in soils with higher stabilization matrix. Sorghum and soybean are more efficient to soil C incorporation in initial stages of residues decomposition.

(9535 - 2081) Correction and maintenance of phosphorus available in Oxisoils under no-tillage at different levels of fertility

Joana Schroeder de Souza[1]; Tales Tiecher[1]; Cimélio Bayes[1]; Magno Batista Amorim[2]; Sandra Mara Vieira Fontoura[3]; Renato Moraes[3]

Federal University of Rio Grande do Sul[1]; Federal Institute of Rondônia[2]; Agraria Foundation[3]

In consolidation system of no-tillage, due to the superficial application of limestone, it is not recommended to apply rock phosphate. In addition, with increasing demand for fertilizers, especially in areas of high production potential, new sources of phosphorus in the market are offered to producers without proper scientific evidence. This study was carried out on Oxisoils in the center-south region of Paraná, with the goal of evaluating how different sources of P could modify the available phosphorus in the soils in SPD with different levels of P. Field experiments were conducted with seven sources of P (Super Simple-SS, Super Triple-ST, Yoorin, Yookarin, FN Bayóvar, Shell TSPS and Mosaic MES9) at three sites with low, medium and high soil P levels. The treatments consisted in the annual application of the recommended dose(115, 190 and 350kg ha-1 of P2O5 for soils with high, medium and low, respectively)based on the soluble P contents of each source and on two special fertilization programs (System and Culture), with three replicates in a randomized block design. Three years after the installation of the experiments, the content of phosphorus available was evaluated by the resin method at 0-20 cm depth. The application of 115 kg ha-1 to the soil with high P content did not alter the levels of available phosphorus of soil, since this is just maintenance rate. For soil with a mean P content only the Yoorin source did not increase the phosphorus content to the critical level (45 mg dm-3) after the annual application of 190 kg ha1, totalizing 570 kg ha-1 of P2O5. However, the soluble sources increased P available content by resin method to the critical level, demonstrating that the recommended dose was effective in correcting soil phosphorus deficiency. In soil with low P content, the correction of available phosphorus content per resin to the critical content was not possible even with the application of 1050 kg ha-1 of P2O5, regardless the source used. The results indicate that the available soil P content is evolving in this soil, where fertilization increased, on average, from 4 mg dm-3 to 20 mg dm-3. Regarding the fertilization program, there was no difference in available soil P for all sources. In general, we can conclude that in soil deficient in P with medium and low content, the correction must be made with soluble sources of P, since the yield of the crops is dependent on the supply of this nutrient.

(1737 - 2864) Cuantification and characterization of humics acids by ^{13}-nmr solid state spectroscopy and ir in andisols under different use systems

William Chavarriaga Montoya[1]; Juan Carlos Montoya Salazar[2]; Juan Carlos Menjivar Flores[3]

Caldas University[1]; Manizales University[2]; UNIVERSIDAD NACIONAL DE COLOMBIA-PALMIRA[3]

Humic Substances (SH) are materials with a high degree of transformation, grouped in Humic Acids (AH), Fulvic Acids (AF) and Humins (H). Andisols are characterized by high accumulations of SOM, constituting very stable complexes with allophane, Fe and Al. The AH extracted from a Typic Melanudands and a Typic Haplustands (0-10cm.), Bellow cover of Forest, Coffee-sun (*Coffea Arabiga* Var-Caturra), Café-Walnut (CA-*Cordia alliodora*) and Grass (*Brachiaria* sp.) were analyzed by ^{13}C-NMR spectroscopy in solid state, IR, and E4/E6 ratio. The Oxidable-C (Walkley-Black) was determined in the bulk, fine and humified fractions of the soil. The SOM was separated by shaking in jars equipment (180rpm) and then by sieves of 106 and 53µm in vertical shaker (50hz). Suspensions were dried (55°C) and sequential extraction was carried out in $Na_2B_4O_7$, $Na_4P_2O_7$ and NaOH 0.1 N and HA was separated in HCl (6N), which were purified using XAD-16, REXIN-101H and dialysis membranes (10,000 Da). The highest OM-Humified contents were recorded in Forest and decreased with the change in land use; Humins predominated in Coffee-Sun and Grass. %OC and number of extractions performed (>13) indicated a higher retention strength of the HS in the Typic Melanudands. The Optic coefficients (>0.38) and E4/E6 (>0.72) indicated were higher in

the Typic Haplustands. ^{13}C-NMR spectra of the HA revealed high contents of COOH groups in Typic Haplustands and aromatics groups in Typic Melanudands; COOH and OH-alcoholic groups contents in Forest are more highly; The IR specter confirmed the differences between the systems evaluated. E4/E6 values indicated differences in molecular condensation of both Andisols for AH (<4.4 and 5.3-6.9). Hydrophobicity indexes were high in all systems and higher in Forest soils (2.22 and 1.91), confirming this characteristic.

(2706 - 1379) Decomposition of Eucalyptus leaves in dystrophic soil in phytophysiognomy of the Cerrado

Sarah Camelo da Silva[1]; Marco Bruno Xavier Valadão[1]; Jonas Inkotte[1]; Karla Monique Silva Carneiro Valadão[2]; Alcides Gatto[1]; Reginaldo Sérgio Pereira[1]
UNB[1]; UNEMAT[2]

In Brazil Eucalyptus is a species with rapid development, but for being an exotic species has little knowledge about its use in the recovery of degraded areas, such as the impact on the balance of edaphic processes. The use of exotic species in the recovery of degraded areas has gained greater visibility after the last modifications occurred in the Forest Code in 2012, by Law 12.651. The restoration of permanent preservation areas and legal reserve, both consolidated, with the planting of exotic species interspersed with native species, where the area reconciled with exotic species cannot exceed fifty percent (50%) of the total area to be recovered. This study aims to analyze the speed of eucalyptus leaf decomposition in a commercial stand, and in a Cerrado Típico area, so as to be able to tell if there is a significant difference in leaf decomposition. The study was carried out at the Fazenda Água Limpa (FAL), which belongs to the University of Brasília, located in the Federal District (15 ° 56'-15 59 'S and 47 ° 55'-47 58' WGr.). The planting of the hybrid *Eucalyptus grandis* x *Eucalyptus urophylla* has 49 months old, planted in 3x2m spacing. At stand, the soil was classified as Red-Yellow Latosol (Oxisol). The soil of the Cerrado Típico was Red Latosol (Oxisol), both areas have dystrophic soils. In each area, 15 litter bags with 20 cm² and 20 g of eucalyptus leaves were randomly placed. The litter bags were rescued after 30 and 60 days of exposure in the field. The results obtained showed a difference in the decomposition with both 30 days and 60 days. At 30 days leaf decomposition in the Cerrado Típico was faster (3.37g) than the eucalyptus stand (1.86g) ($p < 0.05$). The same was observed in the collection with 60 days where the Closed Typical area has a decomposition of 5.97g, and in the eucalyptus area, the decomposition was 4.64g ($p < 0.05$). This difference in decomposition may occur due to soil water content, quantity and quality of microfauna and chemical attributes in general. The results demonstrated that a Cerrado dystrophic soil is able to assimilate more quickly the vegetal organic material of exotic origin. In areas to be recovered this capacity can accelerate carbon and nutrients entering the soil, thus improving its physical and chemical properties.

(7237 - 3141) Determination of Oil in Contamined Soil by Low-Field Nuclear Magnetic Resonance (NMR)

Etelvino Henrique Novotny[1]; Catarina Mendes Rebello[2]; Silvio Roberto de Lucena Tavares[1]
Embrapa Soils[1]; Universidade Federal do Estado do Rio de Janeiro (UNIRIO)[2]

Antropic contamination of soils by oil is an recent issue, which had the XIX century as the begin of oil exploration, and has grown exceptionally ever since. This activity has the potential to be very problematic in its impacts, causing high local degradation. These impacts can affect a large population, such as being a drastic damage to the environment, due to the possibility of acting as central nervous system depressants and presenting chronic toxicity, as well as reaching the groundwater and contaminating it with benzene, toluene, ethylbenzene and xylenes, which are components of oil. For this reason, the management of this product requires the adoption of a high standard of socio-environmental responsibility, once the components of this oil take hundreds of years to be decomposed in nature, being an imminent danger. Several techniques for the recovery of these degraded areas were developed, but one of the most prominent would be phytoremediation, an effective technique for the minimization of these pollutants in the environment, which utilizes plant species. And then, the monitoring of contaminated area and under remediation is necessary. However, the available analytical methods are very expensive, time consuming and usually require dangerous reagents (e.g. GC-MS). Therefore, the present work proposes a new methodology for the quantification of oil in soil using low field Nuclear Magnetic Resonance (NMR). The use of low-field NMR has proved to be very efficient, since it is a low-cost technique, presents rapid quantification measures, and performs measurements in the intact soil, without any preparation. Therefore, preliminary studies were carried out and a calibration curve of the oil in dry soil, from 0.2 till 30% of oil (w/w) was performed, obtaining an excellent model with coefficient of determination (R^2) of 0.9996.

(6822 - 3090) Determination of the parameters: Organic Matter, Density and pH of the soil in areas of plant suppression in the Municipality of Altamira-Pará-Brazil

Samia Cristina de Lima Lisboa[1]; Sandra Andrea Santos da Silva[1]; Rainério Meireles da Silva[1]; Davi da Silva Teixeira[1]; Yuri Rafael da Silva Rodrigues[1]
Universidade Federal do Pará, Campus Altamira[1]

The anthropic use of the soil, brings varied changes on the attributes, be they chemical and / or physical. Among the attributes of soil assessments, organic matter and pH, have been suggested as key indicators in soil quality, influencing soil performance and functions. Due to the intense exploitation of natural resources caused by urbanization, vegetation suppression, among other mitigating factors, the Forest region of the municipality of Altamira in the state of Pará has suffered a significant environmental crisis due to the implementation of Collective Urban Resettlement due to the construction of the Hydroelectric Power Plant Belo Monte. In 2015, an area of secondary vegetation located near the banks of the Xingu River was suppressed for the construction of an indigenous resettlement, leading to the stacking of wood, with the area known as a storage yard. The objective of this work was to determine soil physicochemical parameters in areas subject to vegetation suppression (T1) and storage yard (T2) in comparison to secondary vegetation (T3) in the city of Altamira-Pa. The study area is located 8 km from the city of Altamira, in the west of the State of Pará, at an altitude of 111 meters above sea level. The soil samples were collected from January to March 2017 in three treatments, and the physical-chemical parameters evaluated were: density, pH and organic matter. According to the values of the density amplitude that corresponds to the soil type (clayey, it ranges from 1.00 g/cm³ to 1.25 g/cm³, sandy from 1.25 g/cm³ to 1.40 g/cm), the average density in the area of vegetation suppression and secondary vegetation were 1.13 g/cm³ and 1.04 g/cm³ respectively, the storage yard presented the average

of 1.32 g/cm³, high density value indicating a certain local compaction level (T2). The amount of organic matter is high in all treatments, being higher in the secondary vegetation, observing that, even suppressing vegetation occurred, there was no total organic matter decline, since there is still a presence in the superficial layer influencing positively in the characteristics related to soil fertility. The pH had a high level of acidity in all treatments, such result may have been influenced due to rainwater, since the samples were collected in the rainy months. Statistical analysis reveals that there was no significant difference between treatments, which may be justified by the time of suppression in the area.

Keywords: KEY WORDS: Organic matter, suppression, quality.

(1264 - 1027) Does soil management system affect C content of a coarse sandy loam Amazonian Acrisol?

Itauane Oliveira de Aquino[1]; Deborah Pinheiro Dick[1]; Falberni de Souza Costa[2]

Federal University of Rio Grande do Sul[1]; Brazilian Agricultural Research Corporation[2]

The impact of No-till on the soil C content in comparison to Conventional Tillage (CT) depends greatly on the soil type, climate and initial C content. The main goal of this work was to investigate the effect of conservation soil management systems on the C content and humification in an Acrisol profile, Acre State, BR. The experiment was conducted randomized blocks with three repetitions, for NT and CT (main parcels), employing the succession manioc/green manure/maize. For each system, three treatments (subparcels) were established: Control: slash and burn (C); *Mucuna aterrima* as cover crop (M); as cover crop with addition of P-fertilizer and limestone (MPL). N and C content (dry combustion, C_{DC}, and Walkley-Black, C_{WB}) and humic substances (HS) were determined in samples collected after 10 years within 100 cm. C_{DC} content in the 0-5 cm depth ranged from 13.9 to 16.5 g kg^{-1} and did not differ between treatments. As expected, C_{DC} decreased with depth reaching values between 3.9 and 5.1 g kg^{-1}. C_{WB} values were always smaller than the respective C_{DC}, indicating that part of soil organic matter (SOM) was not susceptible to oxidation. The index C_{WB}/C_{DC}, a proxy for chemical recalcitrance, varied between 0.7 and 0.9 in the 0-5 cm and decreased to values around 0.5 at 75-100 cm depth. No correlation was found between this index and clay content, indicating that chemical recalcitrance was not related to organo-mineral interactions. C/N ratio varied between 11.7 and 16.0 and no difference was detected between treatments. Cation exchange capacity (CEC) increased linearly ($0.75 < R^2 < 0.98$) with C_{DC} evidencing the important role of SOM on the fertility of these soils. Interestingly, liming increased pH and CEC only under NT, but showed no effect for CT. Probably, soil plowing under CT, by removing the protection of cover crop, favored liming wash out along the coarse sandy loam profile by high rainfall (1600 to 2700 mm y^{-1}). The proportion of humin fraction (C_{HU}/C_{DC}) varied between 0.4 and 0.6 and did not differ between treatments. Furthermore it did not correlate with clay content, suggesting that organo-mineral interactions were not determinant on the stabilization of SOM in depth. The AH/AF ratio decreased drastically with depth indicating a possible migration of fulvic fraction in all sites. Our results showed that soil conservation management systems did not affect SOM content and dynamics in a coarse sandy loam Amazonian Acrisol within 10 years.

(3620 - 368) Early stage litter decomposition across biomes

Ika Djukic[1]; Sebastian Kepfer-Rojas[2]; Inger Kappel Schmidt[2]; Klaus Steenberg Larsen[2]; Claus Beier[2]; Björn Berg[3]; Kris Verheyen[4]
Swiss Federal Institute for Forest, Snow and Landscape Research WSL, Birmensdorf, Switzerland[1]; Department of Geosciences and Natural Resource Management, University of Copenhagen, Denmark[2]; Department of Forest Sciences, University of Helsinki, Finland & Section of Biology, University of Gävle, Sweden[3]; Forest & Nature Lab, Department of Forest and Water Management, Ghent University, Belgium[4]

Through litter decomposition enormous amount of carbon is emitted to the atmosphere. Numerous large-scale decomposition experiments have been conducted focusing on this fundamental soil process in order to understand the controls on the terrestrial carbon transfer to the atmosphere. However, previous studies were mostly based on site-specific litter and methodologies, adding major uncertainty to syntheses, comparisons and meta-analyses across different experiments and sites. In the TeaComposition initiative (Fig. 1), the potential litter decomposition is investigated by using standardized substrates (Rooibos and Green tea) for comparison of litter mass loss in 336 sites (ranging from -9 to +26 °C MAT and from 60 to 3113 mm MAP) across different ecosystems worldwide. In this study we tested the effect of climate (temperature and moisture), litter type and land-use on early stage decomposition (3 months) across nine biomes. We show that litter quality was the predominant controlling factor in early stage litter decomposition, which explained about 65 % of the variability in litter decomposition at a global scale. The effect of climate, on the other hand, was not litter specific and explained < 0.5 % of the variation for Green tea and 5 % for Rooibos tea, and was of significance only under unfavorable decomposition conditions (i.e. xeric versus mesic environments). When the data were aggregated at the biome scale, climate played a significant role on decomposition of both litter types (explaining 64 % of the variation for Green tea and 72 % for Rooibos tea). No significant effect of land-use on early stage litter decomposition was noted within the temperate biome. Our results indicate that multiple drivers are affecting early stage litter mass loss with litter quality being dominant. In order to be able to quantify the relative importance of the different drivers over time, long-term studies combined with experimental trials are needed.

(7305 - 2255) Effect of dissolved organic matter and humic substances on transport of ions and low molecular weight molecules by liquid membranes

Mayra Mora[1]; Manuel Palencia[2]; Jaime L. Mercado[3]
1-GI-CAT, Department of Chemistry, Universidad del Valle, Cali, 25360, Colombia; 2-Mindtech Research Group (Mindtech-RG), Mindtech S.A.S, Cali, 25360, Colombia[1]; GI-CAT, Department of Chemistry, Universidad del Valle, Cali, 25360, Colombia[2]; Department of Agricultural Engineering and Rural Development, Universidad de Cordoba, Montería, 230002, Colombia[3]

Soil organic matter can be classified according to different criteria, including solubility in water, state and susceptibility to biodegradation and other. In general, the transport of inorganic and organic substances in water and soil can be strongly influenced by the mobility of natural dissolved organic matter (DOM) and by the contents of humified organic matter (HOM). On the other hand, liquid membrane systems are complex structures formed by liquid phase which can be used to produce a partition of different substances in function of diffusion properties and under different conditions. In this work, liquid

membranes systems were used to promote the molecular differentiation of humic acids and fulvic acid in order to ease the structural characterization. For that, water/oil/water (w/o/w) emulsion systems were prepared using n-decane as membrane liquid and Span 80 and Tween 80 as stabilizing agents. Systems were prepared in a ultrafiltration system and deionised water was used to produce the diafiltration (washing method at constant volume). Samples of humic and fulvic acids were obtained from different soils previously characterized. Permeate fractions were analysed by ultraviolet and infrared spectroscopy. In addition, major and minor elements were used in the feed in order to identify the changes and the concentration in function of the time. Similar experiments were performed using low molecular weight species (naphthalene acetic acid which is a phytohormone used to promote the growth of plants). Results evidenced a marked effect of different type of humic substance on transport of ions. Effect of pH was clearly identified being lower the interaction at low pH.

(4778 - 701) Effect of litter nitrogen storage and nitrogen release of litter decomposition on soil nitrogen in *Pinus koraiensis* mixed forests

Jiang Yi[1]; Chen Lixin[1]; Duan Wenbiao[1]; Bu Fan[1]; Sun Shuanghong[1]; Li Fanfan[1]; Xu Yifan[2]
College of Forestry, Northeast Forestry University[1]; [2]

The influences of nitrogen storage and nitrogen release from decomposition in undecomposed litter layer(H), fermentation layer(F), humus layer(H) and surface soil layer(S) on soil nitrogen in spruce-fir-Korean pine mixed forest and birch-Korean pine mixed forest in XiaoXing'anling Mountains were studied by the direct harvesting method from May to October of 2012. The results showed that during the period of study, the litter standing crops of two forest types were 19.43-27.25 and 21.25-24.28 $t \cdot hm^{-2}$, nitrogen storage were 287.21-418.22 and 274.81-351.21 $kg \cdot hm^{-2}$, respectively. The nitrogen concentrations of different layers in two forest types were ranked in the decreasing order of L, F, H, and S. In *spruce-fir-Korean pine* mixed forest, both litter standing crops and its nitrogen storage in each layer peaked in May and September; monthly nitrogen storage increased from L to F layer; the nitrogen released from litter decomposition was easily enriched in F and H layers, but less leached into the soil. However, in *birch-Korean* pine mixed forest, both litter standing crops and its nitrogen storage in each layer peaked in May and October; nitrogen storage decreased from L to F layer; nitrogen was easily transported among all litter layers, nitrogen transported from litter layer into the soil was more than that in *spruce-fir-Korean pine* mixed forest. In two forest types, significant positive correlations were found between the litter standing crops (in L, F and H layers) and nitrogen in S layer, between nitrogen in H layer and nitrogen in S layer, and between the litter standing crops (in L and F layers) and nitrogen in H layer.

(7176 - 1622) Effect of prescribed burns on soil organic carbon forms in Histosols of the Itatiaia National Park

Robson Altiellys Tosta Marcondes[1]; Lúcia Helena Cunha dos Anjos[1]; Daniel Costa de Carvalho[1]; Elias Mendes Costa[1]; Luiz Alberto da Silva Rodrigues Pinto[1]
Universidade Federal Rural do Rio de Janeiro[1]

The Itatiaia National Park (INP) is a conservation unit located in Rio de Janeiro state and it is the first park of Brazil, set to preserve important ecosystems of the Atlantic Forest biome. Among the soils in the high altitude areas of INP, Histosols have a significant presence, and they function as reservoirs of organic carbon and nutrients for some endemic plants and fauna as water retention, which is important to river resources in INP. On the other hand, Histosols present great environmental fragility. In natural environments, where natural or human induced fires can occur specially in the driest periods of the year may contribute to their degradation. The objective of this study was to evaluate the effect of prescribed burns on organic carbon forms in Histosols, in selected areas of the INP high altitude plateau. Samples were taken in three depths (0 - 0.1, 0.1 - 0.2 and 0.2 - 0.4 m); in different periods of time: previous to burning, followed by 10, 30, and 90 days after that; and in two distinct sites, with different relief (plain lowland and hillside). The contents of total organic carbon (TOC) and labile carbon (LC) were evaluated by Yeomans & Bremner (1988) and Glover Laboratories and Barbercheck methodologies, respectively. The results were submitted to ANOVA and Tukey test with significance of 5%. The TOC and LC fractions showed different patterns according to topography and time. In the plain lowland, ten days after burning, there was a reduction of TOC and LC in all depths, followed by increases of TOC with time but not returning to the initial values. After 90 days there was a tendency of stabilization of LC values in all depths with a slight increase at 0.2 - 0.4 m. Regarding to the hillside area, values of TOC increased after 90 days in all depths when compared to the initial contents (previous to burning). An increase in LC was observed with time for the 0.0 - 0.1m depth, from 5.59 to 6.06 $g\ kg^{-1}$. The influence of prescribed fire was more intense in Histosols from the lowland area. These soils are under hydromorphic conditions most of the year, which reduces the transformation and mineralization of the organic material, thus making them less stable and with less recalcitrant organic substances. Results indicate that the practice of prescribed burn needs different protocols according to the Histosols conditions of formation, in order to maintain the ecological functions associated to the organic matter content in these soils.

(4974 - 583) Exploring properties of soil organic matter at the microscopic level using molecular dynamics and an upgraded Vienna Soil-Organic-Matter Modeler

Yerko Escalona[1]; Drazen Petrov[1]; Chris Oostenbrink[1]
Institute of Molecular Modeling and Simulation (MMS), Department of Material Science and Process Engineering (MAP), University of Natural Resources and Life Sciences Vienna (BOKU), Muthgasse 18, A-1190, Vienna, Austria[1]

The Vienna Soil-Organic-Matter Modeler (http://somm.boku.ac.at/; VSOMM) is an online tool dedicated to generating condensed phase models of humic substances (HS), one of the most important constituents of Soil-Organic-Matter (SOM). This tool has permitted us to investigate the structure and dynamics of different SOM systems, including the Standard Leonardite Humic Acid, as well as, their interaction with small organic compounds. One of the challenges associated with the development of these systems, is to create a representative environment of the humic substances, at a nanoscale, taking into account that HS are composed of complex and heterogeneous organic compounds produced by biological degradation. For that reason, the modeler use a database of organic fragments called building blocks (BBs). Each BB has a different chemical structure, which, in combination, are able to reproduce the carbon distribution estimated by ^{13}C NMR. Here, we have constructed a number of new BBs with the current parameter set 54A8 of the GROMOS force field, including BBs with Methoxyl-C and Alkyl-C groups that improves the agreement with the NMR data.

Additionally, an improved core algorithm of VSOMM was developed and written using PYTHON, which allows us to automatically generate and equilibrate multiple models of greater chemical and geometric diversity. Using the new version of VSOMM, we extend our investigation from the Standard Leonardite Humic Acid to several other experimentally available HA samples, including the Suwannee River II, Elliott Soil, Elliott Soil IV and Pahokee Peat Humic Acids. We characterized these systems by doing a plethora of analyses in order to observe differences in their structure and dynamics. The binding of pollutants and pesticides affects the erodibility, moisture retention and soil structure of SOM impacting possibly the carbon cycle, reducing the Carbon storage on soil. We also investigated the sorption of these systems.

(9382 - 1843) Factors controlling organic carbon storage in tropical soils

Kenta Ashida[1]; Tetsuhiro Watanabe[1]; Arief Hartono[2]; Method Kilasara[3]; Antonie Mvond Ze[4]; Shinya Funakawa[1]
Kyoto University[1]; Bogor Agricultural University[2]; Sokoine University of Agriculture[3]; Dschang University[4]

In this study, we identified the soil component with the strongest contribution to storage of soil organic carbon (SOC) and investigated the effects of the soil component, climate, and geology on SOC storage in tropical soils. Soils from A and B horizons in Thailand, Indonesia, Tanzania, Cameroon, and Japan were analyzed. Total carbon contents as organic carbon contents and soil components that would contribute to SOC storage (clay + silt, acid ammonium oxalate extractable Al and Fe: $Al_o + Fe_o$, sodium pyrophosphate extractable Al and Fe: $Al_p + Fe_p$), were measured. The total contents of elements that reflect geology were determined. Correlation analysis was applied to compare the contribution of soil components to SOC storage. Effect paths and the relative contribution of the soil components and climatic (e.g., mean annual temperature: MAT, mean annual precipitation, net primary production) and geological (e.g., total Si) factors were analyzed by covariance structure analysis. The results of correlation analysis indicated that $Al_p + Fe_p$ and $Al_o + Fe_o$ contributed to SOC storage in both A and B horizons. In A horizons, $Al_p + Fe_p$ was strongly correlated with SOC for moderately and strongly weathered soils, but less correlated for weakly weathered soils from cooler regions, indicating that other factors, such as aggregation, may contribute to SOC storage in weakly weathered soils. The model used for covariance structure analysis explained 56% and 74% of the variance in A and B horizons, respectively. In B horizons, the total effect on SOC was highest for $Al_o + Fe_o$ (0.75) and MAT (−0.63). $Al_o + Fe_o$ had a direct effect (direct effect: 0.75, indirect effect: n.s.), whereas MAT had an indirect effect (direct effect: −0.12, indirect effect: −0.51) mainly via $Al_o + Fe_o$. Geological factor (total Si) affected SOC indirectly mainly via $Al_o + Fe_o$ (direct effect: n.s., indirect effect: −0.23). In A horizons, the total effect on SOC was high for MAT (−0.65) and $Al_o + Fe_o$ (0.24), where MAT had more direct effected on SOC than that in B horizons (direct effect: −0.47, indirect effect: −0.18). $Al_o + Fe_o$ and net primary production also directly affected the SOC in A horizons. We conclude that $Al_o + Fe_o$ controls SOC storage, and temperature indirectly affects SOC via $Al_o + Fe_o$ in B horizons, whereas climatic conditions that affect input and decomposition of organic matter directly control SOC, the effect of which were stronger than $Al_o + Fe_o$ in A horizons.

(4619 - 856) Fire influences on litter decomposition: C chemistry and N transformations in thermally altered *Pinus radiata* needles.

Erinne Stirling[1]; Timothy R. Cavagnaro[1]; Ronald J. Smernik[1]; Lynne M. Macdonald[2]
The University of Adelaide[1]; CSIRO (Commonwealth Scientific and Industrial Research Organisation)[2]

As climate change proceeds, a change in the frequency and intensity of fire events is expected to affect soil organic matter (SOM) transformations within forestry systems. While the effect of fire on woody materials has been extensively studied, less is known about thermal alteration of non-woody plant materials such as leaves. In this study, non-woody OM was exposed to a thermal gradient to determine the effect of temperature on SOM C chemistry and N transformations. Methods: Live Pinus radiata needles <1 year old were collected from a managed forestry plantation. Needles were dried at 40°C ('air dried') before being further heated for 1 hour in a muffle furnace at a range of temperatures >40°C (max. = 320°C), and then coarsely ground and screened (0.5-1.0 mm fraction retained). These needles were characterized for C and N content, extractable N pools (mineral, potentially mineralizable, and microbial biomass), C chemistry (solid-state 13C NMR), and general spectral differences (MIR). An incubation experiment (14 d) was performed to assess the impact of the different litters on soil N transformations. Results: C loss started at 200°C and increased to 56% of the C content at 320°C; N losses started at 260°C and were lower than the C losses (30% at 320°C). While temperatures <178°C (low Temp) resulted in small changes in C chemistry, needles heated to >200°C (high Temp) decreased in O-alkyl groups, and increased in aryl and O-aryl groups; alkyl groups increased slightly until 260°C before decreasing at 320°C. High Temp treatments in the incubated soils generally maintained a larger microbial biomass but had lower microbial activity than low Temp treatments. Although mineral N was rapidly depleted in the low Temp treatments, it is not clear what form it became as nitrate was not detected. Potentially mineralizable N was initially positive for high Temps and negative for low Temps; however, all treatments were positive by day 3. Discussion: The results indicate a step change in the effect of heating on pine needles, with a critical change occurring at or before 200°C. Below 200°C, C and N differ little compared to air dried needles; above 200°C needles experience significant chemical changes, but do not appear to influence soil N transformations to the same degree as air dried needles. From this experiment it is clear that in a laboratory setting, thermally altered non-woody inputs to the soil affect processes governing SOM transformations.

(4330 - 2444) Glomalin Related Soil Protein from the Itataia phosphate-uranium deposit in the Brazilian semiarid

Laura Victoria Márquez Cataño[1]; Maria Eugenia Ortiz Escobar[1]; Cleyton Saialy Medeiros Cunha[1]; José Igor Almeida Castro[1]; Antonio Yan Viana Lima[1]
Federal University of Ceara[1]

Glomalin Related Soil Protein (GRSP) refers to a glycoprotein produced by mycorrhizal fungi and is recognized as a soil carbon pool. High contents have been found in natural systems (2-15 mg g^{-1}) while lower contents are generally reported for soils under frequent tillage as well as in semiarid regions (0.1-1 mg g^{-1}). GRSP is positively correlated with soil quality parameters such as aggregate stability, porosity and soil organic matter (SOM). Moreover, it has been related to heavy metal stabilization in polluted soils. The Itataia phosphate-

uranium deposit comprises approximately 1.54 km^2, considered the largest uranium reservoir of South America, still conserved under native vegetation, known as Caatinga, located in the Brazilian semiarid where have been reported varying levels of heavy metals. This study aims to determine GRSP concentrations of this area in its natural equilibrium condition (prior to industrial extraction activities) and provide information for programs of soil remediation in areas under the influence of ore extraction. We collected 52 simple soil samples from the first 10 cm depth, for the determination of GRSP (sodium pyrophosphate 0.1 M) and total organic carbon - TOC (wet oxidation with external heating). Results are the mean of three replicates and are expressed on dry soil mass basis. Descriptive statistics and Pearson correlation analyses were performed in R software. GRSP concentrations along the area ranged from 0.34 to 11.64 mg g^{-1}, with a mean of 4.72 mg g^{-1}. Mean value of TOC along the area is 24.4 mg g^{-1}, considered high for Brazilian Semiarid. Significant correlation ($p>0.001$) was found between GRSP and TOC ($r = 0.92$), corroborating that factors involved in SOM accumulation also stimulates mycorrhizal fungi propagation, enhancing GRSP concentrations as has been widely suggested by scientists. The levels of GRSP in this study are considered high when compared to other samples from semiarid regions, and are in agreement with reports of high GRSP in heavy metal polluted soils.

(8193 - 2582) How soil C:N ratios vary with depth, particle size and soil fertility in Brazilian forest soils

Marla Alessandra Araujo[1]; Yuri Lopes Zinn[2]; Rattan Lal[3]
Depto. de Agronomia, Centro de Ciências Agrárias, Universidade Estadual de Londrina, Campus Universitário, Londrina, PR 86057 970, Brazil. E-mail: marlaalessandr@gmail.com[1]; Depto. de Ciência do Solo, Universidade Federal de Lavras, Lavras, MG 37200 000, Brazil[2]; Carbon Management and Sequestration Center, The Ohio State University, 2021 Coffey Road, Columbus, OH 43210-1085, USA[3]

Among the many proxies to assess the quality of residues and soil organic matter, C:N ratio is certainly the easiest to determine. However, in regard to bulk soils and particle size fractions, interpretation of C:N ratios is not simple as for organic residues, mostly due to organic interactions with mineral components. In order to study soil factors affecting soil C:N ratios, we sampled 8 soils with contrasting texture and mineralogy, formed from alteration of 8 rocks (quartzite, mica-schist, gabbro, itabirite, serpentinite, limestone, gneiss and phyllite), near Lavras-MG, Brazil. Aiming to provide a *ceteris paribus* sampling, all soils were under native semi-deciduous forests, located on midslopes, and under similar warm temperate humid climate. In each soil, samples were taken in triplicate, in 6 layers from 0 to a 1 m depth. Soil C:N ratios were computed after C and N dry combustion in bulk soils (sieved <2 mm) and in clay, silt and sand separates. Bulk soil C:N ratios in each soil varied relatively little with depth, between 10 and 18, although different soils varied slightly in their C:N profiles. Clay C:N ratios also varied little with depth, and were always ~10 (<10 in 3 soils), whereas in sand fractions C:N ratios increased to 20-60 below the 40 cm depth. Silt fractions C:N ratios were similar to those of bulk soils. Interestingly, in the 0-5, 5-10, 10-20 and 30-40 cm depths, bulk soil C:N ratios were correlated with various fertility indicators. Significant, negative correlations occurred with KCl-extractable Ca (r^2=0.52 to 0.81), sum of bases (0.50-0.80) and base saturation (0.46-0.70). Concurrently, C:N ratios were positively correlated with KCl-extractable Al and H+Al at pH 7. In other words, in the top 40 cm depth, soils richer in base cations had lower C:N ratios, i.e. higher N in relation to soil organic carbon (SOC), suggesting also a higher fertility in regard to N supply to plants. These results are remarkable since the soils did not differ in SOC retention but differed widely in soil fertility (Araujo et al., Geoderma 300, 1, 2017). Although soil C:N ratios per se are weak indicators of soil quality changes upon land use change in Brazil (Zinn et al., Agric. Ecos. Env. 255, 62, 2018), these results suggest that C:N ratios can be useful to study mechanisms of SOC retention in soils and clays. Apparently, ammonia groups in SOC molecules are sorbed to mineral surfaces and thus favor SOC stabilization.

(5152 - 236) Humic substances and total organic carbon of an inceptisol after 21 years under different soil tillage

Luiz Paulo Rauber[1]; Andréia Patrícia Andrade[2]; Barbara Bagio[2]; Neuro Hilton Wolschick[2]; Walter Santos Borges Júnior[2]; Ildegardis Bertol[2]; Álvaro Luiz Mafra[2]
Universidade do Oeste de Santa Catarina-UNOESC[1]; Universidade do Estado de Santa Catarina-UDESC[2]

Soil sustainability depends on its manegement and it may be related with organic matter concentration. The objective of this study was to evaluate chemical and physical fractions of organic carbon in a Humic Dystrudept after 21 years under no tillage and conventional tillage in an experiment established in 1995 in Lages-SC, southern Brazil, conducted in a completely randomized desing with eight replicates. The treatments evaluated were conventional tillage (CT), using one plowing followed by two disking before summer and winter crops and no tillage (NT). During 21 years of the experiment, grass and legume crops were intercropped and rotated among them, using oats, fodder radish and vetch in the winter, and maize, soybeans and beans int the summer. Soil samples were collected in November 2016, at 0-2.5, 2.5-5, 5-10 and 10-20 cm depths and analyzed for the chemical fractionations to separate humin and humic and fulvic acids, and to determine total organic carbon (TOC) and particulate organic carbon (POC). The carbon management index (CMI) and carbon stock were calculated considering a native grassland (NG) as a reference area, according to the equivalent mass basis. The results were submitted to analysis of variance by the F test and the means were compared by the Tukey test ($P<0.05$). The carbon content in the humic fraction of NT was similar to NG in the two surface layers, representing the most stabilized form of the organic matter. NT had 73% more carbon in the humin fraction than the CT in the 0-2.5 cm layer. NT presented 35% more TOC and 48% more POC than the CT in the 0-2,5 cm layer, meaning that the NT sequestrated carbon in the particulate fraction due to the maintenance of crop residues and minimal soil disturbance. TOC increased 9% in the 0-20 cm layer after 21 years NT, resulting in a stock increment of 7 Mg ha^{-1}, while under CT there was a reduction of 3 Mg ha^{-1} in the carbon stock in this period. The CMI was higner in NT than in CT in the 0-5 cm layers, evidencing the negative impact of the mechanical soil disturbance on the organic matter in the surface soil.

Keywords: Humic acids; Soil tillage; Organic carbon, Carbon stock.

(3593 - 2208) Influence of eucalypt residue (root and shoot) and N (internal and external) to C and N incorporation in soil organic matter fractions

Emanuelle Mercês Barros Soares[1]; Rafael da Silva Teixeira[1]; Rodrigo Nogueira de Sousa[1]; Gustavo Conforti Ventura Mayrink[1]; Ivo Ribeiro da Silva[1]

UFV[1]

Eucalypt forests have the capacity to sequester atmospheric CO_2, immobilizing it in its biomass, and later transferring the C to the soil. Root and shoot residues are the main input of C to the soil and their stabilization will depend initially on the decomposition process, which is influenced by residues quality and the N availability. The goal of this work was to evaluate the contribution of eucalypt root and shoots residues with different internal N levels for soil organic matter fractions (SOM) when submitted to external N application. Eucalypt hybrids were previously enriched with ^{13}C and ^{15}N and grown with different N supplies. The experiment was conducted in an incubation room (25 ± 1^{o}C, in the dark) for 119 days. The treatments were based on an incomplete factorial (2 x 2 x 2) + 2: two residues (Eucalypt shoot and Eucalypt root); two internal N levels (High internal nitrogen - HIN and Low internal nitrogen - LIN); two external N levels (0 [-N] and 50 mg dm^{-3} NH_4NO_3-N [+N]) and two soils without residues addition but with application of two external N levels (0 [-N] and 50 mg dm^{-3} NH_4NO_3-N [+N]) arranged in a randomized block with four replicates. Soil samples (0-20 cm; Hapludox) cultivated with pasture (C_4 plant) was used for incubation. During the 119 days of incubation the CO_2-C and CO_2-^{13}C emissions were determined by the CRDS. In addition, after 119 days the soil was removed and C (%), $\delta^{13}C_{PDB}$ (‰), N (%) and the atom in excess of ^{15}N (%) in the particulate organic matter fraction (POM) and minerals associated organic matter (MAOM) were determined by a coupled CN elemental analyzer to an isotope ratio mass spectrometer. The external N application decreased the CO_2-C derived from the HIN Eucalypt shoot residue (3.9%; P = 0.003) and HNI Eucalypt root residue (7.5%; P <0.001). Consequently, it promoted the preservation of POM-C in the addition of HIN Eucalypt shoot residue (11.6%; P = 0.007) and HNI Eucalypt root residue (7.8%; P = 0.014). However, the external N application did not cause contributions to the MAOM-C. Eucalypt root residue presented lower decomposition than Eucalypt shoot residue, independent of internal N levels and external N application. In addition, Eucalypt shoot residue provided higher contributions of residue derived-C and -N to the more stable fraction of SOM (MAOM) in relation to the Eucalypt root residue.

(5797 - 1509) Influence of magnesium silicate on the persistence of the straw of *Brachiaria brizantha* cv. Piatã in no-tillage

Izabela Richena Barbosa[1]; Alessandra Mayumi Tokura Alovisi[2]; Alves Alexandre Alovisi[2]; Luana Gonçalves Perondi[2]; Giuliano Reis Pereira Muglia[2]; Gustavo Henrique Leite Mota Piesanti[2]; Robervaldo Soares da Silva[2]

Federal university of Grande Dourados[1]; [2]

In regions of tropical climate, with high decomposition of plant residues, the application of magnesium silicate can be an alternative to increase the persistence of straw on the soil in no-tillage, interfering with the availability of nutrients to crops. The objective of this study was to evaluate the dry mass production, the percentage of soil cover, as well as the persistence of the straw of *Brachiaria brizantha* cv. Piatã on the ground. The experiment was conducted at the Experimental Farm of Agricultural Sciences of the Federal University of Grande Dourados (UFGD) in a Red Distroferric Oxisol. The experimental design was a randomized block design and the treatments were arranged in a 5x2x5 factorial, involving five doses of magnesium silicate (0, 2, 4, 8 and 16 Mg ha-1), (0 and 300 g ha-1) and five collection times (30, 60, 90, 120 and 150 days after the deposition of the litter bags on the soil), with four replications. Proportional samples of the brachiaria dry mass were conditioned in litter bags, which were arranged on the soil, being collected and weighed every 30 days, up to 150 days after installation, to evaluate the persistence of straw, after forage management. The experimental data were submitted to analysis of variance with the aid of the statistical program ASSISTAT. The application of magnesium silicate linearly increased the dry matter yield of the aerial part of the forage. This greater production provided the permanence of greater amount of straw on the soil over time. The remaining dry mass of B. *brizantha* up to 90 days after its management, associated with the application of magnesium silicate at the dose of 16 Mg ha-1, is enough to provide the amount of straw that must be added annually to the soil surface in the Planting System Direct. The persistence of the straw on the soil persists up to 124 days after forage management, with soil cover percentage above 80%.

(4643 - 2391) Influence of the organic matter on the availability of heavy metals in the soil in vegetable gardens of the Metropolitan area of Belém/Pa.

Nayara Kelly Feitosa Ferreira[1]; Antonio Rodrigues Fernandes[2]; Joselito Santiago de Lima[1]; Angleson Figueira Marinho[1]; Cássio Furtado Lima[1]

Federal Institute of Education Science and Technology of Pará/Óbidos[1]; Federal Rural University of Amazonia[2]

Influence of the organic matter on the availability of heavy metals in the soil in vegetable gardens of the Metropolitan area of Belém/Pa.

Nayara Kelly Feitosa Ferreira[1], Antonio Rodrigues Fernandes[2], Joselito Santiago de Lima[1], Angleson Figueira Marinho[1], Cássio Furtado Lima[1]. [1]Federal Institute of Education Science and Technology of Pará/Óbidos, Av. Nelson Souza, S/N, Óbidos, 68250-000, Brazil (nayara.ferreira@ifpa.edu.br); [2]Federal Rural University of Amazonia, Av. Presidente Tancredo Neves, 2501, Belém, 66077-830, Brazil. The cultivation of vegetables is usually used organic matter high doses. Organic matter (OM) influences the availability of metals in the soil. The main aim this studywas to evaluate the influence of OM on the available concentrations of Cu, Zn, Mn, Cr and Fe in soils cultivated with vegetables. In those areas were collected, the soils in the planting lines of three species most consumed, such as lettuce (Lactuca sativa L.), cabbage (Brassica oleracea L. var. Acephala) and caruru (Talinumesculentum, Jacq.). In each line were collected 10 simple soil samples, to form a composite sample, at a depth of 0-20 cm. The available concentrations were determined with the solution of Mehlich 1. In order toverify the influence of the MO was used Spearman' analysis of correlation between the available levels and the MO of the soil. The MO content found was 96,68; 97.68; 68.18 g kg-1, in Ananindeua, Marituba and Santa Isabel, respectively. It was found that the available concentrations of Mn presented a significant correlation with soil OM (ρ = 0.789) at the 5% probability level (p <0.05).The high availability of this element can be justified by the high decomposition of the organic matter, which is strongly influenced by the pH found in these soils, in the range of (5.0 to 6.5).Besides, the complexation process (chelation) of Mn for organic acids of low molecular weight may increase the availability of this element, because the chelate becomes a form of accumulation of Mn in the soil and, with the fast decomposition by the microorganisms, it is released continuously and gradually to the plants. No significant correlations

were found among OM and available concentrations of Cu, Zn, Cr and Fe metals. In this way, the increment of the OM in the soils was able to increase the availability of Mn. Keywords:plant contamination; available concentrations, toxic elements Financial Support: PPGA/UFRA, CNPQ and IFPA

(5382 - 2098) Leaching of cations and eucalyptus growth under complementary fertilization with K^+ and Na^+

ANÁLIO, Caroline M.[1]; LOTTI, Marina N. N.[1]; AMORIM, Helen C. S.[1]; FERREIRA, Matheus A.[1]; GARDIOLI, Luiz Fernando N.[1]; SILVA, Ivo R.[1]
Federal University of Viçosa[1]

Potassium (K^+) is one of the most deficient nutrients in tropical weathered soils. The maintenance of productivity of eucalyptus plantations depends on the application of high doses of potassic fertilizers, increasing production costs. An alternative to reduce these costs would be the partial substitution of K^+ by sodium (Na^+) in fertilization. The objective of this study was to evaluate the mobility of K^+ and Na^+ in the soil profile, their losses by leaching and the effect of K^+ substitution by Na^+ on the diametric growth of a eucalyptus stand (?) o que eh stand???. The experiment was carried out in a randomized block design with three treatments (100 kg ha^{-1} of K^+ as KCl, 100 kg ha^{-1} of Na^+ as NaCl, and a control treatment without additional fertilization) and three replicates, totalizing nine experimental units.Zero voltage lysimeters were installed in the experimental units at 70 cm depth for the monthly collection of percolated water. Steel dendrometers were installed in the trunk of the trees that contained a lysimeter, to accompany the diametric growth over time. Sixty days after application of the treatments, soil samples were collected in the 0-20, 20-40 and 40-60 cm depth to determine the available K^+ and Na^+ content. Samples of percolation water were collected monthly for the determination of K^+ and Na^+ contents. Monthly readings were performed on the dendrometers to evaluate the diametric increase.Data were submitted to regression analysis. The available K^+ and Na^+ contents were higher in the KCl and NaCl treatments, respectively. The 20-40 cm layer of the KCl treatment and the 0-20 cm layer of the NaCl treatment showed the highest levels of K^+ and Na^+ available, in that order. The treatments with KCl and NaCl caused higher leaching of K^+ and Na^+, respectively, with higher losses up to 66 days after the installation of the experiment, for both cations. The treatment with NaCl had a higher diametric increase up to 66 days; after this period, all the treatments showed decreased increments. The treatment with KCl showed higher average growth during the experimental period. Na^+ is the most vertical cation in soil and can reduce the diametric growth of the trees during a period of water restriction. The partial replacement of K^+ by Na^+ was not fully supported in this study.

(8352 - 396) Long Term Dynamics of Soil Organic Carbon Pools in Oil Palm Plantations following Land Use Change: Insights from Physical Fractionation and natural ^{13}C abundance

Juan Carlos Quezada RIvera[1]; Thomas Guillaume[1]; Alexandre Buttler[1]
École polytechnique fédérale de Lausanne, EPFL; The Swiss Federal Institute for Forest, Snow and Landscape Research, WSL[1]

Quantifying changes in soil organic carbon (SOC) storage is an important step towards identifying more sustainable land use change (LUC) options. However, determining the turnover rates of specific functional SOC pools can provide better insights into the dynamics of SOC. Furthermore, when distinct SOC pools are examined along with changes in natural $\delta^{13}C$ abundance due to vegetation shifts, mechanisms of SOC dynamics can be elucidated. At the moment, LUC to oil palm (OP) plantations is a major pressing issue in the tropics and it has been heavily criticized. Here, we studied SOC dynamics following conversion of tropical pastures into OP plantations. Soil samples from pastures and a chronosequence of OP plantations ranging from 12 to 56 years after pasture conversion were used. We separated SOC by density fractionation obtaining: free light fraction (FLF), occluded light fraction (OcLF) and heavy fraction (HF). Carbon, N contents and $\delta^{13}C$ and $\delta^{15}N$ values were determined as well as mean residence times (MRT) values for each SOC density fraction. Replacement of pasture areas by OP plantations gradually reduced overall $\delta^{13}C$ values with time (from -14‰ to -28‰ in the 56 years plantation). Our preliminary results showed that rates of isotopic changes in the three separated pools decreased in the following order: FLF>OcLF>HF. No pasture-derived C was found in the LF fraction after 18 years of OP cultivation, indicating a very fast decay of pasture derived C. Conversely, about half of total SOC was still pasture-derived in the HF after two rotation cycles. The C content in the OcLF decreased sharply after plantation establishment, but it started to increase again after OP plantation renovation during the second cultivation cycle, indicating a long-term resilience of this fraction against LUC. Apparently, physical protection of SOC within stable soil aggregates is due to almost no soil tillage in OP plantations, together with a significant pulse of OM input following plantation renovation. Nevertheless, whole SOC stocks were depleted by almost 50% after 56 years of pasture conversion. Our results suggest that despite enhanced physical protection of SOC in aggregates, which can increase MRT of SOC, after plantation renovation, OP cultivation following pasture conversion reduces SOC stocks over two rotation cycles. Reductions in overall SOC stocks was directly correlated to significant reductions in the C content of the HF that contained most of the total SOC.

Keywords: $\delta^{13}C$ natural abundance, land use change, density fractionation, mean residence time.

(7135 - 1489) Long-term changes in the composition of organic matter

Kerttu Tammik[1]; Alar Astover[1]; Karin Kauer[1]
Estonian University of Life Sciences, Chair of Soil Science[1]

Organic matter consists of fractions with various degree of decomposition and stability. FTIR spectroscopy is a technique used for distinguishing the principal chemical classes in soil organic matter without extraction solvents which may distort the results. The absorption intensity reflects the proportional amounts of functional groups. This is particularly important in assessing labile organic C fractions which include water-soluble organic C. The aim of this study is evaluate the effect of plant cover on the composition of the soil organic matter (SOM) using data gathered from a longtime experiment located in Estonia. The experiment was established in 1964 using 19 different treatments. From the experimental location, the soil was removed until 1m depth (BC horizon) and replaced with a homogeneous material with a low initial C content (1.28 g kg^{-1}) derived nearby. For analyzing the composition of SOM, samples collected at the start of the experiment (1964) and again after 50 years (2014) were used, allowing to assess the long-term changes in related to vegetation. The vegetation treatments under investigation were bare fallow since 1964 (F), barley (B), a mixture of grasses (G), hybrid lucerne (H) and galega (Ga). F, B and G treatments have remained unchanged since the beginning of the experiment, H and Gg have previously been a mixture of clover and grasses, named cultures have

been sown in 1995. Differences in composition of SOM were analyzed with Fourier Transform Infrared (FTIR) spectroscopy using absorption peaks recorded at 995 cm^{-1} (Si-O vibrations of clay minerals), 1428 cm^{-1} (carboxylic C), 1633 cm^{-1} (aromatic C), 3619 cm^{-1} and 3694 cm^{-1} (stretching of the inner and other hydroxyl group of kaolinite, gibbsite). The peak intensity of carboxylic C was the highest in the beginning of the study and lowest in B treatment. F and other grasses had no significant differences. The intensity of the peak characterizing aromatic C has risen compared to the start of the experiment – it was the highest in H and Ga treatments and lowest in F treatment. The aromatic C compounds considered a representative of the stable C fraction due to resistant bonds between particles. Treatments B and G had no differences. Formation of different groups depends on vegetation, namely the composition of C input. The differences are more pronounced concerning carboxylic and aromatic C groups, bonds describing mineral composition are not affected as much.

(9947 - 1922) Long-term effect of fertilizer and crop residues management under cassava production on changes in soil organic carbon storage

Somrutai Tancharoen[1]; Kobkiet Paisancharoen[2]; Somkuan Klongchang[1]; Chayant Pakdeethai[2]; Suphakarn Luanmanee[1]; Sainam Udpuay[1]; Piyanan Wiwatwittaya[1]; Takeshi Watanabe[3]
Agricultural Production Sciences Research and Development Division, Department of Agriculture. Thailand[1]; Field and Renewable Energy Crops Research Institute. Department of Agriculture. Thailand[2]; Japan International Research Center for Agricultural Sciences. Japan[3]

Fertilizer and crop residues management is important not only for increasing crop production but also sustaining soil productivity. Soil organic carbon is a key indicator of soil fertility and productivity. However, it needs a long period to distinguish the changes in soil organic carbon. Therefore, a long-term field experiment was conducted in 1976 in Yasothon soil series sandy loam; fine loamy, siliceous, Oxic Paleustult, at Khon Kaen Province in northeast of Thailand. The experiment consisted of 8 treatments with 4 replicates laid in randomized complete block design. The treatments varied in fertilizer and crop residues management i.e. without fertilizer application (No CF), No CF with cassava residues incorporation (No CF+R), fertilizer application at rates of 50-100 kg N/ha (N), N 50-100 kg/ha P_2O_5 50 kg/ha (NP), N 50-100 kg/ha K_2O 50-100 kg/ha (NK), N 50-100 kg/ha P_2O_5 50 kg/ha K_2O 50-100 kg/ha (NPK), NPK with 12.5t/ha compost (NPK+C) and NPK with 18.75t/ha cassava residues incorporation (NPK+R). This study investigated the long-term effect on changes of soil organic carbon at 0-20 cm depth during 1985 to 2017. The result showed that fertilizer and crop residues management significantly affected the status of soil organic carbon. The application of NPK fertilizer with 12.5t/ha compost was the most effective management to increase the soil organic carbon about 94 kgC/ha/year. The soil organic carbon under the application of NPK fertilizer with 18.75 t/ha cassava residues incorporation (NPK+R) increased about 28 kgC/ha/year inferior to the NPK+C. This was due to easily decomposition of fresh cassava residues as compared to highly stability of compost. If the soil was applied with chemical fertilizer the soil organic carbon hardly increased about 2 kgC/ha/year. In contrast to those practices, the soil under cassava production without fertilizer application either with or without cassava residues incorporation showed that the soil organic carbon drastically decreased about 43 and 107 kgC/ha/year, respectively. This can be concluded that using cassava production in sandy soil without fertilizer and organic materials application can cause reduction of soil organic carbon over the years whereas using chemical fertilizer can slow down the depletion of soil organic carbon. However, addition of organic materials to the soil by using composts and crop residues is the most effective to maintain the level of soil organic carbon and sustain the soil productivity.

(7109 - 2716) Macaúba (*Acrocomia aculeata* Mart.) contribution to soil organic carbon

Sandro Lucio Silva Moreira[1]; Heitor Eduardo Campos Ferreira Morato Filpi[1]; Aristides Osvaldo Ngolo[1]; Hewlley Maria Acioli Imbuzeiro[1]; Leonardo Duarte Pimentel[1]; Gilberto Chohaku Sediyama[1]; Raphael Bragança Alves Fernandes[1]
Universidade Federal de Viçosa[1]

Macaúba (Acrocomia aculeata Mart.) is a native palm from Brazil, which presents great potential for biodiesel production and for providing food for human and animal consumption. This palm has been the focus of a wide range of studies in the last decade. In general, the palms present a fasciculated root system, and most part of roots tend to concentrate in the upper soil layer, therefore, contributing to soil carbon accumulation. The aim of this study was to evaluate the total soil organic carbon contents (TOC) provided by Macaúba root system. Soil sampling was carried out in a Macaúba cultivated area during five years in Araponga, Minas Gerais State, Brazil. The area influenced by the palm canopy cover was delimitated and the samples were taken considering three different distances from the Macaúba stem (0-0.9 m, 0.9-1.8 m, and 1.8-2.7 m). For each distance, four different soil depths were sampled (0-0.2 m, 0.2-0.4 m, 0.4-0.6 m, and 0.6-1.0 m). The total organic carbon (TOC) contents of all soil samples were quantified in the laboratory. Data were evaluated by analysis of variance and means were compared by post hoc Tukey test ($P<0.05$). Results obtained indicated the distances from the palm stem did not affect the total soil organic carbon content (TOC varying from 2.4 to 2.8 %), whereas different soil depths influence TOC. The highest TOC located on surface and depth reduce its contents. TOC contents varied from 3.8 % (0-0.2 m) to 1.7 (0.4-1.0 m). The highest total organic carbon content of the soil occurs in the initial layers of the soil.

(9766 - 1928) Methods for the determination of organic carbono in soils of Alagoas State, Brazil

Deni Rafaela Silva Barros[1]; Gilson Moura Filho[1]; Stoécio Malta Ferreira Maia[2]; Adriano Barboza Moura[1]; Leila Cruz da Silva Calheiros[1]
Universidade Federal de Alagoas - UFAL[1]; Instituto Federal de Alagoas - IFAL[2]

Currently, different methodologies for the determination of soil organic carbon have been used without taking into consideration the risks they may offer to the environment, neither the high costs involved in carrying out these analyzes. Given the need of adopting an alternative method that is less polluting, has a lower cost and more practicability, new procedures are being tested. The objectives of this work is to determine soil carbon and organic matter by different methods, apply descriptive statistics to the data, correlate the methods and determine the similarity or difference between alternative methods and Elementary Analysis (standard method). Additionally, due to its widespread usage, Walkley-Black modified method was used as a standard and compared with the others. The work was carried out with native forest soils of the Sertão, Agreste and Litoral Alagoano regions. 48 composite samples were collected in

the 0-20 cm layer. Soil carbon contents were determined by wet combustion methods - Walkley - Black modified and Colorimetric, and dry combustion - Elementary and Gravimetric Analysis. The data were evaluated through the descriptive statistical analysis, the coefficients of determination and correlation of the curve and Graybill's F tests, t-test for the mean error and the test of the analysis of the linear correlation coefficient in comparison to the mean-error. The modified Colorimetric and Walkley & Black methods tend to underestimate organic carbon, respectively, at 55.44 and 16.27%, while Gravimetric tends to overestimate total carbon contents by 15.02% compared to Elementary Analysis. The Gravimetric method presented identity with the Elementary Analysis. Although no identity was observed in the comparison between the colorimetric and the other methods, high values for its correlation coefficients were noted indicating the possibility of use to replace the modified Walkley-Black and Elementary Analysis methods.

(5365 - 545) Microscopic analysis of the structure, dynamics and absorption properties of the standard Leonardite humic acid using molecular dynamics simulations

Drazen Petrov[1]; Daniel Tunega[1]; Martin H. Gerzabek[1]; Chris Oostenbrink[1]

University of Natural Resources and Life Sciences Vienna, Austria[1]

Humic substances (HS) are abundant in the environment and play an important role in a number of biogeochemical processes including microbial activity, soil aggregation, plant growth, the retention and release of nutrients, the environmental fate of pollutants and carbon storage. They are flexible, relatively small molecules forming supramolecular structures through weak interactions. Despite the great importance of understanding their behavior at the atomic level, computational modeling, a premier high-resolution technique providing great level of detail, has been surprisingly little employed to study humic substances. Here, we use the recently developed Vienna-Soil-Organic-Matter Modeler to create representative models of a real HS sample, the standard Leonardite humic acid. The strength of sorption was estimated for a range of small organic compounds in a dry and fully hydrated Leonardite model. Strikingly, our results show a remarkable level of matching with experimental sorption data. Moreover, molecular dynamics simulations were used to probe the structure and dynamics of the system at a range of hydration levels, where the studied systems were characterized in terms of their physico-chemical properties, including density, dielectric properties, hydrogen bonding, etc.

(5973 - 2631) Multivariates analysis of mangroves soils attributes from Parnaiba's delta, Piauí, Brazil

Mirya Grazielle Torres Portela[1]; Gustavo Souza Valladares[1]; João Victor Alves Amorim[2]; Jéssica Cristina Oliveira Frota[1]; Andréa Maciel Lima[1]

Universidade Federal do Piauí[1]; Universidades Federal do Piauí[2]

Mangroves are typical ecosystems of tropical and subtropical coastal regions and present high biological productivity and ecological complexity, observing the constant variation in the physical, chemical and biological attributes, besides the existing biodiversity, rich in endemic species. The mangrove soils are hydromorphic and are form from the deposition of sediments brought by the waterways. These factors confer great variability on the physical, chemical and biological attributes of these soils. The evaluation of these parameters is important for the understanding of the dynamics of this environment, mainly in environmental preservation areas (EPAs). Therefore, this study aimed to apply multivariate analysis to group soil profiles under mangroves in the EPA of the Parnaíba's Delta, state of Piauí, from some physical, chemical and biological attributes of these soils. Samples were collect in 5 soil profiles classified as Gleissolos (4 profiles) and Organossolo (1 profile), at depths of 0-10cm for determination of total organic carbon (TOC), carbon stock (Cstock), granulometry, density, carbon of the microbial biomass (MBC), basal respiration and microbial (Q_{co2}) and metabolic (Q_{met}) quotients. Multivariate analysis by clustering test and principal component analysis (PCA) were apply to the data set. In the analysis of clusters, it was observe that, assuming a Euclidean distance of 0.5, the selected variables grouped the profiles studied into three distinct groups. The first group was composed of profile 1, isolated from the other groups and correlated with TOC, MCB, Cstock and Q_{co2}. The second group was form by profiles 02 and 03 that correlated with silt and clay contents and the third group was form by profiles 04 and 05, which correlated with respiration, density and Q_{met}. In the analysis of principal components, the first two main components (CP1 and CP2) were responsible for 82,57% of the total variance, 52,23% for CP1 and 30,34% for CP2. It is conclude that, through the multivariate analysis, profiles of the same classification have properties of soil with characteristics that allowed to group them in different groups, although they are present in the same ecosystem.

(9724 - 2655) Natural, agricultural and contaminated ecosystems exhibit glomalin in soils with different structural characteristics

Andrés Calderín García[1]; Luiz Gilberto Ambrósio de Souza[1]; Camila Pinheiro Nobre[2]; Florencia Varela[3]; Sael Sanches Elias[1]; Fabiana Soares dos Santos[4]; Ricardo Luiz Louro Berbara[1]

Universidade Federal Rural do Rio de Janeiro[1]; Universidade Estadual de Maranhão[2]; Universidade de Buenos Aires[3]; Universidade Federal Fluminense[4]

Glomalin (Glo) is a glycoprotein produced by root-colonizing arbuscular mycorrhizal fungi. Information about the relationship between the structure of Glo and its properties and functions in the soil is still scarce. As a component of soil organic matter, Glo may present different structural characteristics according to the type of ecosystem where it is found. To test this hypothesis, the present study aimed to characterize Glo from three types of ecosystems (agricultural: Argentina- Typic Hapludoll, natural: Brazil- Oxisols and heavy metal-contaminated: Cuba- Oxisols) using spectroscopy (^{13}C CP/MAS NMR and FTIR) and microscopy (SEM microscopy) combined with chemometric data analysis. The present study showed that Glo possesses a characteristic glycoprotein structural pattern that allows its recognition as an independent component of soil organic matter. In addition, the glycoprotein structural pattern of Glo responds to the type of ecosystem in which it is produced. The ^{13}C NMR presented peaks that could be attributed to carbohydrates (peaks close to 71.7 ppm: C_2-OH -carbon contiguous with the anomeric carbon of pyranose monosaccharides, peaks at 90-94 ppm: anomeric C_a/C_b from monosaccharide structures) and amino acids (10-20 ppm: methyl $-CH_3$; 38-45 ppm: methylene $-CH_2-$; 113-130 ppm: aromatic carbons; 173-177 ppm: carbonyl -C=O; and 178-181 ppm: carboxyl -COOH). Glo from the natural ecosystems presented an aromatic character, which could indicate higher structural stability in undisturbed ecosystems. Glo from the disturbed ecosystem was enriched in oxygenated groups (-C=O and -COOH), indicating preservation of structures that are more apt to interact with heavy

metals in contaminated soil and Glo from the agricultural ecosystem was enriched in anomeric carbons. Glo of natural ecosystems presented a similar superficial morphology (2 µm) and grain size (10 µm) and a different morphology from Glo of agricultural and polluted ecosystems. The grain morphology of Glo from polluted ecosystems exhibited a less amorphous appearance, and the superficial morphology of Glo from agricultural ecosystems was more compact (less irregular).The present study is especially important because it shows that ecosystem management affects the properties of organic molecules that are important for the biological-physical and chemical balance of soils.

(5198 - 2820) Organic fertilization in the dragon fruit production

Alexandre Dias Silva[1]; Verônica Andrade dos Santos[1]; José Darlan Ramos[1]; Ana Claudia Costa[1]; Rene Martins Medeiros[1]; Ellison Rosario de Oliveira[1]; Fábio Oseias dos Reis Silva[1]; Leonardo Pereira da Silva Brito[1]; Ranieri Reis Laredo[1]

Federal University of Lavras[1]

The nutrient supply is important for fruit production, especially in tropical soil where the nutrient availability is low. The use of organics fertilizer is a sustainable alternative of nutrient supply for the crops. The dragon fruit is among the tropical fruit with high economic potential, but there is few study regarding to this fruit, mainly related to its nutrient requirement. Thus the objective of this this study was to evaluate the organic fertilizer supply in the white pulp dragon fruit production in the field. For this, eight treatments were performed, (1-control; 2-cattle manure; 3-chicken manure; 4-marine biofertilizer; 5-cattle manure + chicken manure; 6-cattle manure + marine biofertilizer; 7-chicken manure + marine biofertilizer; 8-cattle manure + chicken manure + marine biofertilizer). The supply of chiken manure + cattle manure + marine biofertilizer showed higher productivity in tones per hectare in fruit number per plant, being the best combination to be used.

(1086 - 436) Organic matter content in agricultural soils along main geomorphological units of Vojvodina Province, Serbia

Jordana Ninkov[1]; Snežana Jakšić[2]; Srđan Šeremešić[3]; Jovica Vasin[1]; Stanko Milić[1]; Borislav Banjac[3]; Aleksandra Mihailović[4]

Instute of Field and Vegetable Crops[1]; Institute of Field and Vegetable Crops[2]; University of Novi Sad, Faculty of Agriculture[3]; University of Novi Sad, Faculty of Technical Sciences[4]

Vojvodina Province in the northern part of Serbia represents its most important agricultural area. Regarding the distribution of soil types, as much as 60% of the Vojvodina Province soil is chernozem, and other soil types with considerable areas include hydromorphic black soils (16%), and the alluvial soils (9%). Regarding the pedogenesis of Vojvodina soils, the relief is the dominant factor for development of appropriate soil properties compared to other pedogenetic factors. Alluvial plains (AP) and mountains (M) have higher geological and pedological diversity, unlike sandy areas (SA), loess plateaus (LP), upper Pleistocene terraces (UPT) and alluvial terraces (AT). The aim of this study was to access the content of organic matter (OM) in agricultural soils and its spatial distribution along main geomorphological units of Vojvodina Province. A grid superimposed on Vojvodina soil by means of a GIS tool (GIS ArcView 10) has divided study area into 4 × 4 km units, each representing an area of 16 km^2. Total number of 1,370 bulked soil samples (0-30 cm depth) were taken from agricultural land and analyzed for organic matter content by soil oxidation using the sulphochromic oxidation method by ISO 14235 (1998). The average concentration of OM in soil of Vojvodina Province was 3.05%, with median 3.07%, which is lower than in survey from 1991 when average OM was 3.41%. Causes of OM loss in Vojvodina soils include primarily insufficient use of organic fertilizers and inadequate cultivation practices. Average values of OM concentrations for soils formed on different geomorphological units were: 2.26% for SA, 2.57% for AT, 2.94% for M, 3.03% for AP, 3.12% for UPT, and 3.18% for LP. According to significance of the differences in the OM content between the geomorphological units, UPT, LP, M and AP were in one group, while SA and AT were in two separate groups. OM content in agricultural soil is arranged in a logical sequence along different geomorphological units, except mountainous (M) areas. The obtained results indicated that beside visible anthropogenic influence on OM there is a considerable background in natural and morphological systems. Therefore, the prediction of the future OM trend must encompass geomorphological properties of larger areas.

(4338 - 2853) Patterns of change in soil organic matter along a latitudinal gradient in Atlantic volcanic Islands

Zulimar Hernández[1]; Tomás de Figueiredo[2]; Juan Pedro Pérez Trujillo[3]; Pilar Carral[1]; Ana Mª Álvarez[1]; Gonzalo Almendros[4]

Dpto. Geology and Geochemistry, Autonomous University of Madrid, Spain[1]; Instituto Politécnico de Bragança (IPB), Portugal[2]; Dpto. Chemistry, University of La Laguna, S/C Tenerife, Islas Canarias, Spain[3]; MNCN, Spanish Council of Scientific Research, Madrid, Spain[4]

Volcanic ash soils have been classically considered as active C sinks due to their potential to stabilize organic colloids at mineral surfaces. This function has been attributed to the dominance of non-crystalline minerals. However, this is not the case with all volcanic soils. When subjected to intense tillage, these soils suffer long periods of drought, which increase the loss of soil organic matter (SOM). The above could reduce the cementing capacity of amorphous oxides. This research aims to determine the patterns of change in SOM quantity and quality in volcanic soils, along a latitudinal sequence from wet-cold to dry-warm climates, in the ecoregion known as Macaronesia (between 40º and 14º NL in the Atlantic Ocean). The soil sampling was carried out in representative islands: a) Pico Island (Azores), b) Tenerife, Hierro and Lanzarote (Canary Islands) and, c) Fogo Island (Cape Verde), where the oldest wine-growing regions were selected as study area. Routine physicochemical properties (such as pH, EC, ECEC, SOM, amorphous oxides, available nutrients, texture and aggregate stability) were analyzed using spectroscopic techniques previously calibrated with analytical databases. Chemical composition of SOM was analyzed by pyrolysis. Different statistical treatments were applied in order to evaluate the role of the mineral fraction in soil C sequestration. The results showed that the amount of SOM to large extent is driven by the presence of variable charge minerals. However, the same did not occur with the SOM quality. Pyrolysis showed that different sources of SOM (plant biomass, microbial activity and organic amendments) and degree of soil C stabilization were related to the latitudinal gradient. In Pico Island, with high amount of SOM (>80 g/kg) there was a dominance of easily-biodegradable organic compounds from microbial activity stabilized by amorphous oxides. In the Canary Islands, as expected due to an older agricultural history, the decline in soil C levels is related to the intensity of farming practices. Here, low values of SOM and higher proportion of pyrolytic products from plant

biomass were described. Finally, in Fogo Island, medium values of SOM (<40 g/kg) and low proportion of lignin-derived SOM pointed to high microbial activity, against the expected for aridic climate; which is possible due to the existence of buried soils under volcanic ashes.

(3821 - 2148) Physical fractionation of organic soil matter in different systems of use and management

Ésio de Castro Paes[1]; Fabiane Pereira Machado Dias[1]; Iara Oliveira Fernandes[1]; Elisângela Gonçalves Pereira[1]; Davi Ney Santos[1]; Greice Helen da Cunha Moreira Lima[1]; Júlio César Azevedo Nóbrega[1]
Universidade Federal do Recôncavo da Bahia[1]

Organic matter plays a fundamental role in the chemical, physical and biological properties of the soil, it has been the object of many studies in order to understand its dynamics in agroecosystems. The present study had the objective of evaluating the impact of different systems of use and management on soil organic matter contents through physical fractionation. The study was developed in experimental areas of the municipality of Cruz das Almas, Bahia, in a Oxisol. The treatments consisted of a conventional cassava (MD) system, pasture (PA), agroforestry systems with 7 and 12 years of management (S7 and S12) and native forest (MT). Deformed samples were collected at depths of 0.0-10, 0.10-0.20, 0.20-0.40 m, in five replicates. The total organic C (TOC) was determined by colorimetry and the granulometric fractionation of the organic matter was obtained, obtaining organic C (C-MOP) and organic C associated with minerals (C-Am). TOC levels ranged from 14.17 to 25.06 g kg^{-1}, with no significant difference in surface area. For the 0.10-0.20 m layer the TM presented higher content than the others. What can be attributed, possibly the great density of roots. In the depth of 0.20-0.40 m the MT, SA12 and SAF7 presented higher TOC levels. This may be related to the soil rotation in the MD system, which favors the rapid oxidation of the organic matter, causing the soil aggregates to break down. The levels of C-MOP ranged from 4.06 to 5.98 g kg^{-1}, at depths of 0.0-0.10 and 0.20-0.40 m, and did not detect changes due to management systems. For the depth of 0.10-0.20 m, it was verified that the SAF12 presented higher levels than the other treatments, demonstrating the importance of this system for the maintenance of microbial activity and nutrient cycling, since C-MOP can be considered the labile fraction of the organic matter of the soil. The C-Am contents varied from 6.60 to 22.70 g kg^{-1}, representing around 60 to 80% of the COT, similar to the C-MOP contents, there was no significant difference between the treatments at the different depths, which was already expected, since C-Am is a fraction not affected by the management system, with the exception of the MT system that showed superiority in relation to the others in the 0,10-0,20 m layer, which can be attributed to the higher degree of humification, and MD which was lower by 0.20-0.40 m. The results showed that agroforestry systems tend to recover and/or increase C levels in the long term.

(1339 - 2099) Relation of total and relative cost of nutrient losses among different pasture management

Rafaela Ramos Bertuani[1]; Kamila Cabral Mielke[1]; Paulo Roberto da Rocha Junior[1]
Universidade Federal do Espirito Santo[1]

Most of the cattle ranching areas were formed after the clearing of the forest areas, aiming at the production of milk and meat. However, the use of burning and excessive soil preparation associated with high stocking rates over the years resulted in a decline in nutrient content in soils under pasture, influenced by erosion processes. In this sense, the objective was to study the total and relative cost of nutrient losses in different pasture management. Six pasture managements were studied: control, fire, prepared, managed, fertilization and ILPF. Costs were separated into inputs and services. The input cost calculation was based on six years of work for final calculation of eucalyptus production (m3 ha-1) and meat production (@ ha-1), with bi-annual pasture maintenance practices. The nutrient loss was based on the average data obtained by Bertol et al. (2007). Evaluating the total and relative costs of nutrient losses, it was verified that fire management provided the highest losses (R $ 1,353.40), while the lowest losses were observed in the area of pasture fertilized (R $ 87, 43). The increase in costs of nutrient losses in the pasture area burned in relation to the pasture fertilized was 93.54%, the smallest difference being observed when compared to the prepared area (33.33%). The values of lower costs of nutrient loss found in the area of pasture fertilized is related to the greater coverage of the soil and greater production of dry mass, associated to the absence of soil management practices. Observing the costs obtained with losses in the managed pasture area (R $ 423.43), it was verified that the losses presented soil losses of 31.17% higher than the management with ILPF (R $ 291.43) and 53.08% lower than the prepared pasture (R $ 902.27). In the area managed with ILPF, due to the adoption of no-tillage, an even smaller soil movement is observed, promoting lower loss values. For the relative cost, for all treatments, the highest losses were with K, with no trend when P and Ca + Mg were evaluated. In relation to K, the soil management commonly used for the renewal of pastures, such as plowing and harvesting, are the main responsible for increasing the losses of this nutrient, mainly by surface runoff.

(2011 - 3169) Response Surface of Humic Acids on Rice Roots

Orlando Carlos Huertas Tavares[1]; Leandro Azevedo Santos[1]; Andres Calderin Garcia[1]; Manlio Silvestre Fernandes[1]
UFRRJ[1]

The objective of the study was to evaluate morphological parameters of the root system changes in response to humic acid (HA) from vermicompost application, on the rice roots seedlings in the absence of nutrientes, using the response surface model. The study was carried out in a growth chamber in Department of Soils of Federal Rural University of Rio de Janeiro. The treatments consisted of the humic acid extracted with KOH application, in increasing doses: 0, 20, 40, 60, 80, 110, 150 mg HA L^{-1}, with minimum $CaSO_4$ medium at ¼ ionic strength. Then three seedlings were collected at 24h, 48h, 72h, 96h, 120h and 144h and stored in 50% alcohol at -20 °C. The root system of rice seedlings was analyzed in WinRhizo software. The different root characteristics measured were: total length, total surface area, total volume and total number of roots, number of branches and mean root diameter, as well as within diameter classes (superfine, fine and thick roots). The analyzes were performed through generations of the standard response surface models and the suitability verification of these models through the RSM package in the R software. The response surface model was adequate to analyze dose response experiment. The stimulus pattern of increasing doses of humic acid on root morphology of rice seedlings var. Piaui, for the most part, was quadratic response surface, presenting high statistical significance ($p < 0.0001$). Therefore humic acids modify the root morphology (length, area, number of tips and root volume) of the rice plants

(8868 - 1574) Root composition and soil properties determine CO2

efflux from root residue mineralization

Julius Jose Koritschoner[1]; Edgar Ariel Rampoldi[1]; Susana Hang[1]; Yakov Kuzyakov[2]
Universidad Nacional de Córdoba. Facultad de Ciencias Agropecuarias. Departamento de Recursos Naturales.[1]; Department of Soil Science of Temperate Ecosystems, Department of Agricultural Soil Science, University of Goettingen, Buesgenweg 2, 37077 Goettingen, Germany[2]

Abstract The aim of this study was to explore the effects of root and soil properties on mineralization root residues: Sorghum halepense L. (SA), Sorghum bicolor (L.) Moench. cv. Biosilero INTA (SB), Sorghum bicolor (L.) Moench. cv. Pakari (SP), Glycine max (L.) Merr. (SY), and Zea mays L. (MZ). Soils with wide variability in their physical and chemical properties were sampled in the first 15 cm and characterized. The roots were characterized by their elemental and biochemical composition. The C-CO2 evolution in the soils (control) and in the soil + root treatments was followed via incubations under laboratory conditions over 28 d and related to soil and root properties. The design was bifactorial, with fifteen levels of soil factor and five types of roots. During the first 3 d, the root factor explained 84% of the mineralization process, and between 6 - 49% of the C-CO2 flow occurred during that time. Over the course of incubation, the soil factor increased its contribution, explaining more than 50% of the total variation observed at 14 d and remains stable thereafter. The cumulative C-CO2 averaged over all soils shown the following decreasing order: SP > SB> SA > MZ > SY. The roots with the highest concentration of soluble fraction (SOL) and greatest C-to-N ratio were those that produced a relatively high daily flow of CO2. The lignin (LIG) content did not provide decisive information, although the lowest C mineralization was associated with the root residue having the highest LIG content. The soils with a relatively high total N (Nt) content favoured the mineralization of root residues. CO2 efflux from roots with high lignocellulose content showed a delay phase, and the maximum mineralization rate was reached on day seven. Although cellulose (CEL) was negatively related to the C-CO2 flow, a interaction was obtained between pH and CEL (soil-residue interaction), lower pH of soils favored the decomposition of roots with higher content of cellulose suggesting that in the intermediate stages of root residue mineralization, the microbial attack on less labile forms would be regulated by soil conditions.

(5472 - 332) Slow-cycling fractions are more sensitive to temperature than fast-cycling fractions during long-term turnover of soil organic carbon

Guoan Wang[1]; Yufu Jia[1]
China Agricultural University[1]

The temperature sensitivity of soil organic carbon (SOC) decomposition has been a crucial topic in global change researches, yet it remains substantial uncertainties. One of the possible causes to the uncertainties is interference from other factors, especially precipitation. In this study, the temperature sensitivity of decomposition of four fractions (light fraction (LF), particulate organic matter (POM), acid hydrolizable fraction (HF) and recalcitrant fraction (RF)) was investigated for 12 sites along a temperature gradient with 400 mm of mean annual precipitation (MAP) on the Qinghai-Tibet Plateau of China. ^{14}C analyses of the SOC fractions combined with a model provided estimations of their turnover time and decomposition rate. After minimizing the effects of other factors, such as precipitation, vegetation, parent material, topography, time and human activity, this study shows that the turnover time is LF < POM < HF < RF, and the Q_{10} value is RF > HF > POM = LF. This indicates that stable fractions are more sensitive to temperature than labile fractions. The analyses of Fourier Transform Mid-infrared Spectroscopy (FTIR) reveals that protection mechanisms rather than molecule structure controls SOC turnover. A new conceptual model of SOC decomposition of temperature sensitivity was proposed based on our results, i.e. apparent sensitivity is primarily determined by de-protected sensitivity, and intrinsic sensitivity has a secondary contribution to apparent sensitivity of SOC fractions. This study also reveals that, compared with the estimation based on the Q_{10} values of SOC fractions obtained in this study, the flux of released carbon from the grasslands on the Qinghai-Tibet Plateau is underestimated while the stock of soil carbon is overestimated in the next 100 years based on one-pool model (Q_{10} = 2) or bulk soil (Q_{10}= 5.93). Therefore, the estimation based on one-pool model or bulk soil would exaggerate the negative feedback of soil carbon to global warming.

(7037 - 2884) Soil carbon dynamics under silvopastoral systems in Northern Minas Gerais/ Brazil

Leidivan Almeida Frazão[1]; Luana Larrisa de Souza Almeida[1]; Paula Franciele Melo[1]; Juliana Martins Ribeiro[1]; Álvaro Luiz de Carvalho Veloso[2]; Ângela Maria Quintão Lana[1]
Universidade Federal de Minas Gerais[1]; FUNORTE[2]

Conventional management systems alter the dynamics of soil organic matter, leading to losses in productivity over the years. As a proposal, the integrated production systems were introduced to improve soil quality and promote increase in productivity per unit of area. So, this study aimed to compare the soil carbon dynamic under native vegetion of Cerrado (NV), abandoned pasture (PA), and after the introduction of silvopastoral systems in Northern Minas Gerais, Brazil. The arrangement of silvipastoral systems wih four years of implantation consisted of a consortium of Eucaliptus cloeziana + Urochloa brizantha cv. Marandu (SP1) and Eucalyptus urograndis + Urochloa brizantha cv. Marandu (SP2). We measured total organic carbon (TOC), microbial carbon (Cmic), basal respiration of the soil (SBR) and efflux of CO2 from the soil and calculated the metabolic (qCO2) and microbial quotient (qMIC). Soil samples were carried out in January (wet season) and in July (dry season) in 0-5; 5-10 and 10-20 cm soil deph layer, while CO2 efflux and Wflux were measured using a infrared gas analizer (IRGA) by a soil respiration chamber LCpro-SD. The values of COT, Cmic, qMIC, CO2 efflux and Wflux were higher in the wet season (January) for all evaluated systems, whereas SBR and qCO2 were lower in this period. In July, the climatic conditions with water deficit and low temperatures impacted the activity of soil microbial biomass, causing an increase in SBR and qCO2 in this period. Comparing the evaluated systems, it was observed that the silvopastoral systems (SP1 and SP2) presented similar results to NV in both evaluated periods. The analysis of canonical variables indicated that the soil attributes Cmic, SBR and TOC were the most sensitive indicators to explain the variability between the treatments and the evaluated periods. In addition, we found that integrated production systems promoted positive changes in soil carbon dynamics, since the indicators used in this study presented similar values to those observed in the native vegetation.

(4534 - 317) Soil Labile Carbon and Carbon Management Index under different land use and management systems in the Brazilian Cerrado

Fabiane Pereira Machado Dias[1]; Rodrigo Hübner[1]; Flávia de Jesus Nunes[2]; Wilson Mozena Leandro[1]; Francisco Alisson da Silva Xavier[3]
Goiás Federal University[1]; Federal University of the Recôncavo of Bahia[2]; Embrapa Cassava and Fruticulture[3]

Soil organic matter (SOM) is considered a suitable indicator of soil quality since it is involved with most important chemical, physical and biological processes in the soil. Labile SOM fractions are more sensitive to the changes promoted by soil management, so that can be considered as good indicators of soil quality. We aimed to evaluate the impact of different management systems on the labile C contents of an Oxisol in the Brazilian Cerrado. The study was carried out in the Nossa Senhora Aparecida farm, situated in Hidrolândia municipality, state of Goiás, Brazil. Soil samples were collected from the follow land-use or management systems: 1-Native forest (NF); 2-Degraded grassland (GRAS); 3-No-tillage system (NT) (maize, peanuts, soybean); 4-Conventional tillage (CT) (maize); 5-ORG10; 6-ORG8; 7-ORG6 and 8-ORG2, areas under organic cultivation over 10, 8, 6 and 2 years, respectively. In each selected system, soil samples were taken in four replicates in the 0-10, 10-20 and 20-40 cm depths, and analyzed for total soil C (TOC) and labile C (Lab-C) by using potassium permanganate method. Based on the results of TOC and Lab-C it was calculated the carbon management index (CMI) to evaluate the impacts of soil management practices on organic matter quality. Soil TOC contents were significantly affected by management and varied from 11 to 29 g kg^{-1}. In the upper soil layer, NF and CT areas showed highest TOC contents. Lab-C varied from 0,27 to 1,16 g kg^{-1}, representing around to 4% of TOC. For all soil layers, Lab-C was higher in the CT system followed by NF area. In general, organically cultivated soils presented similar Lab-C contents, with exception in the 20-40 cm depth in which ORG-2 and ORG-6 showed higher Lab-C compared to ORG-8 and ORG-10. The CT system presented the highest values of CMI (> 100) for all evaluated soil layers. This result suggests recovering of SOM quality and enhancement of C sequestration. Organically cultivated sites showed intermediate CMI among studied areas, in which ORG6 was the only site that presented CMI > 100. In GRAS and NT soils CMI values were lower than 100 for all evaluated layers, indicating decreasing of SOM quality and C storage. Our results showed that CT and ORG systems recover SOM levels and increases C lability, while NT and GRAS contribute to SOM depletion. Labile C and CMI reflected recent impacts of management on the SOM levels.

(8833 - 202) Soil microbial biomass and humic substances under Eucalyptus cultivation of different age

Wesley Machado[1]; André Sarabia Zamarian[1]; Maria Elvira Simionato[1]; Gabriela Machineski[1]; João Tavares Filho[2]
Universidade Norte do Paraná[1]; Universidade Estadual de Londrina[2]

Humic substances result from the degradation of organic compounds by microbial activity and play an important role in soil structure and CTC. In fast-growing tree species cultivation, such as Eucalyptus, the input of litter in soil interferes with the dynamics of these substances, which together with microbial biomass might be used as indicators of soil quality. Despite that, changes in soil chemical and biological attributes in Eucalyptus plantation are still poorly understood. Thus, the purpose of this work was to evaluate soil humic substances and microbial biomass attributes in Eucalyptus plantations of different ages in Brazil. Soil samples were collected in São Sebastião da Amoreira-Paraná state, in Eucalyptus plantations of 3, 6 and 15 years-old from 0.0-0.1 m and 0.1-0.2 m depth. Organic matter, humic and fulvic acids fractions and the microbial biomass attributes: microbial biomass carbon and nitrogen and microbial respiratory activity were determined. Organic matter, fulvic acids and microbial respiratory activity were not influenced by the different ages of eucalyptus plantation. The content of humic acids increased significantly (p<0.05, Tukey test) in the oldest areas of Eucalyptus plantation, with the highest concentrations found in 15 years-old area, means of 5.32 mg g $soil^{-1}$ and 5.18 mg g $soil^{-1}$ at depths of 0.0-0.1 m and 0.1-0.2 m, respectively. Microbial biomass carbon was significantly higher (p<0.01) in 3 years-old area at 0.0-0.1 m depth, means of 24.94 mg g $soil^{-1}$, while at 0.1-0.2 m depth, the highest levels of microbial biomass carbon (p<0.01) were found in 6 years-old area, 15.35 mg g $soil^{-1}$, followed by 15 years-old area, 8.68 mg g $soil^{-1}$. Microbial biomass nitrogen in 15 years-old area at 0.0-0.1m depth was significantly lower (p<0.05), 10.87 µg g $soil^{-1}$, than in 3 and 6 years-old, 15.23 and 12.21 µg g $soil^{-1}$, respectively, but there was no significant difference at 0.1-0.2m depth. These results indicate different patterns of microbial biomass dynamics in soil layer. In addition, longer eucalyptus cultivation time increases litter and mineralization of organic compounds and, consequently, tend to increase humic acid storage and to reduce levels of microbial biomass carbon in the soil superficial layers.

(5408 - 495) Soil organic carbon content in topsoil of croatia

Stjepan Husnjak[1]; Aleksandra Bensa[2]; Danijela Jungic[2]
University of Zagreb, Faculty of Agriculture[1]; University of Zagreb Faculty of Agriculture[2]

The main goal of this paper is to present the state of the soil organic carbon (SOC) content in the topsoil of Croatia considering agricultural regions and land use. The data of humus content in the surface horizon of 5.023 soil profiles from the Basic Soil Map of Croatia in scale 1: 50.000 which was made in the period 1965-1985 were used as a source of data. Agricultural regions (Pannonian, Mountainous and Adriatic) were allocated according to Basic et al. (2001) and the inventory of soil profiles under forests, grassland and arable land based on land use map (DZZP, 2004). Data were statistically analysed by analysis of variance with Tukey-Kramer test. The average SOC content in all samples was 2.53% and varied in the range of 0.06-7.56%. Statistically significant differences in SOC content were found between all regions, with a decrease from Mountainous (3.28%), over Adriatic (2.52%) to Pannonian region (1.94%). The average SOC content in grassland and forest were moderate (2,69 and 3.09% respectively) and in arable land was low (1.97%), with statistically justified differences between all class of land use. The most significantly differences between the regions were found in forests, where the SOC content varies from 2.40% in Pannonian to 3.81% in the Mountainous region. The least differences were found in arable land where the SOC content varied from 1.44% in Pannonian to 2.61% in Mountainous region. Considering the age of the data used, the paper points to the necessity of determining their reliability as well as possible changes in relation to today's state.

Natural ecosystems show balance between soil organic matter accumulation and decomposition. However, human actions promote changes in this balance, interfering in the activities of micro-organisms and consequently reducing its activity. To measure the degree of the changes, one of the most used ways is to assess the microorganisms activity responsible for the decomposition of organic matter. The aim of this work was to evaluate the microorganisms activity on Amazon soil under different use and management. The work was carried out in the northern State of Mato Grosso. The treatments were: teak (*Tectona grandis*) homogeneous plantations with 12, 14, 16, and 19 years old; teak (7 years old) intercropped with *Urochloa brizantha* cv. Marandú grass (19 years old), degraded pasture due to sudden death, and native forest, used as reference. The studies sites were adjacent each other. Three soil samples were collected randomly at 0 - 0.10 m depth within each soil use field. To determine CO_2 basal respiration (BR), the soil samples were incubated for 137 days under controlled temperature and humidity, was measured in each soil sample 15 times, with higher frequency in the beginning of the incubation period. Were too evaluated organic carbon (SOC), and microbial biomass (MBC). The data were submitted to analysis of variance and the treatment averages compared by the Tukey test at 5% of probability. Higher values of SOC (67.48 g C/kg soil^{-1}) were observed in the native forest, followed by the intercropped teak/*Urochloa brizantha* (61.60 g C/kg soil^{-1}). Homogeneous teak plantation showed the lowest SOC values, independently of the age. The MBC values ranged from 54.70 to 271.82 mg C/kg soil^{-1}, with the lowest values observed in the homogeneous Teak (16 years old) and the highest values observed in in the native forest and in the intercropped teak/*Urochloa brizantha*. The lower values of BR were observed in degraded pasture (130.90 mg CO_2/kg soil^{-1}) and in the homogeneous Teak (16 years old) (115.28). The largest BR values were observed in the native forest (453.64). Overall, the results showed that the soil microorganisms activity of the intercropped teak/*Urochloa brizantha* is similar to that of the native forest, indicating balance between soil organic matter accumulation and decomposition, by the microbial community. Probably, the low soil microorganisms activity observed in the teak plantation is due to the accumulating of plant material of low diversity and quality.

(9050 - 3079) Soil organic matters in agroflorestais and pastagem systems, in the municipality of Brazil novo-Pará-Brazil

Wemerson Shimon Ladeira da Costa[1]; Sandra Andréa Santos da Silva[1]; Rainério Meireles da Silva[1]; Delziane Araújo Bezerra[1]; Rylla Bryanne Moraes[1]; Ronilson de Sousa Santos[1]
Universidade Federal do Pará, Campus Altamira[1]

The knowledge of the behavior of the soil attributes allows the establishment of appropriate practices in its management that provide the productivity and quality of the crops, this work had the objective to diagnose soil organic matter in pasture agroecosystems and agroforestry systems, under different depths during the rainy season. The soil samples were collected in a property located in the municipality of Brasil Novo – Pará – Brazil, in the treatments with agroforestry system (SAF) and a planted pasture area (PP), in each of the areas were sampled deformed samples, each treatment consisting of two replicates at depths of 0-20 and 20-40cm. The chemical analyzes were performed by the Laboratory of Agronomic, Environmental Analysis and Preparation of Solutions - Fullin. The identification of the existence or not of statistically significant variations between the treatments was performed using the Wilcoxon test. When analyzing the ecosystems separately, it was observed that in the SAF there was a difference in the amount of organic matter compared to the PP at the depths studied, being the highest contribution found in the superficial layer of 0-20cm SAF (2.1dag/kg) and PP (1.65dag/kg), which is due to the accumulation of biomass incorporated in the soil due to the greater number of species in the agroecosystem. For grazing at the same depth was altered, but it was observed that the results of the 20-40cm layer of the same are medium, which allows the recovery of pasture.

(3155 - 979) Soil Texture and organic carbon fractions in ARID-semiarid soils of Argentina

Mirko schiavi[1]; Perla Pesatti[1]; Sergio Quichan[2]; Martin Alejandro Luna[1]; Roberto Melchor Martinez[1]
National University of Rio Negro. Atlantic headquarters.[1]; National Institute of Agricultural Technology (INTA)[2]

The amount of oxidizable organic carbon (OCox) under different oxidation conditions is a sensitive indicator of soil quality; this parameter can change according soil texture and vegetation type. The objective was to determine changes in the amount and quality of the soil organic carbon in sites with different soil textures and vegetation types. Using satellite images, four sites with different type of vegetation cover were selected in the north Patagonia of Argentina (Lat. 41º 58´ S; Long. 62º-50´ O). The area is characterized by a transition from sub-temperate to arid-semiarid climate, and frequent winds, where the natural vegetation is “Monte”, with xerophyte species, and shrub steppes with dominance of *Larrea spp.* (Zygophyllaceae). The mean annual precipitation is 350 mm and the mean annual temperature of 15 ºC. The main soil orders are Aridisols and Entisols. Extensive grazing in natural grasslands is the main production activity in the area. Each site was classified in four conditions: Dispersed vegetation (S1), Low Forest (S2), Low shrubs (S3) and Grassland (S4). In each zone, a composite soil sample was collected at three sampling points at 0.30 m soil depth. The soil samples were air-dried and passed through a 2 mm sieve. Textural composition was determined by Bouyoucos, and the oxidizing conditions for oxidizing C determination were stablish by using different amounts of sulphuric acid: 0.75 mL (fraction 1), 1.5 mL (fraction 2) and 3 mL (fraction 3) specified by Walkley and Black method, resulting in three acid-aqueous solution ratios of 0.5:1,1:1 and 2:1. The four conditions represented a soil-texture gradient, from 8.6% to 54.3% of clay + silt: S4~S1>S3>S2, ($p<0.05$). The amount of oxidizable organic carbon accounted under different oxidizing conditions also showed significant difference. In all cases, S4 site presented the highest values, with 9.19 mg g^{-1} in fraction 1, 14.96 mg gr^{-1} in fraction 2 and 17.30 mg g^{-1} in fraction 3. The average values for the three fractions were 71%, 53% and 24% for S3, S1 and S2, respectively, of the S4 value. The OCox/(clay + silt) ratio was higher in S2 site. Using this ratio for fraction 1 allows to differentiate S4 (higher) from the other sites. The combined use of the textural composition together with different OCox fractions could represent a better indicator to evaluate the soil quality, and to minimize variations associated to texture.

Federal University of Amazonas[1]

The Amazon is an important biome for the world, highlighting high and rich biodiversity that is one of its great attractions and interest to researchers, much of this biome is concentrated in the state of Amazonas. Soils of the Amazonas have as characteristics soil with a high degree of weathering, presenting predominance of the Latosols and Argisols class, with high aluminum content, low CEC and light, great values of organic matter and verify the behavior of certain attributes is crucial to be it may be possible to understand its characteristics. The objective of this work was to verify the spatial variability of the carbon and organic carbon stock of the soil in an area under cupuaçu management in the South of Amazonas. The study is located in the in Canutama municipality in southern Amazonas, Brazil, where he was selected an area with management cupuassu and held a mesh of 80 points with an area of 70x90 me 10 m spacing between points where these were georeferenced with a device of GPS, and in each point samples were collected in three depths 0.00-0.05; 0.05-0.10 and 0.10-0.20m. After samples were taken, they followed the shed where the leftovers were dried and then discharged, to carry out the analyzes of soil density(Ds), organic carbon (CO) obtained by calculation from the organic matter and soon after the carbon stock (est C). The results were submitted to analysis of variance, descriptive statistical analysis, and finally, the spatial variability was evaluated using geostatistics. By the descriptive statistics it was observed that the mean and median were close having a symmetrical distribution two data, where also the asymmetry and kurtosis were close to zero. The values obtained for R^2 and VC indicate perfect adjustment of the semivariograms, all being higher than 0.7. The spherical and exponential models were the ones that best fit the variables analyzed, thus confirming these models as the ones that best apply to studies within soil science. At the degree of spatial dependence, these were in moderate and strong degree of spatial dependence, and the scopes were higher in the attributes of Est. C, Organic Carbon and soil density in the depth of 0.00-0.05m evidencing a high variability and consequently a low degree of correlation. Thus, the highest reaches were found in the soil surface layer, as well as the highest values of organic carbon.

(4836 - 1847) Spatial variations and influencing factors of soil organic matter contents in different layers and agricultural land uses in Taoyuan, Taiwan

Xiao-Nan Liu[1]; Chun-Chih Tsui[2]; Horng-Yuh Guo[3]; Zueng-Sang CHEN[2]
Guangdong Institute of Eco-environmental Science & Technology[1]; Department of Agricultural Chemistry, National Taiwan University[2]; Division of Agricultural Chemistry, Taiwan Agricultural Research Institute, Council of Agriculture[3]

More and more studies focus on spatial variations and influencing factors of soil organic matter (SOM) in different agricultural land uses. In this study, SOM contents and other soil properties were obtained from a detail legacy soil survey data by Taiwan Agricultural Research Institute (TARI). 1163 soil profiles with different agricultural land uses (paddy field, dry land, orchard, and abandoned agricultural lands) were sampled by soil auger to 0-15 and 15-30 cm depth. Annual average Normalized Difference Vegetation Index (NDVI) was calculate by the NASA's Vegetation Indices 16-Day L3 Global 250m data. Slope, Curvature, Topographic Wetness Index (TWI), and Terrain Roughness Index (TRI) were calculated by 20-m grid resolution DTM. Correlation and regression analysis was performed by SAS 9.4 software. Results showed that the distribution of SOM contents, CEC, and other nutrient elements were higher in the 0-15 cm layer. The elevation and CEC were significantly correlated with SOM in both 0-15 and 15-30 cm soil layers ($p<0.001$), and pH was significantly correlated with SOM in 15-30 cm layer as well. Regression analysis by using the DEM(elevation), CEC, and pH, 52%, 69%, 35%, and 71% of variation on 0-15 cm SOM can be explained in land uses of paddy field, dry land, orchard, and abandoned agricultural lands. In 15-30 cm layer, 52%, 55%, 48%, and 64% of SOM variation can be explained in land uses of paddy field, dry land, orchard, and abandoned agricultural land, respectively. The different explaining ability between land uses may be caused by different farming management. Taoyuan is the mainly origin of rice and fruits, and farmers used many intensive management methods such as weed control, irrigation and drainage control for higher yields of rice and fruits. Therefore, the SOM contents may be more agree with the natural situation on abandoned agricultural land and dry land. Moreover, the explaining ability was lower on paddy filed and orchard, and higher abandoned agricultural land and dry land. These results can help us estimate SOM contents and stocks more accurately and efficiently between different agricultural land uses.

(1932 - 1860) Stock of organic carbon in spodic horizons of Brazilian Spodosols

Andressa Rosas de Menezes[1]; Ademir Fontana[2]; Lúcia Helena Cunha dos Anjos[1]; Marcos Gervasio Pereira[1]
Soils Department – Federal Rural University of Rio de Janeiro[1]; Embrapa Solos[2]

Soils classified as Spodosols in Brazil occur at different landscapes, from coastal plains to high altitude areas. Although they are present in different environments, these soils are formed mainly under humid climates, from sandy parent materials, and usually with shrub and grasses vegetation. They differ from Spodosols from the cold climates and under coniferous forests, from where the concept of podzolization process derived. This order of soils is defined by the Brazilian Soil Classification System (SiBCS) by the presence if a spodic horizon, which must have organic carbon (C org) accumulation in relation to the overlying horizons. To highlight the importance of the preservation of these soils due to their storage of carbon in subsurface, among other reasons related to the flora and fauna they support, the objective of this work was to estimate the organic carbon stock (Ec) of spodic horizons in Brazil. From an extensive bibliographical search, 38 profiles identified as Spodosols according to the SiBCS were selected, and the C org in g kg^{-1}, bulk density (Ds) in Mg m^{-3} and thickness (E) in cm of the spodic sub-horizons data was organized in a spread sheet for evaluation of descriptive statistics. The Ec in Mg ha^{-1} was estimated according to the equation: Ec = (E.Ds.C org) / 10. The thickness of the 67 spodic sub-horizons ranged from 1 to 95 cm, with a mean of 26 cm and a median of 20 cm. The Ds varied from 1.14 to 1.93 Mg m^{-3}, indicating that the spodic horizons varied

from high porosity to dense ones, the last are the cemented types. The mean and median values of Ds were 1.49 and 1.47 Mg m^{-3}, respectively. The levels of C org ranged from 0.4 to 99.2 g kg^{-1}, with the mean and median being 17.2 g kg^{-1} and 14.4 g kg^{-1}, respectively. As for the Ec of the spodic sub-horizons, the mean was 52.9 Mg ha^{-1} and the median was 41.7 Mg ha^{-1}. The maximum value of Ec was of 220.5 Mg ha^{-1} and the minimum value of 0.7 Mg ha^{-1}. Although the tropical climate favors the intense cycling of organic matter added to the soil in the surface, and thus reduce the amount available for translocation and thus accumulation of C org in sub-surface, the spodic horizons showed overall high carbon stock in depth, which is them protected from losses to the atmosphere by emission of CO_2. Thus the safeguarding of areas with Spodosols, besides the preservation of important ecosystems, contributes to minimize the effects of global warming in the regions where these soils occur.

(2586 - 1550) Structural study of humin and its interaction with humic acids by Fourier-transform mid-infrared spectroscopy

Manuel Palencia[1]; Enrique Combatt[2]; Angélica García[1]
Universidad del Valle[1]; Universidad de Córdoba[2]

Soil organic matter (SOM) is a complex mixture of molecules with different physicochemical properties, with humic substances being the main component. Humin is the insoluble component of SOM that remains after extraction of the other humified components that are soluble in alkaline aqueous solutions (humic acids). Humin usually makes up a substantial component of humified organic matter, but its lack of solubility and intractable nature have made it difficult to study. On the other hand, attenuated total reflectance spectroscopy (ATR) in the mid-infrared is a promissory technique for the study of characteristic functional groups on organic molecules, as well as, as for the study of intermolecular interactions by the analysis of the change in the vibration spectrum of molecules. The aim of this work was to study, by Fourier-transform mid-infrared spectroscopy, the structural features of humin and its interaction with humic acids (fulvic and humic acids, FA and HA, respectively). For that, different soil samples were selected from different zones and characterized physicochemical. FA and HA were extracted by alkaline dissolution, fractionated by acidification and purified by ultrafiltration. Sequential washed were performed in order to remove all humic substance and obtain the clay-humin system. FA, HA and humin were analysed by ATR. Interaction between humic acids and humin was studied by mixtures of humified components with humin in different proportions. In order to achieve a major structural resolution of humin different interactions with different low-molecular weight molecules were performed (acetic acid and sorbitol). Spectra were analysed by Pearson spectral similarity index and Functionally-enhanced derivative spectroscopy. It is concluded that the composition of humin differs considerably from the alkaline-soluble components of the SOM, in addition, supramolecular aggregates are formed mainly by the formation of hydrogen bonds.

(9741 - 1635) Study by attenuated total reflectance spectroscopy of structural changes of humified organic matter by chemical perturbations via alkaline dissolution and peroxidation

Manuel Palencia;[1]; Diego Restrepo[1]; Víctor J. Palencia[2]
GI-CAT, Department of Chemistry, Universidad del Valle, Cali, 25360, Colombia[1]; Mindtech Research Group (Mindtech-RG), Mindtech S.A.S, Cali, 25360, Colombia[2]

The humified organic matter is an important parameter for physicochemical description of soils; the cationic exchange capacity (CEC), pH buffering capacity, ability to form particle aggregates, porosity, water storage and other properties are defined or influenced by HOM contents. The objective of the present work was to evaluate the applicability of the attenuated total reflectance spectroscopy (ATR), in the medium infrared, for the description of changes in the spectral response of soil samples subjected to controlled perturbations by chemical methods of humified organic matter and to explore its potential use for quantitative applications: determination of the CEC. For this, six types of soil samples were characterized in terms of physicochemical properties (pH, content of HOM, CEC, exchangeable cations, salinity and texture, as well as by ATR in the mid infrared. Soil samples were chemically disturbed by two methods: alkaline dissolution with NaOH and chemical oxidation with H_2O_2. Chemical treatments were performed at different concentrations and contact different times. Later, samples were analysed by ATR and infrared spectra were analysed by spectral correlation analyses in function of pH, MO and texture using Pearson spectral similarity index and Functionally-enhanced derivative spectroscopy of Fourier-transform infrared spectrum. Finally, CEC for all samples were calculated by perturbation-ATR results and compared with results obtained by ammonium acetate method. It is concluded that the use of the ATR in conjunction with chemical perturbation techniques of the MOH is a promising method for the simple and fast monitoring of the CEC and the study of HOM in soils.

(1959 - 530) Study of the molecular structure of peat and humic substances from peat soils

Roman Vasilevich[1]; Evgeny Lodygin[1]
Institute of Biology, Komi Science Center, Ural Branch, Russian Academy of Sciences[1]

Raw peat and humic substances from the mire peat soils of the forest-tundra zone of the European northeast part of Russia have been characterized in terms of molecular composition. This was accomplished using solid-state ^{13}C NMR techniques and ESR spectroscopy. The composition depended on the intensity of cryogenic processes in the active layer, the quality of the humification precursors (the degree of peat material transformation), and the biochemical selection of aromatic fragments during humification. It was shown that climatic factors are the main driver of the formation of soil organic matter (SOM) as well as the quality and degree of natural polymer destruction. These parameters are reflected in the functional groups and molecular compositions of the humic substances studied in both relic and modern formed peat layers. Humic acids (HAs) and fulvic acids (FAs) of the permafrost peat soils presented low-density molecular structures with a low portion of carbon species from aromatic fragments (15,2-36,3% for HAs and 1,6-12,8 for FAs). In comparison with the mineral soils, the content of carboxylic groups was lower in the peat materials. This reflected the anaerobic conditions in the permafrost peat soils. The content of functional groups and molecular fragments in the HAs illustrated a trend of decreasing paraffin groups and the accumulation of aromatic species of HAs, as well as carboxylic groups from FAs along the depth of the peat soils profile. This resulted from the higher degree of SOM transformation. Transformation of the linear aliphatic fragments leads to the cyclization of paraffin chains with the formation of stabile aromatic fragments. As a result of the low biochemical activity of the permafrost peat soils, labile fractions of carbohydrates demonstrate a

low transformation rate. The effects of low temperatures result in increment of the aromatic fragments of HAs extracted from the layers in contact with the permafrost. The highest indexes of biological activity from bare permafrost peatlands indicate possible climate changes in cases of increased soil temperatures. This results in a stronger alteration of the SOM content in the solum active layer. We conclude that the data on SOM content and molecular quality can be used as an indicator of the degree of organic matter alteration in the sequence of vegetated and bare permafrost peat soils.

(4057 - 2227) The effect of biostimulants on the yield, water and nutrient use efficiency of wheat in drought stress condition

M.M. Tehrani[1]

Soil and Water Research Institute[1]

The experiment was carried out in field of Soil and Water Research Institute, Karaj, 2016-2017. The main factor of irrigation regime was in two levels (full irrigation and 35% less than plant water requirement), the sub factor includes fulvic acid sprayed on three levels (0, 5 and 10 per thousand water) in three growth stages of tillering, stem elongation and heading and soil application of humic acid on two levels (0 and 20 Kg per hectare) in plant emergence and stem elongation stages. The results displayed that the drought stress caused a significant reduction in yield and concentration of the phosphorus in grain and increased concentration of the potassium and water use efficiency in control plots. Application of fulvic acid (5 per thousand) with humic acid on all trial plots had a significant increase of quality and quantity factors such as seed yield, seed kernel weight, shoot and panicle height, number of grains per panicle, concentration of nitrogen, phosphorus, potassium, iron, manganese, zinc, copper and grain protein, nitrogen and phosphorus use efficiency and water use efficiency. The results showed that in drought stress plots, soil application of humic acid increased grain yield in comparison with control treatment of full irrigation. Fulvic acid with a concentration of 10 per thousand had 25 percent increase in grain yield in stress condition compare to control treatment of full irrigation. Therefore, in drought stress conditions using organic acids could resist the wheat against drought stress and increase plant growth and yield.

(8350 - 3181) The forest systems influence in the dynamics of the carbon and nitrogen in soils of Tabasco and Campeche, Mexico.

Aaron jarquin sanchez[1]; Lorena Del Carmen Hernández Nataren[2]; Miguel de Jesús de la Rosa Carrillo Perez[1]; Consuelo Sarracino Vázquez[1]

El colegio de la frontera sur[1]; programa de Ciências do solo da Univeridade Federal de Lavras[2]

The contents of Carbon and nitrogen in the soil are important components of the fertility and play an important paper in the mitigation of the greenhouse gases, these contents are determined by the type of predominant vegetation in the zone of study. The total Carbon (Ct) and the total Nitrogen (Nt) in the forest soils are generated by the contributions of the communities of plants and the interaction by the climatic present conditions. In the forest zones of the conditions of Tabasco and Campeche, sites under influence of tropical climate the dynamics of mineralization are constant, for what there becomes important the evaluation of the contents of these elements in them, sites under these influences. The study was realized in 1240 samples of soil of different depths: litter, fermentation and mineral horizons. The average Ct of the soil was of 13.38 ± 13.31 % with minimal values of 0.03 and maximums of 46.56 %. In case of the Nt the average is 0.76 ±0.59 % with minimal values of 0.01 and maximums of 3.11 %. The relations Ct/Nt were 20.16 ±30 with minimal values of 0.12 and maximums of 475.5. For the carbonates the average value was 13.35 ±29.29 with minimal values of 0.02 and maximums of 96.92 %. In general, the carbon represents 67.55 % and the carbonate 32.45 %, of the total carbon of the soils of these conditions; the relations Ct/Nt indicate that there is an important dynamics of recycling of vegetable residues and mineralization. What they return to these vulnerable ecosystems.

(2086 - 1256) The properties and age of organic matter in soils developed under conditions of rapidly retreating Arctic glaciers

Elya Zazovskaya[1]; Nikita Mergelov[1]; Vasiliy Shishkov[1]; Andrey Dolgikh[1]; Alex Cherkinsky[2]; Evgeniy Abakumov[3]; Nikolay Osokin[1]; Sergey Goryachkin[1]

Institute of Geography Russian RAS, Moscow[1]; University of Georgia, Center for Applied Isotope Studies Athens, GA, USA[2]; Saint-Petersburg State University, Saint-Petersburg , Russia[3]

Recent climate warming has caused rapid thawing of Arctic glaciers and the development of soil-forming processes on freshly exposed substrates. Sediments that have accumulated over the lifetime of these glaciers have mostly aeolian genesis and include both minerogenic and biogenic components. Such sediments are termed cryoconites and act as a storage of organic carbon within glaciers formed during the Pleistocene-Holocene. The retreat of glaciers is accompanied by the release of cryoconite material into water flows that carry and deposit such material usually within areas sheltered from winds. In comparison to other deposits within the modern periglacial zone of the Arctic, the cryoconite parent material of soils has special properties such as a high content of biogenic compounds and fine texture, which favour the colonization by higher plants and the development of pedogenesis. The study sites were located within the glacio-nival system of the rapidly retreating Aldegonda Glacier (its snout was reduced by 2 km in the last 100 years) and on third marine terraces of the East-Fjord in Svalbard, Norway (77.98 N, 14.11 S). The objects studied were as follows: (1) soils formed on moraines of different ages (free from glacial ice for either 18, 70 and over 100 years), (2) fine earth and moss residues in cryoconite holes on glacial ice surface and (3) soils on marine terraces that were free from glaciers for the entire Holocene, according to palaeogeographic data, and, therefore, unlikely to contain any carbon of cryoconite origin. Data were obtained on C and N contents (dry combustion), C and N isotopic compositions, radiocarbon ages of TOC and of densitometric fractions and magnetic properties (NMR-spectroscopy). Results of this study led to the conclusion that cryoconites served as a source of organic matter for the soils on moraines and, as was shown by the radiocarbon dating, such organic matter was originated from deep layers of the rapidly thawing glacier. In soils formed either with or without cryoconite material, densitometric fractions with >1.6 g/cm^3 densities were older than light fractions. In soils with cryoconite material the heavy fractions were dominant and significantly more ancient than in soils without such material. Thus, carbon deposited by glaciers thousands of years ago has been included into carbon exchange cycle, with its properties being retained for over hundred years.

(9645 - 1405) The role of Humic Substances in the root growth of

lettuce plants

Andressa Classer Bender[1]; Deborah Pinheiro Dick[1]; Daniel Hanke[2]
Federal University of Rio Grande do Sul[1]; Federal University of Pampa[2]

It is estimated that by 2050 world food production will increase 60%. The use of plant growth promoters derived from humic substances is an alternative to increase plant productivity. The aim of this work was to investigate the effect of commercial products GrowMate Soil (16% humic acids, HA) and GrowMate Plant (35% fulvic acids, FA) on root growth of lettuce plants. Sterilized lettuce seeds (*Lactuca sativa*, veronica variety) were conditioned on germination paper, in dark at 25 ºC for 4 days. After germination, seedlings were transferred to the following nutritive growth solutions: Saruge nutrient solution + 16% m / m HA (SN + 16HA), Saruge nutrient solution + 8% m / m HA (SN + 8HA), distilled water + 16% m / m HA (H_20+16HA), distilled water + 8% m / m HA (H_20+8HA), Saruge nutrient solution + 35 % m/ m FA (SN + 35FA), Saruge nutrient solution + 17.75% m / m FA (SN + 17FA), distilled water + 35% m / m FA (H_2O + 35FA), distilled water + 17.75% m / m FA (H_2O + 17FA). A solution with Saruge (SN) and another with distilled water (H_2O) were used as control treatments. The experimental design was completely randomized design (CRD) with 5 replicates. Plants were harvested at 20 days after implantation. Root growth evaluation was performed using Safira software for root digitized-images. Volume (mm^3), area (mm^2) and root average diameter (mm) were determined. Variance analyses (ANOVA) was performed to evaluate root parameters. The difference among treatments was determined by Tukey's test ($p < 0.05$). In relation to root volume of lettuce seedlings, treatments with HA, addition (SN + 16HA, SN + 8HA, H_20 + 16HA and H_2O + 8HA) showed the highest values. When nutrients were available in the solution, 50% of the recommended HA dose was sufficient for a higher root yield when compared to SN treatment. In the absence of nutrients, the use of 100% of HA dose it is recommended, since the treatment H_2O + 8HA did not differ from SN and H_2O treatments. In relation to the root area, treatment SN + 8HA presented a higher value in comparison to the treatments without HA. On the opposite to HA, FA decreased the root development of lettuce plants. The average root diameter did not differ among treatments. The use of HA directly in nutritive solution significantly increased root development and surpassed the effect of the nutrient solution . On the other hand, the FA present an inhibitory effect, and its application is not recommended at this stage of lettuce growth.

(8923 - 582) Variations of organic carbon and phosphorus in ARID-semiarid soils of Argentina

Luna Martín Alejandro[1]; Juan Alberto Galantini[2]; Liliana Suñer[3]; Juan Manuel Zeberio[1]; Roberto Melchor Martínez[1]
Universidad Nacional de Río Negro. Sede Atlántica.[1]; Comisión de Investigaciones Científicas (CIC) - CERZOS-UNS.[2]; Universidad Nacional del Sur. Departamento de Agronomía.[3]

Organic carbon (OC) and phosphorus (OP) are key elements of soil quality and health. Both are influenced by the input of organic material to the soil. The aim of this research was explored variations of OC and OP to different depth in natural soils of the Patagonian. Six sites were selected, from satellite images, with different type cover vegetation, of northeast Argentina (Lat. 40º-41º S; Long. 62º-63º O). The climate is arid- semiarid, with average precipitation and temperature of 400 mm and 14,5 °C respectively, and frequent winds. The vegetation that characterizes this area is of the typical Monte, with xerophyte species; shrub steppes with dominance of *Larrea spp.* (Zygophyllaceae) are the most common landscapes. The main soil orders are Aridisols and Entisols. Each site was classified in: forest (F), shrub (S) and shrub-forest (SF) according to their physiognomy, in all of them three plots of 10x10 m were delimited. Five soil samples were taken in each plot to different depths: 0-0.01; 0.01-0.05; 0.05-0.10; 0.10-0.30 and 0.30-0.60 m. All samples were wet sieving, obtaining two particle size fractions: between 2000-53, and lower than 53 µm. In each fraction the concentration of OC by humid combustion and OP by Saunders and Williams method was determined. The type of vegetation influenced on relationship between the most labile fractions ($OC_{2000-53}$) with respect to most stabilized ones ($OC_{<53}$); this relationship in general was higher in the S, and in deeper layers these ratios were significantly different. In F were obtained 9.10 and 9.08 mg OC gr^{-1} soil for the 0.30 and 0.60 m. of depth; F presented a 75.5 and 123% more OC<53 that S in those depths, and SF an 8.5 and 48% less. Whereas, $OC_{2000-53}$ not showed significant different. The OP was strongly influenced by the particle size, the particles less than 53 µm ($OP_{<53}$) presented the highest concentration of OP. The average concentration of $OP_{<53}$, was of 140.7 mg OP gr^{-1} soil for entire profile, whereas to $OP_{2000-53}$ was of 37.4 mg OP gr^{-1} soil. These results indicate that the variations of OC and OP respond differently in environments according to place characteristics: vegetation type, soil and climate variations, uses different, etc.

(8146 - 2329) Vertical phosphorus (P) mobility in soil under natural pasture

Vanessa Dias[1]; Frederico Costa Beber Vieira[2]; Alisson de Mello Deloss[2]; Joscelina Paranhos Rosa de Vargas[1]
Federal University of Santa Maria[1]; Federal University of Pampa[2]

Natural pastures represent a wealth for the state of River Big of South, and some of these fields are poor in phosphorus. They are currently under threat due to some poorly managed handling practices. In this sense, it is important to seek a balance between productivity and conservation of natural resources, and therefore strategies for intensification of forage production should be sought in a way that improves production without deteriorating the natural pasture environment. Phosphate fertilization and the insertion of forage species are interesting options for such intensification. The objective of this work was to verify the vertical mobility of phosphorus after surface application and to demonstrate the effects of natural pasture interference strategies on soil chemical quality. The experiment was installed in 2014 in a natural pasture area belonging to the Anacreonte Ávila de Araújo Research Center (FEPAGRO Forage), in a Red Argissolo, in the municipality of São Gabriel, RS. The experiment has four treatments: 1) natural pasture (PN); 2) PN + liming + mineral fertilization of phosphorus (P) and potassium (K); 3) PN + liming + PK + ryegrass + legumes; and 4) PN + liming + PK + ryegrass + N mineral. In order to evaluate soil chemical attributes, the soil was sampled in 2014, 2015 and 2016, to the depth of 40 cm, stratified every 2 cm to a depth of 20 cm. The samples were air dried, ground and the phosphorus content determined. The results were submitted to analysis of variance, and when significant were compared by the Tukey test. The phosphorus content at 3 months did not show a response between the treatments. In treatment 3, the phosphorus content was higher in relation to the others in the more superficial layer, decreasing to a third of this content in the subsequent layer and demonstrating the low mobility that P presents in the soil. At 18 months, the effect of P fertilization was more evident, and the treatment without phosphate fertilization (PN) showed a significantly

lower P content than fertilized treatments.

(7022 - 2663) Zn, Ni, Pb and Cu contents in two organo-soils of Rio de Janeiro state.

Talita de Santana Matos[1]; Sidnei Julio Beutler[1]; Marcos Gervasio Pereira[1]; Everaldo Zonta[1]
Universidade Federal Rural do Rio de Janeiro[1]

The objective of the present study was to evaluate the alteration of the chemical element contents (Zn, Ni, Pb and Cu) as a function of the subsidence rate in two organic soils located in Rio de Janeiro state. The experiment was conducted under greenhouse conditions. Undisturbed samples were collected using PVC tubes in two profiles of *Thyomorphic organosols*, one in Santa Cruz neighborhood (Profile SC, and the other one in Magé (Profile MG). Three levels of drainage were evaluated at 30, 60 and 100 cm depth. And soil samples were collected at layers of 0-10, 10-20, 20-30 and 30-40cm. The first evaluation was done at the experiment implantation and the second 365 days later. After the sample preparation, pseudo total digestion was performed by SW-846 3050b method (USEPA, 2007). Chemical elements contents were determined by Atomic Absorption Spectrometry. The parameters average obtained was compared by Tukey's test at 5% probability in a completely randomized design, using the R software. In both profiles no significant differences were observed between the two evaluation times. However, different behavior was observed in drainage blade and in the profile height. In the SC profile soil, the Ni contents presented a significant difference between the depths in the drainage level of 100 cm, in the 30 - 40 cm depth different from the others. The Cu concentrations showed similar behavior when compared to Pb. For Pb, differences were observed between the height of the water blade and the profile depths, with the 100 cm blade showing the lowest value. For Ni, the highest levels were found in the first 20 cm of the soil profile. The Zn contents varied according to the profile depth, with the largest differences found in the layers of 0-10 and 10-20 cm. By evaluating the MG profile it was observed that the behavior between the two profiles is quite similar exception made for Ni and Pb contents. These results indicate a significant interaction between water blade height and the profile depth at the level of 60 cm, with the 30-40 cm depth showing the lowest values. Therefore, deeper drainage has contributed to increase element contents in the most superficial layer of the soil profile, possibly by interference of adsorption in the element dynamics.

Wlly Cristiny Mendes de Oliveira[1]; Julia Maria Ferreira Freiberg[1]; Salomão Lima Guimarães[1]; Edna Maria Bonfim-Silva[1]
UFMT[1]

The hydrogenionic potential, commonly referred as pH, is one of the limiting factors for the establishment of any agricultural culture, including the rice. Soils with low pH, as well as most of the soils of the Cerrado, may be difficult to adsorb the nutrients and make them available to plants. The effect of pH on microbial activities in both the soil and the plant are of the utmost importance to mitigate errors in management and optimize the agricultural processes. In view of this, the objective was evaluate the effect of inoculation of diazotrophic bacteria and acidity levels on the production of non-irrigated rice grown in Oxisol. For that, the experiment conducted in a greenhouse, at Federal University of Mato Grosso, Campus of Rondonópolis. The treatments were composed of two factors, being them, levels of acidity (4,8, 5 and 6) and sources of nitrogen (urea, H2-strain - Bacillus sp., and commercial inoculant-composed by AbV5 and AbV6 strains of Azospirillum brasilense), resulting in a 3x3 factorial scheme, with four repetitions, in completely randomized design, totaling 36 experimental units. For differentiation of the treatments, after the solo collection, set to achieve the predetermined pH. The soil was allocated in vases of 9 dm3 and before sowing the seed pelleting was carried out, using peat as vehicle of inoculation. The duration of the experiment was 117 days after sowing. The variables analyzed were the 100 grain weight and grain dry mass. Initially, the spikelet of rice were collected and had their grain removed. The grains were counted and weighed in the semi-analytical balance. Then, the grains were allocated in paper bags, and then taken to an oven at 65°C for 72 hours or until reaching constant weight. The statistical program used for analysis of the data was the SISVAR, and the averages submitted to the test of Tukey at 5% of probability. There was interaction between the factors (acidity levels and nitrogen sources), however, no significant difference was observed among treatments. For the 100 grains weight and grains dry mass, the treatments consisting of the pH 5 and 6, relating to nitrogen sources, demonstrate that inoculation can supply up to 68% the need of nitrogen required by rice crop. With this, it is concluded that at all levels of soil acidity, inoculation with diazotrophic bacteria were able to meet, the need for nitrogen required by rice plants.

(5825 - 547) Bioenergy sub-products as fertilizers: C, N and P soil dynamics after biochar and digestate application

Gastón Alejandro Iocoli[1]; Luciano Orden[2]; Maximiliano Garay Schiebelbein[3]; Marisa Anahí Gómez[1]
Centro de Recursos Naturales Renovables de la Zona Semiárida (CERZOS), Universidad Nacional del Sur (UNS)-CONICET, Bahía Blanca, Argentina[1]; EEA H. Ascasubi, Instituto Nacional de Tecnología Agropecuaria (INTA), Buenos Aires, Argentina[2]; Departamento de Agronomía, Universidad Nacional del Sur (UNS), Bahía Blanca, Argentina[3]

Amendments incorporated to soil of arid and semi-arid environments are quickly mineralized, with little incorporation into the stabilized soil organic matter. Anaerobic digestates contain a high proportion of available nutrients but a vestigial C content, while Biochar provides C whit great stability. The objective of this research was to evaluate the advantages of the combined use of biochar and digestate for soil fertilization through the C, N and P mineralization in a microcosms assay. Biochar was obtain by slow-pyrolysis *of Aspidosperma quebracho-blanco,* while anaerobic digestate of pig slurry was collected from a pig farm (SW Buenos Aires, Argentina). The parameters C, N and H (CHN 440 Analyzer), TKN, NH_4^+-N and NO_3^--N (semi-micro Kjheldal) were determined. The H/C atomic ratio and C/N mass ratio were calculated. Two sets of microcosms were prepared with 100 g of sandy-loam Entic Hapludoll soil. The treatments were: unamended soil; biochar (B); pig digestate (PD), and the combination of both (B+PD) (with three replicates), levelled according to the TKN content (6.5 g 100 g^{-1} soil). One set of microcosms was sampled repeatedly to follow C mineralization, while for the other set a destructive sampling was used to evaluate N and P dynamics periodically during 119 days. The CO_2 released was captured in a NaOH solution and was determined by back titration

with HCl. The parameters NH_4^+-N, NO_3^--N, water soluble P (Ps) and extractable P (Pe) were determined. Data were subjected to ANOVA followed by Fisher LSD for mean comparison. The B presented a lower H/C that the PD (0.51 and 1.66 respectively), indicating a lower degree of saturation (greater aromaticity), and a greater C/N (53.82 and 1.97) as consequence of high inorganic-N content of PD. B showed a short-lived primer effect at the beginning of incubation, possibly as a result of the presence of short-chain organic acids resulting from low pyrolysis temperature. As consequence of the higher proportion of recalcitrant C this period is short-lived. B presented increased CO_2 accumulated, DC presented a decreasing trend ($p>0.05$), but it was lower than B and B+PD ($p<0.05$). B+PD increased the initial mineralization rate of biochar, reducing the average life time and improving stabilization; reduced C mineralization, increased N availability; and increased labile P. Overall this results show performance improvements of B+PD with regard to the single amendments and the control.

(1647 - 578) Chemical description of the soils of environments occupied by Euphorbia hirta L. (Euphorbiaceae)

Thalia Inês Aleixo Barbosa[1]; Victor Barros Damacena[1]; Giovana Fornaciari Moreira[1]; Jeferson da Silva Muniz[1]

Instituto Federal de Mato Grosso - Campus Profº Olegário Baldo[1]

A current problem that haunts the integrity and diversity of ecosystems and characterized by the dynamics of exotic species, which due to favorable environmental conditions, settle and colonize the environment in a systematic and dominant way. In addition to ecological damage, such behavior often causes economic damage to various crops. At this juncture, the edaphic quality and directly affected in terms of levels of organic matter. In the middle of the above, this study aimed to analyze the chemical characteristics of the soils of areas invaded by Euphorbia hirta. For this, six areas with the occurrence and monodominance of the species were selected. The research areas are located in the Brazilian Midwest, state of Mato Grosso in the municipality of Araputanga. The geographical position is defined by the coordinates of latitude 15º28'16 "S and longitude 58º21'11"W (altitude of 200 m). The samples were collected in areas where the soil is classified as Eutrophic Red-Yellow Argisol. The collection was carried out in two institutions and three depths. The first time obtained under and between the projections of plants, a second vertically in the strata (0-5, 5-10 and 10-20 cm). The samples (composites) were obtained from six simple samples. As an emissary, they were sent to the laboratory, where they were air dried and sealed in a 2mm mesh for chemical analysis. A chemical characterization made from pH in water, phosphorus (P), potassium (K), sodium (Na), soil acidity ($H + Al^{+3}$), exchangeable aluminum (Al^{+3}), calcium (Ca^{+2}), magnesium(Mg^{+2}), sum of bases (SB), effective CTC (e), CTC pH7 (T), aluminum saturation (m%) and base saturation (V%). The experimental design used for the integrated storage in subdivided plots. Present the institutions (under and between the projections of plants) in the subplot and sub-plot were studied the depths. The averages were compared by the Tukey test at 5% probability. All statistical analyzes were performed using software R. As for soil pH, there are no significant features as areas. However, these showed variability in soil fertility, which indicates an adaptability of E. hirta. In relation to areas not belonging to the area of the areas. Evaluating the depths of the highest pH value in the 0-5 cm layer. Finally, it was verified that I released singles as projections of the species holds higher levels of P.

(6762 - 2215) Effects of U*rochloa sp.* invasion on soil chemical properties in riparian forests edges

Giovanna Gomes Cordeiro[1] ; Gabriela Bielefeld Nardoto[1]

Universidade de Brasília – Brasília DF[1]

Biological invasions have the potential to dramatically change the functioning of natural ecosystems. Invasive species have morphological traits that favor their establishment in environments under anthropogenic pressure. Grasses of the genus *Urochloa* are invasive alien species widely used for livestock settlements in Brazil. When cultivated near to Cerrado fragments or riparian forests, *Urochloa* outcompete native species, expanding their distribution. Because of its different C:N ratio compared to tree species, they may modify nutrient cycling. In addition, edge effects may facilitate biological invasions because of changes in local abiotic conditions, such as the light availability. The goal of this study was to evaluate the effects of biological invasion on soil chemical properties at the edge of riparian forests under pressure of pastures established for more than 30 years. The study was conducted in a watershed located in the Cerrado biome of Brazilian Central Plateau. Soil samples were collected in three sampling points (one in pasture, one in forest edge and one in wet forest area) at 0-20 and 20-40 cm depth, in five study sites (riparian forests). Soil fertility was determined by common chemical analyzes. The forest edge was more similar to the wet forest ($r = 0.65$) than the pasture ($r = -0.14$). There was no difference between the forest edge and the wet forest for any of the variables ($p > 0.05$). The forest edge had higher available phosphorus (P), potential acidity ($H+Al^{3+}$), cation exchange capacity (CTC) and organic carbon (OC), while lower remanent phosphorus (P-Rem) compared to the pasture. Soils with lower CTC retain less cations increasing nutrient losses by leaching, which may explain the lower levels of P in pasture soils. The highest value of P-Rem in the pasture indicate the long-term establishment period of these grasses. The higher OC content in the soil at the forest edge compared to pasture and wet forest may indicate that this ecotone also has higher C:N ratios and carbon stock, which may be influenced by invasion. These results suggested that the presence of *Urochloa* at the forest edge did not modify soil chemical properties. However, differences in organic carbon content in the forest edge indicate that the decomposition process may be changing in the face of biological invasion.

(9318 - 2922) Estimation of potencial acidity by the SMP method in representatives soils of Alagoas, Brazil.

Wendel Cristephan Carapeba Coelho[1]; Gilson Moura Filho[1]; Adriano Barboza Moura[1]; Leila Cruz da Silva[1]; Lucas da Silva Lopes[1]; João Batista Melo Santos[1]

UFAL[1]

In order to obtain the lime requirement, it's necessary to know the soil potencial acidity to proceed with the appropriate amount of limestone in its correction. The SMP pH is a method which obtains the equilibrium pH in a suspension between the soil and the SMP solution. SMP is one of the most utilized methods to analyze acidity. The objective of this work was to estimate the values of potencial acidity in representative soils of Alagoas through pH measures by the SMP solution method. This work was carried out at the Laboratório de Solo, Água e Planta of the Centro de Ciencias Agrárias of the Universidade Federal de Alagoas. The soil sampling was done beforehand in a study with the use of Zoneamento Agroecológico do Estado de Alagoas (ZAAL) software in order to identify, quantify and locate the most representative soils of the state. 50 soils samples were collected in the

0-20 cm layer. The samples were taken to a soil drying oven at 38 degrees Celsius for 4 days and later were sifted and stocked in plastic bags. pH in water, pH in $CaCl_2$ were determined and, in both cases, using the relation 1:2,5. In order to extract the potencial acidity (H+Al), calcium acetate was used at 0,5 mol L^{-1} ph 7,0, the latter determined by the NaoH titration 0,025 mol L^{-1}, adjusted to pH 7,0 with an acetate acid solution. 5 cm^3 of air-dried fine sand, posteriorly added to a 125 ml erlenmeyer together with 75 mL of the calcium acetate extractor solution. After that, the final solution was stirred for 15 minutes and left to rest for one night, together with a blank proof. At the end of that period, 25 ml of the supernatant was removed for the titration with 0,025 mol L^{-1} NaOH with three drops of alcoholic phenolphthalein 10 g L^{-1}. The SMP pH was dettermined according to the methodology proposed by Raij and Quaggio (1983). With the data in hand, a significant correlation was verified between the H + Al values measured with the SMP pH, thus showing that the potential acidity can be estimated by the SMP pH method. The sensitivity of the SMP pH method was higher when the equilibrium pH was determined in the 10:25:10 ratio, and the pH was determined in water using the equation $Y = a + b / x^2$

(3258 - 951) Evaluation of the development and productivity of maize culture in different fertilization managements in a direct planting system

Amanda Silveira Reis[1]; Ana Maria Conte[2]; Marcos Rafael Nanni[1]; Pedro Francisco da Silveira Reis[2]; Luiz Carlos Reis[2]; Teresinha Esteves da Silveira Reis[2]

Universidade Estadual de Maringá[1]; Universidade Estadual do Norte do Paraná[2]

In Brazil there was an increase in the production and cultivation of maize, destined for both human and animal consumption, but it is still considered low when compared to the United States and China, first and second largest producers, respectively. This is due to the management practiced by the producers, because proper practices of correction and fertilization of the soil require a complex decision-making process, where the caracteristics of the plants and soil, climate, among others, should be taken into account. The objective of this work was to evaluate the technical feasibility of the modes of application of sowing fertilization in the direct planting system, in the phytometric parameters and in the productivity of the maize culture. The experiment was carried out in the experimental farm of the State University of Northern Paraná, in the city of Bandeirantes/PR, using the culture of maize, implanted in the year 2015. The experimental design was in randomized blocks with 7 treatments, being T1 (without fertilization), T2 (application of NPK to the haul), T3 (application of NPK on line), T4 (NP in the haul and K on line), T5 (NP in line and K to the haul), T6 (NK to the haul and P on line) and T7 (NK on line and K to the haul), with 4 repetitions. The parcels consisted of 6 lines of maize, 6 m long by 4.5 m in width resulting in 27 m^2, considering as a useful area the 4 central lines and despising one meter from each end of the parcel. The treatments were performed with application in the sowing of 20 kg ha^{-1} of N, 80 kg ha^{-1} of P_2O_5 and 40 kg ha^{-1} of K_2O, using the fertilizers urea, simple superphosphate and potassium chloride. For fertilization in coverage applied 90 kg ha^{-1} N, parceled in two applications. Phytometric parameters have been evaluated: plant height, leaf number, stem diameter, ear and cob, ear weight, the cobs and 100 grain size of cob, dry weight of shoot and productivity. The data were compared by Duncan's test at 5% probability, using the SASM-Agri software. The results allowed to conclude that the method of application of NPK affected significantly the productivity, the application of the NP haul + K line presented the highest productivity and between the treatments NPK line and NPK haul, the application to the haul obtained the best result for the productivity.

(9147 - 2224) Lettuce production under the residual effect of the interaction between selenium and sulfur

Patriciani Estela Cipriano[1]; Maria Ligia de Souza Silva[1]; Anderson Ricardo Trevizam[1]; Matias Siuéia Junior[1]; Luiz Roberto Guimarães Guilherme[1]

Universidade Federal de Lavras[1]

The study of the residual effect of the fertilization is of great importance, since it can promote a better utilization of the nutrients by the plants. Se is not essential for higher plants, but all plants absorb and metabolize this element. Little is known about the residual behavior of selenium fertilization in the soil, but since selenate and sulphate make the same path in plant transport, the objective of this study was to evaluate the residual effect of the interaction between Se and S on lettuce (Lactuca sativa) after onion cultivation (Allium cepa L.). The experiment was carried out in a greenhouse, in a randomized design, in a factorial scheme of 5 x 3, with five doses of Se (0.0, 0.3, 0.6, 1.2 and 2.4 mg dm^{-3}) and three doses of S (0, 20 and 40 mg dm^{-3}) with three replicates. Se and S were supplied in the form of sodium selenate and calcium sulfate, respectively. Pots with 4 dm^{-3} of soil were used, filled with samples from the 0-20 cm layer of a dystrophic Red-Yellow Latosol typical of medium texture. The cultivation of onion cv. Diamantina was made, at the end of the cycle the harvest was made. Then, the lettuce seedlings cv. Veronica. After 40 days the lettuce plants were harvested, and the plant material was divided into shoots and roots, the shoots being measured for the determination of fresh matter production. The data was submitted to analysis of variance, to evaluate significant differences between the treatments. When the interaction between Se and S was significant, a multiple regression analysis was performed using the Euler Backward method. The results show that the fresh mass production was influenced ($p < 0.05$) by the residues of the interaction between the doses of S and Se. The maximum dose of Se applied when not applied S was responsible for the lower values obtained in the fresh mass produced. The maximum fresh mass production (76.6 g $plant^{-1}$) would occur in a combination of approximately 25.7 and 1.8 mg dm^{-3} of S and Se, respectively. It is concluded that the residual effect of the interaction between Se and S, possibly affects lettuce production.

(9729 - 2909) Modification of Nonexchangeable Potassium Extraction Method in Calcareous Soils

Kambiz Bazargan[1]; Mojgan Yegane[1]; Karim Shahbazi[1]
Soil and Water Research Institute, Agricultural Research, Education and Extension Organization (AREEO), Karaj, Iran[1]

Potassium (K) is an essential plant nutrient. Soil K is often subdivided into soluble, exchangeable, nonexchangeable, and structural or mineral forms. Nonexchangeable K constitutes a slowly available reserve that may significantly influence K fertility of soils. It is held between adjacent tetrahedral layers of dioctahedral and trioctahedral micas, vermiculites, and integrated clay minerals such as chloritized vermiculite. The most common method for extraction of nonexchangeable potassium from soils is using boiling 1M HNO3. Because of low precipitation and parent materials, most of the arable soils of Iran are affected by nonsoluble or lowly soluble salts such as CaCO3. Reaction between CaCO3 and HNO3 consumes part of acid and can affect the amount of extracted K in these soils. Different levels, 0-50%, of CaCO3 and neutral sand were added to a

noncalcareous soil separately and non exchangeable K was extracted with conventional method using 1M HNO3 in all samples. Comparing results, improved the effect of different CaCO3 levels on the soil nonexchangeable potassium extraction. Experiments showed that increasing acid/soil ratio to 40, improved the effect of CaCO3 on extraction of soil K. New extraction method with 100ml HNO3 added to 2.5g soil was compared with old method in 70 noncalcareous soil samples. Results showed that new method extracted higher amounts of K comparing with the old method, but the extracted K amounts by two methods were highly correlated. It improved that new method can substitute the old one to be suitable for calcareous and noncalcareous soils.

(9080 - 2856) Multivariate analysis of chemical attributes in anthropic soils under forest at different positions gives landscape in Amazonian

Fernando Gomes de Souza[1]; Alan Ferreira Leite de Lima[1]; Milton Cesar Costa Campos[1]; José Mauricio Cunha[1]; Douglas Marcelo Pinheiro da Silva[1]; Marcelo Dayron Rodrigues Soares[1]; Eduardo Antonio Neves do Santos[1]; Thalita Silva Martins[1]; Elyenayra Nogueira Pinheiro[1]; Elilson Gomes de Brito[1]; Estefani de Souza Oliveira[1]; Rafael Jorge do Prado[2]

Federal University of Amazonas[1]; Federal University of Roraima[2]

In the Amazon, anthropic soils known as Terras Pretas de Índios (TPIs) have a very peculiar characteristic, with high natural fertility, possibly resulting from prolonged anthropic occupation and the incorporation of pyrogenic coal incorporated in the soil surface horizons matrix. In the simultaneous analysis of many variables, multivariate statistics it is efficient tool, which can help in decision making on the use and proper management of the soil, based on the variations of soil attributes. Thus, the objective of this work was to perform the multivariate analysis of the chemical attributes in anthropic soils under forest area in different positions of the landscape. A mesh with 88 collection points was delimited with the following dimensions: 60 x 42 totaling an area of 2,520 m2, with regular spacing between the collection points of the soil of 6 x 6 m. Were collected soil blocks in layers 0.0-0.05 m, 0.05-0.10 m and 0.10-0.20 m, with a preserved structure in the form of a clod dry that, the analyzes based on the methodology proposed by EMBRAPA (2011), followed by analysis of variance multivariate of (MANOVA), through factorial and cluster analysis, in order to find statistical significance of the sets of soil chemical attributes. Using the multivariate analysis, it was possible to observe the attributes of the soil that suffered the greatest change when the soil slope. From the percentage of variance explained, in the 0.001-0.05 m layer the CP1 is responsible for 44.22% of the total variance, while CP2 is responsible for 25.91% in the 0.05-0.10 m layer CP1 accounts for 38.79% of the total variance, while CP2 accounts for 30.80% and in the 0.10 - 0.20 m layer the CP1 is responsible for 37.37% of the total variance, while CP2 accounts for 28.99%. Both the first and second factor have a percentage of explanation for the chemical characteristics of the soil. Thus, the discrimination between the strands refers to these characteristics, with CP1 representing the chemical characteristics COT and P for three studied layers, while CP2 to the chemical characteristics pH and Al + H in the three layers studied. The techniques of multivariate analysis showed that the upper medium showed the attributes better pH, COT, P and Al + H. The use of multivariate techniques in soil studies can be an important tool in environmental monitoring.

(5295 - 1409) Soil chemical and mineralogical attributes of altered forest by pasture and agricultural use in the north Amazonia

Valdinar Ferreira Melo[1]; Luciana da Silva Barros[1]; Taline Katlen de Oliveira Nunes[1]

Federal University of Roraima[1]

The agriculture practiced in the extreme north of Amazon forest still maintains the conventional production system, by slash and burn, with posterior use of the ashes as a fertilizer in the first year of cultivation. However, this practice leads to the loss of soil quality. The characterization of soil chemical and physical attributes and their response to forest/agriculture/pasture conversion will provide responses of a better sustainability of a land-use system that maintain soil quality. The objective of this work was to characterize the soil chemical and physical attributes from a forest and from altered forest areas by pasture and conventional agricultural system use in at the northern Amazon. The soil samples were collected at two pasture areas (degraded pasture - DP and well managed pasture - WMP), two agricultural areas (corn under conventional cropping system after pasture - CT and subsistence agriculture with intercropping - SF), freshly burned land for pasture (FB) and forest (For). Samplings were performed at three different depths (0-5, 5-15 and 15-30 cm) and four replication each. The soil acidity presented by all areas (DP, WMP, CT, FB and For) reflected the advanced degree of soil weathering, as well as the mineral exhaustion caused by the inadequate soil management. The burn used at FB area contributes to raise the pH only at the first 5 centimeters of soil layer. The highest levels of exchangeable cations (Ca^{2+}, Mg^{2+} and K^{+}) and P in surface (0 - 5 cm), especially at FB area, which represents the ash contribution to increase the availability of nutrients. The soil organic carbon levels found in this study demonstrate that the conversion of forest areas to pasture and forest areas to agricultural areas did not change over time. The highest soil bulk density were recorded at PGD and PGC areas, associated with the management applied to the areas, however, they are still below the critical limit for the development of plant roots. The abandonment of pastures with time, promote the resurgence of spontaneous plants creating conditions similar to native forest. The agricultural areas in function of slash and burnet, soil disturbance with aggregate breaking and soil particle spraying were very different of the native forest.

Keywords: deforestation by burning, soil quality, land use

(6679 - 1161) Stratified chemical analysis in soils submitted to different fertilization management.

Lucimara Rodrigues Padilha[1]; Lethícia da Rosa Neto[2]; Luiz Clery Burin Fruet[3]; Rudinei Balem[4]; Willian Garzon de Freitas[5]; Cleudson José Michelon[4]

Instituto Federal Farroupilha Campus Júlio de Castilhos, Júlio de Castilhos-RS, 98130000, Brasil (luci.r.padilha@gmail.com).[1]; Universidade Federal de Santa Maria, Santa Maria-RS, 97105-900, Brasil.[2]; Universidade Federal de Santa Maria Campus Frederico Westphalen, Frederico Westphalen-RS, 98400-000, Brasil.[3]; Instituto Federal Farroupilha Campus São Vicente do Sul, São Vicente do Sul-RS, 97420-000, Brasil.[4]; Instituto Federal Farroupilha Campus Júlio de Castilhos, Júlio de Castilhos-RS, 98130000, Brasil.[5]

The objective of this work was to analyze the changes in the chemical attributes of a typical Dystrophic Red-Yellow Argisol, cultivated with soybean in no-tillage system, submitted to two fertilization treatments in the last 10 years of cultivation: fertilization added in the sowing line and fertilization added on surface. Two properties were evaluated, one located in Júlio de Castilhos / RS and the other in Tupanciretã / RS. The samples were collected at depths of 0.0-0.10 m and 0.10-0.30 m. The analyzes were carried out in the laboratory of

the IFFar Campus SVS, following a methodology described by Tedesco et al, 1995. In this work the results of the potassium (K) and phosphorus (P) contents are presented. The P content was 64 mg dm^{-3} and the K content was 60 mg dm^{-3}. At the depth of 0.10-0.30 m, the content of K were 40 mg dm^{-3}. When the management of the fertilization was on a surface at a depth of 0.0-0.10 m, the P content was 50 mg dm-3 and that of K was 160 mg dm-3. At the depth of 0.10-0.30 m, the content of P were 4 mg dm^{-3}. With the accomplishment of the work it was observed that when the management of the fertilization in the sowing line was used, a more uniform distribution of P and K occurred between the evaluated depths. In the management of the fertilization on the surface, there was concentration of the P and K in the superficial layer. These results show that surface fertilization may favor the contamination of water sources due to the ease of nutrient loss due to the superficial runoff of the water, besides that, in this management of fertilization, in conditions of water stress, the culture may have a greater limitation of yield because your root system tends to focus on the soil surface.

(7777 - 1954) The iron isotopic fractionation in human-polluted river from soil to the ocean

Zih-Jie Lin[1]; Kuo-Fang Haung[2]; Shan-Li Wang[1]; Der-Chuen Lee[2]
National Taiwan University, No. 1, Sec. 4, Roosevelt Rd., Taipei 10617, Taiwan[1]; Institute of Earth Sciences Academia Sinica, No. 128, Sec. 2, Academia Road, Nangang, Taipei 11529, Taiwan[2]

The iron isotopic fractionation in human-polluted river from soil to the ocean Zih-Jie Lin[1]; Kuo-Fang Haung[2]; Shan-Li Wang[1]; Der-Chuen Lee[2]
[1] National Taiwan University, No. 1, Sec. 4, Roosevelt Rd., Taipei 10617, Taiwan (r06623004@ntu.edu.tw); [2] Institute of Earth Sciences Academia Sinica, No.128, Sec. 2, Academia Road, Nangang, Taipei 11529, Taiwan Abstract Iron is a limiting micronutrient for marine organism, and is crucial to boost ocean production and regulate global climate. Soil may contribute considerable iron to the ocean, but the transformation of iron species during riverine transportation has not been well understood. To have insight into the iron transformation during the transportation from soil to ocean, river water was collected from different sites in the Dan-shuei River, which flows through the high population city, Taipei (~9,000 people / km^2). Sampling was carried out in wet and dry seasons. The concentration of total organic carbon (TOC), dissolved organic carbon (DOC) and chlorophyll a in water samples were measured. The results of iron isotopic fractionations show significant transformation of iron phase in the areas with high population density. High concentration of chlorophyll a was detected in the same area, where phytoplankton plays an important role on iron isotopic fractionation. This study reveals the fractionation of iron isotope during the transportation in river and the contribution of iron from soil to the ocean. Key words: iron isotope; fractionation; soil; river transportation
Keywords: iron isotope; fractionation; soil; river transportation

(8900 - 2598) Phosphorus and silicon fertilizer rates effects on dynamics of soil phosphorus fractions in oxisol under common bean cultivation

Alessandra Mayumi Tokura Alovisi[1]; Ademar Pereira Serra[2]; Alves Alexandre Alovisi[1]; Luciene Kazue Tokura[3]; Elaine Reis Pinheiro Lourente[1]; Robervaldo Soares da Silva[1]; Silvia Corres Santos[1]; Livia Maria Chamma Davide[1]
Universidade Federal da Grande Dourados (UFGD)[1]; Brazilian Agricultural Research Corporation (EMBRAPA)[2]; Universidade Estadual do Oeste do Paraná[3]

The purpose of the research was to evaluate the effects of P and Si fertilizer rates in dynamic of P fractions in clay soil under greenhouse. The research was carried out in a Dystroferric Red Latosol of a very loamy texture from Lavras city, Minas Gerais State, Brazil. The experimental design was entirely randomized, arranged in 4 x 3 factorial design, with four repetitions. The treatments included four inorganic fertilizer P rates (0, 110, 330 and 560 mg dm^{-3}) and three Si rates (0, 110, 330 and 560 mg dm^{-3}). The preview application of Si fertilizer did not contribute to decrease P desorption. Possibly, the silicate has lower affinity with the bound sites of adsorption than phosphates. The effects of inorganic fertilizer P were higher in increasing the moderately labile P fraction and labile P fraction. Among the organic P fractions, the $NaHCO_3$-Po fraction was the only one that contributes to plant nutrition. The Hedley sequential phosphorus fractionation promoted information about different pools where P was accumulated in the soil after common bean cultivation. The highest amount of P was obtained in stable P fraction, followed by moderately labile and labile P fraction. The moderately labile P fraction decreased after common bean cultivation possibly due to the time of P contact in the soil and redistribution to stable P fraction. The labile form was the lowest P pool in soil, nevertheless the increase in P fertilizer rates increases the amount of P content in labile fraction.

C2.2.3 - Soil and water pollution: dynamics and evaluation

(1536 - 574) Adsorption isotherms of Mn, Zn, Cu, Pb AND Cd in soils and sediments within la villa river Basin-Panama

Jose Ezequiel Villarreal Nuñez[1]; Neldis Ballesteros[2]; Adolfo Santos Pineda[1]; Jhon Villalaz Perez[1]
IDIAP[1]; USMA[2]

The present study was carried out within La Villa river basin (provinces of Herrera and Los Santos). In these lands historically a great agricultural activity has been developed standing out the prodcution of corn, tomatoes, melons, watermelons, beans, chilli peppers, sugarcane, beef cattle and milk. They are lands subjected to an intensive use of agrochemicals and influenced by discharges of waste waters of some industrial and agroindustrial companies located within the basin. The objective of the study was to determine by Langmuir isotherms the maximun adsorption capacity of Mn, Zn, Cu, Pb and Cd in soils and sediments of areas with intensive agricultural activity within the La Villa river basin. Ten samples of soil and sediments were taken in lands of farmers in the rainy season (june-november 2016) and ten in the dry season (january-april 2017). The total heavy metals concentration was determined by extraction with HNO_3 + HCl (3:1) using continuous source atomic absorption equipment. The trace metal isotherm were determined in soil and sediments in the samoples taken in both seasons by applying different metal concentration in a 0.01 M $CaCl_2$ solution. In general, the total concentration it was below the levels considered toxic in all the sites.The soils of the area are characterized by having a pH higher than 6 on average, high concentration of Mn and Fe and are classified in order alfisols, ultisols and inceptisols. The Mn isotherm showed low values and a high adsorption strenght, Cu and Zn showed high values of adsorption but with low retention energy. For the Pb, high values of adsorption were observed, but very low retention strenght, contrary to the Cd that obtained low values of adsorption but with a higher strenght. This behavior has a lot of relation with the texture of the soil, in general, those that showed the greatest retention strenght

are more acid soils with a higher content of clay and organic matter. The sandy soils showed low values of maximun adsorption and lower retention energy, with the sediments being the main ones that presented lower metal adsorption strenght, which implies theat if the metal concentration increase and the aqueous and interchangeable phase of the these sediments could cause greater environmental problems of the ecosystem.

(4362 - 2789) Anatomical characteristics of adult eucalyptus plants irrigated in the molting phase with wastewater

Thaís Andrade de Carvalho Silva[1]; Joiran Luiz Magalhães[2]; Arthur Almeida Rodrigues[1]; Douglas Almeida Rodrigues[1]; Sebastião Carvalho Vasconcelos Filho[1]

Goiano Federal Institute of Education, Science and Technology (IFGoiano), Campus Rio Verde[1]; University of Rio Verde - Campus Rio Verde, Farm Sources of Knowledge[2]

The rapid economic development associated with accelerated population growth and urbanization has led to scarce water resources, restricting the sustainable development of agriculture. Thus, the use of irrigation of forest species cultivated for fuel and wood with waste water is an alternative, which can help in the proper disposal of effluents and in the fertirrigation of crops. The objective of this study was to evaluate the anatomical characteristics of eucalyptus (GG100 and 3335) after six years of field cultivation, irrigated in the seedling phase with wastewater from the treatment plant (WTP). Initially seedlings with approximately 30 days were irrigated with soybean WTP and urban WTP wastewater at concentrations of 25%, 50%, 75% and 100% dilution and a control with 0% for a period of 165 days, after this period, the seedlings were transplanted to the field where they were cultivated for six years. Subsequently, leaf samples were collected from the middle region of the last fully expanded leaf of all the eucalyptus plants of the varieties GG100 and 3335 and performed an anatomical analysis of leaf surface. The eucalyptus (GG100 and 3335) varieties have anisthymatic leaves, with uniseriate epidermis, dorsiventral mesophyll formed by one to two layers of paliçadic parenchyma and prominent lacunal parenchyma, with secretory cavities dispersed in the mesophyll under the epidermis. The WTP waste water treatments and urban sprawl did not affect the leaf anatomy of the GG100 variety eucalyptus. However, the eucalyptus 3335 presented mesophilic expansion with the increase of wastewater concentrations from the overwhelming WTP and urban WTP. Thus, it is concluded that irrigation with wastewater of the eucalyptus GG100 and 3335 in the molting phase did not affect the anatomical characteristics of the plants after six years of cultivation.

(2923 - 3065) Andisol top-soil as support of a biopurification system to treat water contaminated with atrazine

Marcela Levío[1]; Felipe Gallardo[2]; Olga Rubilar[3]; Maria Cristina Díez[4]

Biotechnological Research Center Applied to the Environment (CIBAMA-BIOREN). University of La Frontera[1]; Biotechnological Research Center Applied to the Environment (CIBAMA-BIOREN) and Chemical Sciences and Natural Resources Department. University of La Frontera[2]; Biotechnological Research Center Applied to the Environment (CIBAMA-BIOREN) and Chemical Engineering Department. University of La Frontera[3]; Biotechnological Research Center Applied to the Environment (CIBAMA-BIOREN) and Chemical Engineering Department. University of La Frontera[4]

The pesticides use in the world for agricultural activities has generated the water contamination producing a decrease in water quality and reducing the use for human consume. In this sense, arise the importance and interest to find new technologies for the treatment of wastewater contaminated with this pollutants and the use of sustrates like andisol soil as support in the degradation and adsorption process. Therefore, the present work evaluated the operation of a packed bed reactor using an organic biomixture composed in volumetric proportion with Andisol soil to treat water contaminated with atrazine pesticide. The biomixture has a capacity of adsorb and degrade pesticides and was prepared mixing an Andisol topsoil (37% sand, 34% silt, 28% clay, 7% organic carbon, pH 5.4), commercial peat (36% organic carbon), and wheat straw (34% organic carbon) in a proportion of 1:1:2 by volume. The reactor was made of high quality glass material (15 cm x 8 cm) packed with the biomixture (ρ 0.35 g mL^{-1}).The stock solution was prepared with commercial atrazine (ATZ) at a concentration of 500 mg L^{-1} in water. This reactor was operated at different hydraulic loads (10, 30 and 50 mL per hour) and concentration of ATZ (5, 10 and 15 mg L^{-1}). Finally atrazine concentration and degradation products in the effluent were analysed by HPLC. Data obtained were evaluated through the surface response methodology (RSM). From the results obtained it was demonstrated that the most important factor in the process was pH. Because, to acidic pH (pH 4), atrazine removal was greater (>90%) without significant differences ($p < 0.05$) according to concentration and flow rate analysed. While, at alkaline pH (pH 8) atrazine removal was lowest (19.96%). The adsorption process is more significant at pH 4 than pH 6 and 8, with optimum result of 152.22 mg atrazine adsorbed per gram of biomixture under operation conditions: pH 4, 15 mg L^{-1} and 50 mL h^{-1}. Thus, packed bed reactor to atrazine removal is a viable alternative for wastewater treatment contaminated with atrazine and similar characteristics pesticides, since the removal can be increased considering optimum reaction conditions: pH 4.07, atrazine concentration of 7.18 mg L^{-1} and flow rate of 34.23 mL h^{-1}, which would be reflected in a 97.83 % atrazine removal.

(7936 - 912) Arbuscular Mycorrhizal Fungi community in areas affected by iron ore tailings from the Mariana Disaster – MG

Thuany Cerqueira Jordão[1]; Paulo Prates Júnior[1]; Marliane de Cássia Soares da Silva[1]; Nayron Diogo Vilela[1]; Raphael Bragança Alves Fernandes[1]; Maria Catarina Megume Kasuya[1]

Universidade Federal de Viçosa[1]

The iron ore tailings released with the disruption of the Fundão Dam, owned by Mineradora Samarco, located in Mariana - MG, Brazil, in November 2015, reached 600 km from the Rio Doce Basin to its mouth and removed 1469 hectares of vegetation. This disaster changed the physico-chemical and biological characteristics of soils, difficulting the natural restoration of vegetation. Revegetation is considered essential for the recovery of degraded areas and micro-organisms such as arbuscular mycorrhizal fungi (AMF) can accelerate this process, provide innumerable benefits to plants such as increased nutrient uptake and abiotic stress tolerance. The objective of the present work was to evaluate the profile of AMF community and the physico-chemical characteristics of the areas affected by the iron ore tailings. Samples of soil/tailing were collected in the municipality of Paracatu de Baixo, a region affected by the disaster, in February 2017. Three areas were selected for sampling: natural forest of the region (UND);

two areas affected by the tailing, being one with natural recovery process (REC 1) and other with revegetation process (REC 2). The structure of AMF community was evaluated by extracting DNA from the soil and analyzed by PCR-DGGE. The dendrogram was constructed using Cosine Coefficient-Ward by the Bionumerics program. A Principal Component Analysis (PCA) was performed using DGGE results and soil physico-chemical characteristics. Diversity indices were calculated. The dendrogram showed that the areas were separated into three distinct groups, being that REC 2 present higher similarity with UND than REC1. There was no difference in the diversity indices between UND and REC 2, and REC 1 presented lower diversity index. The PCA showed that changes in the physical and chemical characteristics of the soil, caused by the disaster, altered the profile of the AMF community. Iron, copper, manganese and phosphorus presented effects on the AMF community structure in REC 1, while organic matter, litter and a cation exchange capacity influenced the AMF community structure in UND. We can conclude that the revegetation process adopted after the tailings dam rupture has been effective for reestablishing the structure of FMA community.

(3394 - 1401) Assessment of nonylphenol monoethoxylates and nonylphenol bioavailability in soils treated with biosolids

Inés Ahumada, Loreto Ascar, Francia Pérez[1]

Universidad de Chile, Facultad de Ciencias Químicas y Farmacéutica.[1]

The addition of biosolids to soil is beneficial due enriching soil with essential nutrient elements, allowing the improvement of the physical features and productivity of agricultural and forest soils and the recovery of degraded soils. Biosolids also could contain trace elements, organic compounds that could be transfer these into terrestrial and aquatic environments, giving rise to possible accumulation in plants. Examples of these organic compounds are alkylphenols (APs), synthetic organic compounds that are not found naturally in the environment. These are used in the surfactant industry, paints and wetting agents in products for personal. The APs are considered endocrine disruptors, which simulates the action of steroidal hormones. In addition to entering the organism, they can generate reproductive problems, particularly found in animals of marine origin. The environmental risk of the alkylphenols contained in the biosolids depends on the concentration, persistence, lability, biotoxicity and capacity to incorporate these the trophic chain. The objective of this study was to evaluate the bioavailability of 4-nonylphenol mono-ethoxylate (NPE) and its degradation product 4-n-nonylphenol (NP) in three soils treated with biosolids. The bioavailable fraction of these two compounds was determined throuth bioassays using wheat plants, and this result was compared with a bioavalability predictive method using hydroxypropyl-β-cyclodextrin. Three agricultural soils (Codigua, Pomaire and Ostolazas) obtained from the Metropolitan Region of Chile were treated with unspiked and spiked biosolids at 10 mg kg^{-1} with NPE and NP, at rate 90 Mg ha^{-1}. NPEs and NP were determined in biosolids, soil and plants using a QuEChERS-based extraction procedure and gas chromatography coupled to mass spectrometry. Only the nonylphenol monothoxylate was found in a concentration of 25.7 ± 2.6 mg kg^{-1} in the biosolids. The bioavailable fraction of both compounds was obtained through a bioassay with wheat plants. The results showed that the NPE was found mainly concentrated in roots rather than shoots. The predictive capability of the hydroxyprolyl-β-cyclodextrin (HPCD) extraction was assessed using a simple linear correlation test, for NPE concentration in wheat plants. The study yielded a linear relationship, which demonstrated the validity of the chemical method as a biosimulation technique.

(4119 - 2690) Assessment of trace element accumulation in soils with mining influence

Tapia-Sánchez, X.[1]; Bobadilla-Ballesteros, M.D.[1]; García-Calderón, N.E.[2]; Fuentes-Romero, E.[2]; Velázquez-Rosas, N.[3]
Licenciatura en Ciencias de la Tierra (Ciencias Ambientales) , Unidad Multidisciplinaria de Docencia e Investigación- Campus Juriquilla, Facultad de Ciencias, Universidad Nacional Autónoma de México[1]; Laboratorio de Conservación y Rehabilitación del Recurso Edáfico, Unidad Multidisciplinaria de Docencia e Investigación- Campus Juriquilla, Facultad de Ciencias, Universidad Nacional Autónoma de México Boulevard Juriquilla 3001, CP 76230, Querétaro, Qro.[2]; CITRO-Universidad Veracruzana, Xalapa, Veracruz, México.[3]

In México, mining activities are among the main sources of increasing trace metal concentration. The aim of this study was to assess the accumulation of trace elements in organic and mineral fractions from soil profiles with mining influence. This research was conducted inside the "Biosphere Reserve of Sierra Gorda, Guanajuato", in a toposequence covered by deciduous low forest and xerophytic scrub, close to a former mining area in Xichú, Gto. With a warm and semi-dry climate, mining tailings were deposited along the lower part of the steep slope, close to the Xichú riverbed. Samples were selected from profiles previously classified as Calcaric Protic Endoleptic Regosol in the upper part of the slope, in the middle part as Calcaric Endoleptic Cambisol and in the lower part as Epileptic Spolic Technosol. For total trace element (TTE) analysis soil samples were crushed and sieved though <53 µm. Total soil organic carbon (TOC) and dissolved organic carbon (DOC) were determined. Granulometric fractions were quantified by Bouyoucos and laser diffraction methods. TTE were extracted by 4H1a1 USDA, 2014 method. As, Cd, Cu and Pb were measured by ICP-OES Thermo Icap 6500 Duo View and Zn by AAS Perkin Elmer Analyst 3000. Data were analyzed by Spearman correlation (p>0.5) in statistica v11. The total trace elements showed the following concentration sequence Technosol>Cambisol>Regosol. From them in the surface horizons of the Regosol and Cambisol the sequence was Zn>Pb>As>Cu>Cd (243.13~2.93 mg kg^{-1}); meanwhile, in the Technosol was As>Zn>Pb>Cu>Cd (1791.69~19.98 mg kg^{-1}). In the Cambisol and Technosol subsurface horizons TTE were Zn>As>Pb>Cu>Cd (3730.52 ~4.37 mg kg^{-1}), and Regosol showed Zn>Pb>Cu>As>Cd (107.94 ~ 2.53 mg kg^{-1}) concentration. From them, Cd and TOC had a higher concentration on the soil surface. Data analysis showed strong correlation between silt, TOC and clay with As, Cd and Zn in the surface horizon of the Cambisol, also between the mineral fraction and the TTE assessment. In the Technosol a lower interrelation between clay and DOC with Pb and Zn was obtained; otherwise, in the subsurface Regosol horizon, Pb and Zn were related with clay. Higher TTE concentration in the soil could be associated with a high risk potential for As and Pb pollution according with the limits of NOM-147 country soil legislation. Assessment of the sink potential on these soils seems to be favoured by pedogenetic and soilscape processes through the toposequence.

(6466 - 2040) Availability of Cr, Cu, Pb and Zn in soils under *Laguncularia racemosa* from a tropical estuary – Brazil

Djennyfer Karolaine de Melo Ferreira[1]; Caroline Miranda Biondi[1]; Paula Renata Muniz Araújo[1]; Arthur Felipe Valença Araújo[1]; Franklone Lima da Silva[1]; Fernando Bruno Vieira da Silva[1]

Universidade Federal Rural de Pernambuco[1]

The estuary of the Botafogo river, located in the north coast of the State of Pernambuco, Brazil, is a site of fishing activities and it contains the largest hydrographic basin fully inserted in the region. Previous studies have shown that there is contamination in the mangrove areas by heavy metals. However, investigations about the dynamic and potential availability of metals are necessary to base analysis of risk to the environment and human beings. The objectives of this study were to determine the total contents of chromium (Cr), copper (Cu), lead (Pb) and zinc (Zn) and to evaluate their availability to the environment. Based on previous data, three areas under *Laguncularia racemosa* vegetation in the Botafogo Estuary and one area without contamination were selected. In each area, there were four collected profiles of soil (0-50 cm). Analysis for organic matter (MOS), particular size distribution and total digestion (HNO_3, HF, $HCLO_4$ and HCl) were performed in samples of 0-4, 4-8, 8-12, 12-16, 16-20, 20-30, 30-40 and 40-50 cm. The potential of availability of metals in the environment was evaluated by sequential extraction of the soil from the area of high contamination. The average levels of Cr, Cu, Pb and Zn (0-50 cm) were found to be higher than the reference area and it was not found to be decreasing with the depth of the soil. The average variation within depth (0-50 cm) was 31%, 60%, 41% and 39% for Cr, Cu, Pb and Zn. Elevated variations of metals can be attributed to the variations in texture (32%) and MOS (32%) observed among the profiles, especially in the third area where the layer 40-50 cm is predominantly sandy (sand: 668 g kg^{-1}) and confirmed with the positive correlations between MOS, clay and metals ($p < 0.05$). From the sequential extraction (soil of second area), it was verified that Cr, Cu, Pb and Zn were mainly associated with the residual fraction (metals associated with silicates and organic matter). However, 27% of total Cu was associated with the pyrite fraction. In anoxic conditions, this fraction is stable. About 18% and 32% of Pb and Zn were associated with amorphous iron oxide and carbonate fractions. The Pb-carbonate association is stable near neutrality as found in the analyzed soil (pH: 6.57). The contents of Cr, Cu, Pb and Zn were found above the reference area, however, they are associated with stable fractions of soil, indicating the low potential of availability of these elements to the environment.

(6439 - 2881) Availability of heavy metals and other elements in soils under influence of the Itataia uranium-phosphate deposit in Brazil

José Igor Almeida Castro[1]; Cleyton Saialy Medeiros Cunha[1]; Maria Eugênia Ortiz Escobar[1]
Federal University of Ceara[1]

Heavy metals and other potentially toxic elements in soils might pose risks to humans or ecosystems even in small concentrations. Although the knowledge of the total content of heavy metals in soil is important, there is still concern related to the available forms of these elements, which are able to be absorbed by the living beings and thus enter the trophic chain. The objective of this work was to evaluate the levels of heavy metals and other elements available in soils under influence of the uranium-phosphate deposit of Itataia, considered the largest uranium reservoir in South America. Simple deformed soil samples were collected at 53 points in the 0-20 cm layer, and the available levels of Al, B, Cd, Co, Cu, Fe, Hg, Mn, Mo, Ni, Pb, Ti, Zn e Zr were extracted (Mehlich 1) and determined using inductively coupled plasma-atomic emission spectrometry (ICP-AES 6300 DUO).Were found available levels of Cd, Hg, Ni, and Pb in all samples, and no values of Cu, Ti or Zr were detected. Available B and Co was detected in more than 80% of samples, and for Mo, Al, Zn, Mn and Fe in less than 60% of the samples. The results showed many extreme values and asymmetric distribution for most of the data and no normality was observed after the Kolmogorov-Smirnov test. Pb was the element that presented the highest levels in the area, with a median of 16.35 µg kg^{-1}. Al although detected in only 40% of samples, was the element that showed the highest extreme value, 431.92 µg kg^{-1}. The available heavy metal contents showed the following decreasing order: Pb> Ni> B> Hg> Co> Mo> Cd> Al> Zn> Mn> Fe> Cu, Ti, Zr. The available content was compared with the total content of these elements in the soil. In this way, Lead was the element that presented the largest amount available in relation to its total content (approximately 25%), then Cd> B> Mo> Ni> Zn> Co> Mn> Al> Fe. The low availability of the metals in the area can be due to pH (7.43) and soil organic carbon (26.56 g kg^{-1}). The present study indicated that due to the low levels of heavy metals and other elements of soils from the Itataia deposit, there is no risks of pollution to the local environment.

(5879 - 831) Biochar from biosolids microwaved-pyrolysis: Characteristics and potential for use as growing media amendment

Bhawana Bhatta Kaudal[1]; Cristina Aponte[1]; Graham Brodie[1]
University of Melbourne[1]

Biochar, produced from biosolids using microwave pyrolysis technology, is energetically a more efficient alternative to that produced with conventional convective heating. However the potential of microwave generated biochar as a growing media amendment has not been sufficiently explored. Here we produced biochar from biosolids using microwave energy. The pyrolysis experiments were conducted in two stages, initially using a custom built single mode chamber to explore the energetics and product distribution of the pyrolysis process at different temperatures and secondly in a 1 m3 6 kW multi-mode chamber, to explore potential scale-up of the process. The second phase of the pyrolysis experiments was focused on biochar generation for use in the remainder of this research. Microwave pyrolyzed biochar (MB) was characterised for its chemical and physical properties. Then, we conducted a greenhouse experiment, where we compared the ability of four growing media mixes that combined pine bark with (i) sphagnum peat and fertilizers; (ii) 20% MB and fertilizers; (iii) 60% MB and fertilizers; and (iv) 60% MB and no fertilizers, to promote plant growth and nutrient uptake and to minimise leaching losses. MB had high mesoporosity (average pore width of 4.46 nm), moderate surface area (75 m2 g−1), elevated nutrient content and low heavy metal concentrations as compared to other biosolids biochars reported in literatures. Substitution of peat with 60% MB on volume basis reduced leaching loss of nitrate and phosphate from the media but increased leaching loss of ammonium. Addition of MB in conjunction with fertilizer increased plant growth and plant nitrogen and phosphorus use efficiency. Our study has shown microwave pyrolysis as a promising technology for pyrolyzing biosolids and also has demonstrated the synergistic interaction of MB and fertilizer which results in greater plant growth and nutrient uptake and use efficiency.

(9218 - 2053) Biogas and biofertilizer production from dairy cattle manure under organic and conventional production systems in Seropedica, Rio de Janeiro (Brazil)

Camila F. Matos[1]; Érika Flávia Machado Pinheiro[1]; David Villas Boas de Campos[2]
Federal Rural University of Rio de Janeiro (UFRRJ)[1]; Embrapa Solos[2]

The production of milk in Brazil stands out as one of the main agricultural activities. The quality and efficiency standards in the milk production have been required in recent years with the objective of intensify even more the production system. As a consequence, there is an increase in the amount of residues generated during the milk productive chain which can lead to a contamination of the soil, the water and the air. The goal of this study was to evaluate the production of biogas potential and biofertilizer resulting from the anaerobic biodigestion of dairy cattle manure under organic and conventional production system. The experiment was built eight prototypes of benchtop biodigesters, being the supply system discontinuous. The treatments evaluated were: a) CMOS - cattle manure under organic production system, from Agroecological km 47 Farm; b) CMCS - cattle manure under a conventional production system, from the dairy cattle sector of the Agricultural Research Company of the State of Rio de Janeiro. Analyzes were performed based on the methodology described by APHA (2005), United States Environmental Protection Agency and CONAMA 357/06. After the anaerobic biodigestion process it was observed that the concentrations of thermotolerant coliforms were below than the limit established by law. The cumulative biogas production was 6.18 L and 11.15 L, when using the CMOS and CMCS, respectively. DBSO and DBSC biofertilizers presented a carbon content (392.4 and 411.9 g kg^{-1}) to be considered an organic fertilizer. Magnesium, potassium and iron contents were higher in DBSO biofertilizer but calcium, manganese, copper, zinc and barium contents were higher in DBSC. DBSC biofertilizer had cadmium content above that allowed by organic fertilizers law. The organic and conventional management production of milk influenced the production of biogas. CMCS presented a higher accumulated biogas production with higher energy potential when compared to CMOS. The management adopted can have influenced the production of biogas through the feed supplied to the animal, demonstrating that in the conventional management a feed based on concentrate, roughage and commercial feed contributed in a more significant way for biogas production in relation to the one where the animals fed only from a roughage-based feed produced on organic property. On the other hand, dairy cattle manure from CMOS showed greater potential to be used as organic fertilizer when compared to the CMCS.

(3037 - 2241) Building of probe-type passive sampler to study the contents of heavy metals in the aqueous phase

Viviana Garces Villegas[1]; Manuel Palencia[1]; Tulio Lerma[2]
Universidad del Valle[1]; Mindtech Research Group[2]

"Dissolved" concentrations of contaminants in the soil provide a more relevant description for risk assessment than the total concentrations. But also, the perturbation of the soil during sampling process must be highly minimized in order to obtain the best results regarding the real field conditions. In this context, passive sampling methods for estimating "Dissolved" concentrations offer the potential for cost-efficient and accurate in situ characterization of pollutants in the soils, exactly, the aqueous phase. In this work, the building of probe-type passive sampler to study the contents of heavy metals in the aqueous phase of soils was developed. For that, clay (montmorillonite) was immobilized on the poly(vinyl chloride) surface by thermal methods. Next, surface functionalization or chemical activation was performed by chemical insertion of vinyl units easily polymerizable by free-radical polymerization. Later, poly(sodium vinyl estearate) chains were inserted using ammonium persulphate as radical initiator and deionised water as reaction phase. Different chain lengths were promoted by the modification of initiator amounts. In all cases, materials were characterized by infrared, scanning electron microscopy, thermogravimetric analysis and contact angle measurements. Retention properties were evaluated as a function of pH and ionic strength using Pb^{+2}, Hg^{+2} and As^{+2} as target ions. Aqueous extract of soil samples were used to identify the effect of composition on retention properties. Results demonstrate that probe-type passive samplers can be made by described methodology; in addition, retention of ions was identified to decrease as pH is decreased and affected by metal speciation as pH is increased.

(6371 - 1158) Cadmium buffer capacity in Chilean soils with different reactivity

Belen Henriquez Caurapan[1]; Laura Navarro Vigueras[2]; Susana Valle Toledo[3]; Dante Pinochet Tejos[3]; Mauricio Pereira Carvajal[1]
Escuela de Graduados, Instituto de Ingeniería Agraria y Suelos, Facultad de Ciencias Agrarias, Universidad Austral de Chile[1]; Instituto de Ingeniería Agraria y Suelos, Facultad de Ciencias Agrarias, Universidad Austral de Chile[2]; Instituto de Ingeniería Agraria y Suelos, CISVo, Facultad de Ciencias Agrarias, Universidad Austral de Chile[3]

The cadmium availability for plants is related with their mobility, transport and distribution of the metal in the soil. This availability is determined by the soil buffer capacity, which depends on their reactivity. Cd dynamics is described by sorption and desorption processes which depend of the chemical form of the metal and the soil intrinsic characteristics. This study aimed to assess the variation of the Cd buffer capacity (CP) among different agricultural soils. Three types of soils (Ultisol, Andisol and Alfisol) which present differences in their reactivity were characterized. Each soil was enriched with 5 different amounts of CdCl (0, 10, 50, 80, 120 mg kg^{-1} Cd; estimated in function the Cd input to the soil related to the use of fertilizers and agricultural residues) and incubated during 17 days (at 25°C and 50% humidity). The available Cd was determined at days 1, 9 and 17 during the incubation. The available Cd was extracted by EDTA (0.05 M), pH 7.0, at soil:solution ratio of 1: 2, $MgCl_2$ (1M), pH 7.0, 1: 2; and, $CaCl_2$ (0.01). M) 1: 2. Differences in the Cd buffer capacity of the studied soils were observed, with Andisol (CP = 0.4) < Alfisol (CP = 7.2) < Ultisol (CP = 50). These results suggest that the soil reactivity is an important factor in the fraction of Cd available for plants. However, the amount of Cd extracted was different between the three methods evaluated. However there are certain equivalences between them, e.g., $CaCl_2$ extracts 50% less of Cd comparing with EDTA and $MgCl_2$, where the two last extractantes showed differences of 2-10% in the available Cd extracted from the three soils. There was no significant effect of the times considered in this study on Cd buffer capacity evaluated.

(5559 - 2807) Cerium content in roots of arabica coffee cultivated in soil amended with phosphogypsum

Pedro Renato leandro de Souza[1]; Luís Paulo Patente Tanure[1]; Joésio Leandro de Souza[1]; Jaime Wilson Vargas de Mello[1]; Carlos Roberto Bellato[1]
Universidade Federal de Viçosa - UFV[1]

Phosphogypsum is used in coffee plantations to favor the deepening of the plants roots. However, in addition to the nutrients, the phosphogypsum present low amounts of rare earth elements (REE), like cerium (Ce), which is generally found in higher concentration. There are scientific evidences of diseases pulmonary, neurological, and even cancer in animals due to chronic exposure to high

concentrations of Ce. Therefore, absorption of Ce by coffee plants, from soils amended with phosphogypsum, increases the risk of human exposure to this element. In this context, this research aimed to evaluate the accumulation of Ce in roots of arabica coffee (*Coffea arabica* L.) due to high doses of phosphogypsum applied to soil, under field conditions. The study area was a commercial plantation of arabica coffee in Minas Gerais State, Brazil. Five doses, 0 (control), 9, 16, 24 and 48 t ha^{-1} were considered in a randomized block design, with four replications. The roots were collected from 0 to 60 cm deep, in trenches at 20 cm from the stem of the plants. After collection, the roots were washed, oven dried (65 ° C) and ground in a Willey mill. Samples of roots (1 g) were then submitted to nitric-perchloric digestion. Cerium concentrations in the extracts were determined by inductively coupled plasma mass spectrometry (ICP-MS). The results indicate a significant increase in Ce content in the roots of the coffee plants due to application of high doses of phosphogypsum. Nevertheless, the rate of recovery of Ce by the roots of coffee under field conditions was low.

(1297 - 2517) Contents of Pb, Cu and Zn in soils cultivated with parsley the in municipality of Nova Friburgo, state of Rio de Janeiro - Brazil

Júlio César Ribeiro[1]; Uliana Ribeiro Silva[2]; Nelson Moura Brasil do Amaral Sobrinho[3]; Everaldo Zonta[3]
Federal Rural University of Rio de Janeiro, Postgraduate Program in Agronomy - Soil Science.[1]; Federal Rural University of Rio de Janeiro, Agronomy student.[2]; Federal Rural University of Rio de Janeiro, teacher of the Department of Soils.[3]

The mountain region of Rio de Janeiro - Brazil leads the production of vegetables in the state, and the municipality of Nova Friburgo is one of the main pole producing of parsley of agriculture of Rio de Janeiro that supplies the metropolitan region of the same state. However, the production process has been sustained by the high contribution of agrochemicals in order to meet the nutritional requirements of the plants, in addition to pest and disease prevention and control. In view of the above, the present study aimed to determine by means of the 3050B method (USEPA, 1996), the pseudototais Pb, Cu and Zn contents of the soil cultivated with parsley at the depth of 20-40 cm of 10 family farms in the municipality of Nova Friburgo, RJ, Brazil. The results compared to the guideline values recommended by the National Council for the Environment - CONAMA (2009). The soil Pb ranged from 10,19 mg.kg-¹ to 42,07 mg.kg-¹, with an average content of 25,64 mg.kg-¹. Cu ranged from 14,62 mg.kg-¹ to 63,11 mg.kg-¹ among the properties, with a mean content of 32,22 mg.kg-¹. The Zn content ranged from 29,06 mg.kg-1 to 105,56 mg.kg-1, with an average content of 57,02 mg.kg-1 of the evaluated properties. For the pseudo-values of Pb and Zn determined in soil samples cultured with parsley, it was verified that 100% of the properties presented values below the Prevention Value (PV) recommended by CONAMA (2009). Only for Cu; 10% of the properties evaluated presented value above that recommended by CONAMA (2009). The levels of Pb, Cu and Zn in the majority of evaluated properties are below the values of prevention recommended by the current legislation established by CONAMA. However, soil monitoring should be periodic, since the agrochemicals supply in the study region is very high and may lead to future contamination.

Keywords: heavy metal; ground contamination; *Petrosolium sativum*.

(2129 - 2566) Depth distribution of Glyphosate and AMPA, "pseudo-persistent" pollutants, in long-term experiments under no-till and conventional tillage

Virginia Carolina Aparicio[1]; Jose Luis Costa[2]; Eduardo De Geronimo[1]
INTA, EEA Balcarce, CONICET[1]; INTA, EEA Balcarce[2]

Glyphosate (N-(phosphonomethyl glycine) is a post-emergence, non-selective, foliar herbicide. More than 200 million liters of this herbicide are applied every year in Argentina, where the main agricultural practice is no-till (NT), accounting for 78 % of the cultivated land. In this work, we studied the distribution of glyphosate in long-term experiments (more than 15 years) at different locations under NT and conventional tillage (CT). Samples from 0-2, 2-5, 5-10, 10-15, and 15-20 cm depth were taken with four replication and two treatments NT and CT at 6 locations: Balcarce (BA) a loam soil, Bordenave (BO) a sandy loam soil, Marcos Juarez a silty loam soil (MJ), Parana Vertisol a clay soil, Paraná Mollisol a clay loam soil y Pergamino a silty loam soil. No difference between tillage practices was found regarding glyphosate concentration, significant differences were observed among locations and depth and interactions between depth and locations. Nevertheless, the concentration of AMPA at 0-2 cm depth was 1.6 times higher in no-till than in conventional till. To our knowledge, this study is the first dealing with the accumulation of glyphosate and AMPA in soils under different tillage systems. In the present study, it was demonstrated that glyphosate and AMPA are present in soils under agricultural activity with maximum concentration in the first two cm of soil and the AMPA concentration at this depth is greater in NT than in CT.

Keywords: Keywords: Glyphosate, AMPA, soil pollutants, no-till.

(3034 - 966) Determination of Carbon in São Paulo state soil sample by Near Infrared Spectroscopy

Catarina Celeste Duque[1]; Aline Reneé Coscione[2]; Felipe Bachion de Santana[3]
Agronomic institute[1]; Agronomic Insitute[2]; University of Campinas[3]

Soil organic matter (SOM) is an important component in soils because it contributes to the improvement of water retention capacity, decreases soil density and is a source of carbon and nitrogen for soil microorganisms. The quantification of MOS is done, indirectly, with the determination of organic carbon form or total carbon. Among the conventional methods of carbon analysis are the Mebius method, using visible or titrated spectrophotometry (Walkley-Black method adaptation) or the Elementar Analyzer (CN). The Near Infrared Spectroscopy (NIRS) has been used in soil analysis as a quick, non-destructive practice that does not require expensive reagents or inputs, which contributes to the elimination of waste generation and waste of natural resources. In the present work, the soil carbon was determinated with the use of the NIRS together with the multivariate calibration with the partial least squares (PLS) regression modeling was performed. A total of 106 soil semples from the State of São Paulo were used, components of the MOS calibration curve of the Laboratoty of Chemical Analyzes of the Soil for Fertility Purposes of the Agronomic Institute (IAC) currently in use, macerated to pass through a 100 mesh sieve. Models were constructed and compared using the values obtained by titration with Mebius or with the CN. To obtain the spectra the ground samples were oven dried at 65ºC (±5º) and spectra were collected in the total wave lenght of the spectrometer, being 400 to 2500 nanometers (nm). The models were evaluated using the quadratic mean calabration and prediction errors (% RMSEC and RMSEP) and correlation analysis between the values of rganic carbon predicted by the model and the respective reference value (Mebius or CN). For the model with Mebius the RMSEC was 5.3%

and the RMSEP was 11.3%, respectively, while for the CN were 3.1% and 6,5%. Both models presented a coefficient of correlation superior to 0,95. Tho model based on the elemental analyser is slightly superior to that with Mebius. This can be attributed because of the greater accuracy of the analysis of the CN method in relation to the Mebius. Even though, the NIRS can be indicated to routine procedure to SOM quantification in soil samples.

(8530 - 2465) Determination of tetracyclines by electrochemical methods, to its application in the adsorption on the clay fraction of volcanic soils

Constanza Venegas[1]; Mónica Antilén[1]; María Angélica del Valle[1]
Pontificia Universidad Católica de Chile[1]

The tetracycline family is formed by Tetracycline (TC), Chlortetracycline (CTC), Doxicycline (DX) and Oxitetracycline (OTC). These antibiotics are used in the livestock industry as growth agents, but especially for treating infections. However, between 25 and 70 % is excreted by the animal through its urine or feces in their active way, reaching the soils and the groundwater. The inorganic fraction of the soil presents interactions with the antibiotics, because it is the most reactive part of soil, since it confers charge and is the responsible of the cationic exchange capacity (CEC). In this work, a new analytical method based on electrochemical methods has been developed, with the aim to determinate the tetracycline family in an aqueous system, considering its applicability in the evaluation of adsorption/desorption of these antibiotics on the clay fraction of volcanic soils (Andisol, Osorno series). The chemical-physical properties, pH and electric conductivity have been measured according recommended methods for Chilean soils and, the variable charge, by electrophoretic migration. Recently, some electroanalytical techniques have been used for Tetracycline determination, since different soils fractions do not act as interferences in the measurements. The electrochemical measurements were carried out by cyclic voltammetry, at 100 $mV \cdot s^{-1}$, in a certain window of potential and by using 0.1 mol L^{-1} KNO_3 as supporting electrolyte. The results show that the clay fraction coming from an Andisol soil does not have an electrochemical response, so it does not interfere in the antibiotics determination. Then, in the analytical method developed, it is observed an oxidation peak current that it is dependent of the analyte concentration which allows to evaluate the adsorption/desorption of these antibiotics in the clay fraction by the analysis of a calibration curve.

(7067 - 367) Digital mapping of the natural contents of heavy metals in soils of the Serrana Region of the State of Rio de Janeiro

Leonardo Durval Duarte Guimarães[1]; Nelson Moura Brasil do Amaral Sobrinho[1]; Helena Saraiva Koenow Pinheiro[1]; Erica Souto Abreu Lima[1]
UFRRJ[1]

The study was developed in a hillslope area from Rio de Janeiro (Região Serrana). The area comprises a great agricultural center, embracing family farmers and producers of vegetables for supplying the Metropolitan Region of the State. The actual knowledge about soil heavy metals contents is based on natural contents (reference values to natural occurrence on the environment). Which are commonly used to study the impacts of the anthropic activities on the environment, as well regarding the soil contamination and pollution. The objective was to analyze the spatial distribution of heavy metals natural contents at two depths (0-0.2 m and 0.2-0.4 m) by using geostatistical analysis comparing the performance of two softwares. A dataset with sixty-one representative pointswere collected, at both depths, in sites with none or low anthropogenic activity.. From those soil samples were obtained data regarding soil fertility and soil geochemical fractionation to determine the metal contents (Fe, Mn, Zn, Cr, Al, Co, Cu, Ni, Cd and Pb). The geostatistical analysis (normal kriging) were performed in GeoEst and R software. The final maps of natural contents for both depths were created with support of ArcGIS Desktop v.10.4. The modelling evaluation was based on cross-validation through the statistical indexes Root Mean Square Error (RMSE), Mean Bias Error (MBE), coefficient of determination (r^2), and the Pearson correlation coefficient (r) were also calculated. Results showed no difference between softwares suggesting that regardless of the choice of software the final product are statistically equal. Based on the relative semivariogram the concentrations of metals (Fe, Mn, Zn, Al, Co, Cu, Ni and Pb) showed spatial dependence for a range of 35.0 km. Isotropy was observed for all metals under study. The theoretical spherical, exponential and Gaussian models were those that represented the best adjustments to the points of the experimental semivariograms, agreeing with the literature consulted. The analysis of spatial distribution of the natural contents based on the maps for both depths reveals a remarkable influence of lithology, soil type and relief on the contents of the studied metals, to the studied area.

(4009 - 710) Effect of anthropization in the water table level change of mountain tropical peatlands

Uidemar Morais Barral[1]; Alexandre Christofaro Silva[1]; Christiano Christofaro Matosinhos[1]; Camila Rodrigues Costa[1]; Aparecido de Penafort Abreu Filho[1]; Geisla Mendes Macedo[1]
UFVJM[1]

Peatlands are ecosystems formed by the accumulation of plant tissues, which are slowly decomposed due to anaerobic conditions. Its importance is related to your environmental services: carbon and water storage and palaeoenvironmental reconstitution. In Brazil, peatlands occupy an estimated area of ~5554,730 km^2, which corresponds to 0.6% of the national territory. In the northern portion of the Serra do Espinhaço Meridional, Minas Gerais State, they occupy 142 km^2 corresponding to 1.2% of the total area. Fluctuations of water table are crucial for the maintenance of the tropical peatlands, since they control the dynamics of the accumulation and decomposition of the organic matter. The aim of this study was to evaluate the change of the water table levels in two montain tropical peatlands. The peatlands are located at the head of the Araçuaí river, main tributary of the Jequitinhonha river. These are the only two perennial water courses in the semi-arid region of the northeast of Minas Gerais State. The peatland 1 (P1; 23 K 067719 S 7982972 W), with 3.6 ha, is protected by the Rio Preto State Park. The peatland 2 (P2; 23 K 0678749 S 7982411 W), with 11.2 ha, is used by extensive livestock and burnings are frequent. Four and three piezometers were installed with level meters, model U20L-01 with 1 cm precision, respectively in P1 and P2. In P1, the measurements were carried out from September 26, 2016 to November 16, 2017. For the P2, the measurements were carried out from October 23, 2016 to November 16, 2017, interval between measurements of 30 minutes. The results show that the water level of the two peatlands suffers the highest positive changes from November to May. Negative changes occur mainly from June to October. For P1 (protected), the maximum elevation and lowering of the surface water table level were respectively 37.2 and 4.7 cm, regarding to the reference level in the piezometer located near the outlet of the microbasin. For P2 (anthropized), the maximum elevation and lowering of the water

table levelwere 22.4 and 19.1 cm, respectively, regarding to the reference level, in the piezometer located near the outlet of the microbasin. Anthropization is reducing severely the water retention capacity of the P2.

(3495 - 1944) Effects of electrochemical changes on barium content in flooded soil

Douglas Gomes Viana[1]; Amanda Duim Ferreira[1]; Fábio Ribeiro Pires[1]; Fernando Barboza Egreja Filho[2]; Kerwin Araújo Costa[1]; João Carlos Madalão[1]; Paulo Roberto da Rocha Junior[3]; Robson Bonomo[1]
Universidade Federal do Espírito Santo[1]; Universidade Federal de Minas Gerais[2]; Fazenda da Toca[3]

Barium is a toxic metal and the main anthropogenic input form this element into ecosystems is the contamination by oil drilling fluids. This fluids contains barium sulphate, which is low in toxicity due to its low solubility, being relatively immobilized in the soil and biologically unavailable. However, under poor drainage conditions, the sulfate and sulfide residues may release the most toxic form of barium (Ba^{2+}) into the environment, potentially contaminating water courses and introducing barium into the trophic chain. We aimed with this study to evaluate how the changes eletrochemical of soil along 180 days altered the bioavailability of barium in the soil. The experiment was conducted in a randomized complete block design in a greenhouse located at the Experimental Farm of the Federal University of Espírito Santo - Campus São Mateus, evaluating the pH, Eh and content of barium in two layers of the soil (0 to 0.1 m and 0.1 to 0.2 m). The evaluations were carried out in seven times,at 60, 75, 90, 105, 120, 150 and 180 days. The data obtained were submitted to correlation analysis between the parameters pH, Eh and soil barium content. In both soil layers the correlation between pH and Eh was negative, that is, the reduction in Eh was followed by increase in pH. This increase in pH is typical of soils subject to flooding due to consumption of protons, and as a result, a change in pH is expected. The barium content in the soil was variable in the two soil layers. In the depth of 0.0 to 0.1 m was observed high and negative correlation, but not significant, between pH and barium content in the soil. The correlation between barium content and Eh was high and positive, but also not significant. In the 0.1 to 0.2 m layer, the Eh correlated with the barium content in a negative, high and significant way, as expected, since it is known that in low values of Eh the reduction of sulfate in sulfide by bacteria in the soil can occur, leading to the availability of barium to the water courses and the entire trophic chain. The barium content in soil remained constant throughout the period of conduction of the experiment, with non-significant variations. Therefore, we can conclude that in the saturated soil condition, the barium mobility can be increase due the change in the Eh, independent of pH values.

(8482 - 2741) Effects of sewage sludge application in a soil with high natural contents of Cd, Zn, and Pb

Rafaella Campos[1]; Maurício Paulo Ferreira Fontes[1]
Universidade Federal de Viçosa[1]

The use of organic wastes as amendments in soils contaminated with heavy metals is a sustainable alternative to reuse these materials. However, depending on their properties, they may increase the heavy metal bioavailability. Knowing that different organic wastes acting in different ways on the heavy metal bioavailability, this study aimed to evaluate the bioavailability of heavy metals after the application of sewage sludge (SS) in a soil with naturally high contents of Cd, Pb, and Zn. A greenhouse experiment was carried out with six doses (0.0; 1.0; 2.5; 5.0; 7.5; and 10 % w/w) of SS, with three replicates. To evaluate the bioavailability, the *Canavalia ensiformes* L. (pork bean) was used. The metals concentration present in the soil solution was monitored by rhizon (soil solution samplers). At the end of the experiment, the heavy metals content in the above-ground portion of the plants and dry biomass was determined and a sequential extraction was carried out in the soil samples. The sequential extractions results pointed out that SS significantly increased the availability of Cd, Pb, and Zn and the increases were proportional to the dose used. The dose of 10% increased in four-fold the soluble Cd; five-fold the soluble Zn; and 19% the exchangeable Pb. These results were ratified by the heavy metals contents found in the soil solution collected by the rhizons. As consequence, there was an increase of Cd in above-ground portion of the plants equal to 107, 245, 250, 335 and 276% for the doses of 1.0; 2.5; 5.0; 7.5, and 10%, respectively. The magnitude of these increases for Zn was 48, 76, 128, 106, and 70%. The increase of metals in the plant tissue was accompanied by the reduction of dry mass produced, which reached 85% of reduction for the dose of 10%. These results may be a consequence of the pH reduction promoted by SS application and of the high content of soluble carbon presents in the SS, which may be promoted the availability increase of the heavy metals. These results permit us to state that the sewage sludge was not a suitable amendment to reduce the bioavailability of Cd, Pb, and Zn in the studied soil.
Keywords: organic wastes, heavy metals, amendment, immobilization

(9804 - 2669) Emissions and releases from primary mercury mining activities into terrestrial systems of the Sierra Gorda, Querétaro, México

G. Hernández-Silva[1]; S. Martínez-Trinidad[2]; N. García-Calderón[3]; S. Solís-Valdez[1]; P. Scharek[4]; C. Centery[5]; L. F. Vassallo[1]
UNAM, Centro de Geociencias[1]; UNAM, Instituto de Geografía[2]; UNAM, UMDI-J, Qro.[3]; MAFI, Hungary[4]; Szent Iztvan University, Hungary[5]

The cinnabar (HgS) mining exploitation for over two thousand years in the mineralized zone of Sierra Gorda, Querétaro, México, has affected the terrestrial systems (soil, water, air and biota) and the human health. The extensive use of Hg in the last and present centuries has increased its potential risk for exposure in ancient and present inhabitants and in the environment as well. The study area occupies 175 km^2 in the San Joaquin municipality; and the region is composed of several Mesozoic marine formations. Our goal is to contribute with the Minamata Convention to protect the human health and environment from anthropogenic emissions and releases of mercury. 103 soil and sediment samples, were analyzed by AMA 254; 19 maize plant structures was determined by ICP-OES. Hg° in vapor phase was measured in two sampling sites (TEKRAN 2537A). Two rainwater collectors were used to analyze 24 samples (ICP-OES). Soil carbon sequestration was determined in 38 soil samples. To construct maps the ArcView 8.1 was used. An approach of flow of total Hg interactions within the terrestrial systems and some landscape ecology characteristics are presented. Three groups of mining tailings showed the highest Hg with a maximum of 4164 mg/kg. 46 % of agricultural soils sampled are above the permitted limit by NOM-2004; 17 % of total Hg in grain maize sampled, is higher than values allowed by WHO-2004. Hg in rainwater ranged from 1 to 339µg l^{-1}, too high compared to a pristine areas of 1-2 µgl^{-1}. Levels of Hg found in air showed an extremely high content, from 5.3 to 415.8 µg/ m^3 (<1 µ/m^3 by WHO-2002). Most of the area with a medium level is shown in the

soil carbon sequestration map. Due to continuous volatilization of Hg-enriched soils and HgS tailings, the inhabitants of the region keep a constant direct contact with Hgº through inhalation. On the other hand, Hg in agricultural soils and maize grains is a continue risk into the food chain. Therefore, a constant monitoring of Hg emissions are necessary in a long term, to determine the scope of the environment and health Hg problems.

Keywords: Mercury, terrestrial systems, environment and health, Sierra Gorda, México

(5921 - 3228) Engineering Trees into Site Remediation: Case Studies of Using Eucalyptus in Brazil

Lawrence Morris[1]; Diego Barcellos[1]; Aaron Thompson[1]; Daniel Moura[1]; Tiago Moura[1]; William Hall[1]; William Odle[1]; Aristides Ribeiro[1]; Bruno Furtado[1]; Nairam Barros[1]

University of Georgia[1]

Contamination of soils and groundwater by organic compoundsare common problems at industrial sites worldwide. Phytoremediation with tree planting can be part of a successful remediation strategy for contaminated sites. We demonstrate this using examples from Brazil. The first example is an industrial site near Porto Alegre, RS. Soil and groundwater of this site were contaminated bychlorobenzene and benzene. Primary remediation of this site consisted of both excavation and injection of sodium persulfate for in-situ chemical oxidation. To further treat contaminants after in-situ oxidation, Eucalyptu surograndis were planted. We first demonstrated the potential of Eucalyptus to accelerate removal of these compounds in a greenhouse study. A solution of chlorobenzene and benzene at concentrations of 50 mg.L-1 each was added to large columns planted with Eucalyptus or maintained as a no plant control. In the absence of Eucalyptus, contaminant mass in leachate decreased 50-60%. In the planted Eucalyptus treatment, contaminant mass in leachate decreased 91-98%. At the end of the experiment, ~1% of the added contaminant remained in plant components or the substrate. In the field site, Eucalyptus seedlings were planted in bored holes downgradient from the sodium persulfate injection zone. They grewup to 10 m height in 3-4 years. We were unable to directly measure the contribution of phytoremediation to overall remediation; however, we estimated the 200 m2 Eucalyptus plantation had the potential to remove 4.53 kg.year-1 of chlorobenzene and 0.93 kg.year-1 of benzene. A second example is for a site contaminated with Aldrin and Dieldrin near Paulína, SP. On this site, the primary remediation was designed to control groundwater movement to a nearby river. A network of wells was installed as part the primary pump-and-treat remediation approach. To investigate the potential to augment this approach with Eucalyptus plantings, we instrumented mature Eucalypts and native forest trees with stem-flow collars and monitored soil water with TDR to 2.3 m depth. Due to the shallow depth to the water table, transpirational patterns of vegetation had a significant impact on potentiometric surfaces and groundwater movement. Field measurement and modeling showed that a zone of mature Eucalyptus could play a significant role in reducing the potential movement of contaminants to the river and remediating contaminated soils.

(5331 - 2461) Estimate of the sorption atrazine (ATZ) in horizontal samples of a red-yellow latosol

Alba Rocio Aguilar Piratoba[1]; Antônio Alberto Da Silva[1]; Claudio Ferreira Lima[1]; Gustavo Antônio Mendes Pereira[1]; Natalia Milena Escobar Marulanda[1]; Marcos Santana Miranda Júnior[1]

Universidade Federal De Viçosa[1]

Agronomic efficiency and environmental risk of herbicides applied directly to the surface of the soil depends on its ability to be dripped by soil colloids. This capacity depends on the attributes of the soil which vary according to the type and management used for planting the crops. Knowledge of the dynamics of a herbicide in the soil becomes, still, more important for the pesticides that have history of groundwater contamination, as is the case of ATZ. In this research was estimated, by biological method, the sorption of the ATZ in samples of a red-yellow latosol collected in the Horizons A, B, C, mixtures AB and ABC; beside to an inert substrate (sand). Physicochemicals characteristics of the soil samples evaluated concerning horizons A, B, C, AB and ABC were respectively pH: 5.4, 5.3, 5, 5.3 and 5.3; Clay content: 43, 56, 5.0, 56 and 37; Organic matter (MO): 3.1, 1.7, 0.86, 2.18 and 1.97. The assay was conducted in DBC in 6x8 factorial with 4 repetitions, substrate factor (5 soils and sand) and dose factor (8 levels of ATZ in g ha^{-1}). Experimental units were vases of 0.33 dm^3, filled with substrates. In these were applied the doses of ATZ on the surface of the soils with sprayer. Then the species *Cucumis sativum* was sown to detect the free herbicide in the substrate solution. At 21 days after the emergency of the indicator plant was determined the dry matter (MS) of the aerial part of these plants. Non-linear log-logistic model of Seefeldt et al., (1995) was using to estimate the concentration of the applied herbicide which reduced by 50% the accumulation of plant droughts. Before the sorption ratio was calculated (RS). Symptoms of intoxication of the indicative plants by the ATZ were characterized chlorinese in the tissues of the plant that evolved for necrosis and plant death. The dose of ATZ able to reduce by 50% (C_{50}) the accumulation of MS of cucumber plants went from: 209.9; 21.4; 9.7; 47.8; 54.1 and 2.3 g ha^{-1} for A, B, C, AB, ABC and sand respectively. RS in the soils followed the ascending order of C<B<AB<ABC<A. The C_{50} and RS data have a positive correlation with the MO content. This concluded that the sorption of the ATZ by colloids in differents depths of the profile of a soil varies according to the physicochemicals characteristics of each horizon. According to this, it is noted that for studies that consider sorption to classify the movement of the herbicide in the soil, special attention should be paid to the samples to be evaluated.

(1611 - 2867) Evaluating the pollutant removal potential of swales for the treatment of metaldehyde and other pesticide pollutants within agricultural surface runoff.

Lloyd Cockram[1]; David Hopkins[1]; Ian Grange[1]

Royal Agricultural University[1]

Metaldehyde pollution of surface and drinking waters is presently a matter of particular concern to the UK water industry due to its intractable nature; furthermore there is a drive, in both science and policy, toward finding nature based solutions to water treatment and the utilisation of the catchment based approach. The use of swales (vegetated conveyance channels) for the treatment of a wide variety of pollutants in surface waters is reasonably well established within the literature, no study has yet however evaluated the applicability of such an approach for the removal of pesticides. Moreover, previous studies have focused primarily on evidenced pollutant removal efficiencies, with little or no attention to understanding the mechanisms of swale water treatment. Through a theoretical consideration of swale dynamics, as well as an evidence based analysis of the potential application regarding metaldehyde and

other pesticide pollutants, this study aims to fill these knowledge gaps while making a case for more integrated management of water resources within the water and agricultural industries. In such a way this work can investigate the application of swales as a nature based solution to a contaminant of particular concern, while also better elucidating the concept of swales as a whole, aiding future theoretical and experimental considerations of other potential applications.

(8440 - 2642) Extraction of heavy metals from contaminated soils and sediments using different surfactants

Ingrid Hagarová[1]; Marek Bujdoš[1]; Martin Urík[1]; Peter Matúš[1]; Filip Polák[1]; Martin Šebesta[1]
Slovak Spectroscopic Society, member of the Association of Slovak Scientific and Technological Societies; Comenius University in Bratislava, Faculty of Natural Sciences, Institute of Laboratory Research on Geomaterials, Ilkovičova 6, 842 15 Bratislava[1]

In this work, synthetic non-ionic surfactants such as Triton X-100 and Triton X-114 (*octylphenoxypolyethoxyethanol* with PEO chain length of 9.5 and 7.5, respectively), biosurfactant saponin (isolated from *Quillaja saponaria*), and metabolites of microscopic fungi (*Aspergillus niger*) were compared for extraction of heavy metals (such as Cu, Pb, Ni, and Zn) from contaminated soils and sediments. In this case, batch experiments were performed for evaluation of removal efficiency. While non-ionic surfactants and metabolites of *Aspergillus niger* have shown weak capability to remove the studied metals (removal efficiency less than 6 % in all cases), natural plant-based biosurfactant saponin can be considered as a promising biodegradable agent for remediation of Cu, Ni, and Zn from contaminated soils and sediments. The removal percentage was in the range of 14 – 46 %. Maximal removal yields were achieved at saponin concentration of 2 % (m/v) and removal incubation time of 24 hours. Higher concentrations and longer incubation times have shown no improving in removal efficiences. Now, a sequential extraction study is made on the soils and sediments before and after washing to determine from what fraction the saponin removed the heavy metals.

(2291 - 408) Fe and Al (hydr)oxides mineralogical phases resulting from co-precipitation with Rare Earth Elements

Gisely Souza Barcelos[1]; Jaime W. V. de Mello[1]; Massimo Gasparon[2]
Universidade Federal de Viçosa[1]; The University of Queensland[2]

Trivalent cations of rare earth elements (REE) present quite similar chemical and physical properties. Cerium and europium, however, can also be found as Ce^{4+} and Eu^{2+}. The REE present an unusual behaviour named “lanthanide contraction” which leads to a decrease in the atomic radii with increasing in atomic number. The use of such elements is related to the development of new technologies due to their applications in high-tech industry. Consequently, REE mining has grown, which leads to environmental concern due to effluents of mining processes. Thus, methods to remove or stabilize such contaminants from wastewater are warranted. Use of lime is an usual technique to neutralize AMD, which also leads to precipitation of Fe/Al (hydr)oxides. The aim of this study was to characterise mineralogical phases resulting from treatment of wastewater containing La, Ce, Nd, Eu and Ho by co-precipitation with Fe/Al (hydr)oxides. Five sets of 60-day experiments using individual REE were carried out with different Fe:Al:REE molar ratios in order to assess the efficiency of water treatment, as well as the mineralogical phases precipitated. Co-precipitation of Fe/Al (hydr)oxides was obtained by increasing pH, which was periodically buffered with 5.0 mol L^{-1} KOH. X-ray diffraction was used to identify the crystalline phases in precipitates, using Co Ka (λ = 0.1789 nm), from 4 to 70° 2θ at 1º s^{-1} rate. For lower REE concentrations, the most common mineral precipitated was magnetite in the absence of Al. As REE concentration increased, goethite became more common, excepted treatments with higher Al concentrations where gibbsite was also present. REE concentrations influenced the mineralogical phases irrespective to Fe:Al molar ratios. High REE concentrations favoured lepidocrocite precipitation in detriment of magnetite. La and Ce studies presented lanthanite and cerianite, respectively, as segregated phases. On the other hand, for Nd, Eu and Ho such segregated phases were not noticed, suggesting that the decrease in the atomic radii of such elements favours their association to Fe/Al (hydr)oxides structures.

(6214 - 1062) Feasibility of the Bio-sulfur for Soil Remedial Amendment

Hyuck Soo Kim[1]; Jong Geon Lee[1]; Sang Phil Lee[1]; Seung Min Oh[1]; Seok Soon Jeong[1]; Jae E. Yang[1]
Kangwon National University[1]

‘Bio-sulfur (Bio-S)’ is defined as the solid phase byproduct generated in the chemical and biological desulfurization processes of landfill gas. Approximately 5,000 tons of Bio-S have been generated annually in the Seoul Metropolitan landfill site, Korea and it is expected to increase in the future. This necessitates the recycle of the Bio-S as the environmentally acceptable ways. The Bio-S has high pH and EC values with the S-containing functional groups which have a high affinity for metal ions. This research assesses the feasibility of the Bio-S for treatments of metals in water and soil. Experiments of batch, soil treatment and bioassay were conducted to evaluate the efficiency of the Bio-S in complexing or immobilizaing metals in aqueous solution and soil on which to base the criteria for the remedial agents to be used in the contaminated water and soil. The efficiency of the Bio-S was comparatively assessed with that of the activated carbon in the batch experiments. Results showed that the removal efficiencies of the Bio-S for Cd (25 mg L^{-1}) and Pb (300 mg L^{-1}) removal were 73% and 56%, respectively, after 360 min in the aqueous batch reaction. The respective efficiencies of the activated carbon were 26% and 17%. The SEM-EDS and XPS data reveal that the main mechanism was the complexation of metals with S-containing functional groups in Bio-S. Kinetics of such complexation were very fast to stabilize within 5 to 10 min ranges depending upon the kind of metals. When the Bio-S was treated in the metal contaminated soil, the bioavailable fractions of metals were decreased but those of unavailable fractions were increased, indicating a possible immobilization of metals in the soil. The 0.1 M HCl extractable Cd and Pb concentrations in 5% (w/w) Bio-S applied soil were 11% and 8%, respectively, lower than those of the control soil after 48 hours incubation. In bioassay, treatments of the Bio-S (2 and 5%, w/w) to the metal contaminated soil could not germinate the young radish seed (*Raphanus sativus* L.) possibly due to a high NaOH in the Bio-S inherent from the desulfurization process of the landfill gas. However, the Bio-S washed with the distilled water showed 76% seed germination rates at 5% treatment after 10 days while the germination of young radish seed in control soil was 40%. Consequently, it was concluded that the Bio-S could be used as a remediation material for the removal of Cd and Pb from water and soils.

(6388 - 2665) Fractionation of aluminium in acidified soils

Peter Matúš[1]; Jana Kubová[1]; Marek Bujdoš[1]; Ján Medveď[1]; Martin Šebesta[1]; Filip Polák[1]; Michaela Matulová[1]; Bence Farkas[1]
SSS, member of the Association of Slovak Scientific and Technological Societies; Comenius University in Bratislava, Faculty of Natural Sciences, Institute of Laboratory Research on Geomaterials, Ilkovičova 6, 842 15 Bratislava, Slovakia[1]

Aluminium occurs in various chemical species, of which free Al^{3+}, $AlOH^{2+}$, and $Al(OH)_2^+$ species were found to be the most crucial to evaluate its toxicity and to predict the impact of proton inputs on soils and surface waters. The concentration of such Al species may be difficult to determine directly. For that reason these species are determined in one or more fractions. Generally, these fractions are defined operationally and according to the method of determination are termed reactive or labile aluminium. An optimised BCR three step sequential extraction procedure (SEP), several single extractions (with water, KCl, NH_4Cl, $CaCl_2$, $BaCl_2$, $LaCl_3$, NH_4F, NTA, EDTA, DTPA, $(NH_4)_2C_2O_4$, HCl solutions) and the reactive aluminium (Alr) determination in water extracts after solid phase extraction by chelating ion-exchanger Iontosorb Salicyl (cellulose resin containing covalently bound salicylic acid functional groups) were used for the fractionation of Al in ten acid soil samples (1-10, pH~1.8-3.6) from a mining area with sulphidic deposits (Šobov, central Slovakia). The precision, accuracy and repeatibility for all steps of the optimized BCR sequential extraction procedure were checked on various reference materials (CRM BCR 483 freshwater sediment, SRM 2710 and 2711 Montana soils). The aluminium amounts released by used extraction procedures were valuated and discussed from aspect of Al contents in plants (grass) growing on five acidified soils (A-E, pH~2.8-5.1) from the same locality. The calculation of the aluminium toxicity indexes (ATI) and determination of reactive aluminium in soil extracts were used for assessment of Al toxicity to plants. The ATI is defined as the ratio of nutrient cations (Ca, Mg, K, Na) sum to Al concentration. It can be concluded, that acid extractable Al fraction is most Alr selective from optimised BCR three-step SEP. The dilute HCl extraction can be the alternative for routine monitoring of Al mobility instead of optimised BCR three-step SEP when the phase associations estimation is not necessary. Some simple salt extractants, mainly $CaCl_2$ seem to be suitable for the estimation of labile and reactive Al species in acid soils and they can be a rapid tool in some applications of Al fractionation. The determination of Alr (samples 1-10, A-E) and calculation of ATI data (samples A-E) are most useful simple tools for the estimation of Al availability and toxicity to plants.

(9562 - 875) Heavy metals contents in agricultural and forest fragment soils of the city of Nova Friburgo, RJ

Diogo Muniz Alexandre[1]; Daniele Rodrigues Barbosa[1]; Erica Souto Abreu Lima[1]; Nelson Moura Brasil do Amaral Sobrinho[1]
Universidade Federal Rural do Rio de Janeiro[1]

The heavy metals occur naturally in soils, and their contents depend on the soil parent material on which the soil formed and on formation processes. However, in search of an increase in agricultural productivity, with the indiscriminate use of agrochemicals and improper land management, the processes of soil physical and chemical degradation are favored, resulting in serious impacts to the environment. Therefore, the purpose of this study is to evaluate the levels of Cd, Ni and Pb in agricultural and native forest soils of Nova Friburgo, RJ, and thereby verify which factors are responsible for increasing these elements in the environment. The study was carried out in family farming properties in Nova Friburgo, RJ. For the determination of heavy metal contents, samples were collected in depth of 0-20 cm and were submitted to the of EPA digestion method 3051A. The resulting extracts were analyzed by atomic absorption spectrometry. It also determined the chemical attributes of the soil, according to Donagemma et al. (2011). Descriptive statistic analysis was performed of the contents of the metals, in addition principal component analysis (PCA). The contents of Cd, Ni e Pb detected in soils with agricultural activity presented wide variation, with maximum values 1.42, 16.89 e 31.78 mg kg^{-1}, minimum values of 0.08, 1.20 e 17.20 mg kg^1, and average of 0.47, 9.10 e 24.25 mg kg^{-1}, respectively. Comparing with the levels obtained in areas of forest fragment (0.001, 0.54 e 7.31 mg kg^1), there were a very high increase of the analyzed elements. Pointing out the anthropogenic contribution, mainly through the indiscriminate use of fertilizers, it presents high levels of metals in their composition (Amaral sobrinho et al.,1992). When compared to the guiding values established by CONAMA (2009), it is observed that in only one property the value of Cd was higher than the PV (Prevention Value) (1.3 mg kg^{-1}). However, the values found are above the QRVs (Quality Reference Value) proposed by (Matos, 2016) for the region, that for the G3 are of 0.04, 8 e 27 mg kg^1. Through the PCA it was verified a close relationship between the contents of metals and of P and K, ratifying what was previously discussed. The obtained results allow to conclude that there was an increase of metals analyzed in the areas with agricultural activity compared to the areas of forest fragment, which was possibly caused by an anthropogenic activity in the region.

(3952 - 1481) Heavy metals in floodplains affected by collapse of the Samarco's dam: a comparison between mine waste and non-affected soils.

Rafael Biscotto Davila[1]; Mauricio Paulo Ferreira Fontes[1]; Anderson Almeida Pacheco[1]; Raphael Bragança Alves Fernandes[1]; Matheus da Silva Ferreira[1]
Federal University of Viçosa[1]

At the end of 2015, a dam of the Samarco mining company collapsed, releasing about 40 million m^3 of iron ore tailings into Doce river basin, Minas Gerais State, southeastern Brazil. The first area hit by the mud, between the district of Bento Rodrigues and the Candonga dam had the most affected flood plains, comprising 15 km^2 of soil covered along the rivers Gualaxo do Norte, Carmo and Doce. Two years after the incident, there is still a concern about heavy metal contamination by the deposited material. The aim in this study was to analyze the concentration of the heavy metals As, Ba, Co, Cr, Cu, Ni, Pb, V and Zn in the tailings deposited on floodplains and to compare with uncontaminated river sediments of the same area. Thus, mine waste on floodplains and sediment from non-affected areas were collected from 38 sites along the Gualaxo do Norte and Carmo river until Candonga dam. These were digested according to EPA 3051A method and the heavy metals content were further determined by ICP-OES. The mean values obtained for the mine waste and sediments from non-affected areas were, respectively: As (5.2 and 37), Ba (37.5 and 119.5), Co (3.6 and 12.9), Cr (19.5 and 52.4), Cu (7.9 and 25.7); Ni (5.3 and 21.3); Pb (10 and 12.3); V (17.7 and 51.8), Zn (22.8 and 33.9) mg kg^{-1}. For all elements analyzed, the concentration of sediments from non-affected areas were higher than for the mine waste. The heavy metals content from mine waste were compared with the regulatory guidelines for soils according to the quality reference values established for the Minas Gerais state (Brazilian environmental laws).

The result showed that only one sample had Ba and Co levels higher than the limit (1.3 and 1.2 times higher, respectively) and three samples presented higher levels of As (up to 6 times higher). For the sediments from non-affected areas, all samples showed Co and As levels higher than the guidelines, up to 5.6 and 13.8 times higher, respectively. Three samples showed high values of Ni and Ba (up to 1.8 and 4.2 times higher) and one sample had Cr and Cu levels higher than the guidelines (1.2 and 1.3 times). Therefore, we conclude that although the disaster has caused serious social and environmental damage, there is strong evidence that the released mine waste poses no risk of contaminating the environment with heavy metals. It is important to highlight the need to control potential sources of contamination that have been present in this area for some decades.

(3566 - 2272) High copper and zinc doses in acid soil changes the physiological state in young grapevines (*Vitis vinifera*)

Tadeu Luis Tiecher[1]; Hilda Hildebrand Soriani[2]; Lessandro De Conti[2]; Paulo Ademar Avelar Ferreira[2]; Isley Cristiellem Bicalho da Silva[2]; Edicarla Trentin[2]; Letícia Morsch[2]; Daniela Facco[2]; Adriele Tassinari[2]; Gustavo Brunetto[2]
Federal Institute Farroupilha[1]; Federal University of Santa Maria[2]

The Campanha Gaúcha is one of the main wine regions of Brazil that suffers from climatic factors favorable to the development of fungal diseases on the leafs of the grapevine (*Vitisvinifera*). Generally, the control of these diseases is carried out with successive applications of copper-based (Cu) fungicides, such as the Bordeaux mixture, which generates Cu accumulation in the soil up to toxic levels for the vines. In the vineyards of the Campanha Gaúcha, the Cu toxicity to plants is observed at relatively low Cu-levels in the soil, compared to other wine growing regions of the world, due to the characteristics of the soils from this region, that are generally sandy, acidic and have low soil organic matter (SOM) content. In order to reduce the amount of Cu applied in the vineyards, Zn-based fungicides have been used as an alternative to replace the Bordeaux mixture that have zinc (Zn) in its formulation. As the number of fungicide applications is still high, a quick increase in soil Zn content has been observed in vineyard soils that already have a high Cu content. The objective of the study was to assess the effects of high Cu and Zn contents in a sandy acid soil on the physiological state in young grapevines. We collected a Typic Hapludalf soil, with 5.4% of clay and 0.9% of SOM, of a natural field of Rio Grande do Sul, the southernmost state of Brazil. Soil treatments were addition of 0, 30, and 60 mg Cu kg^{-1}, and addition of 0, 15, 30, 60, 120, and 180 mg Zn kg^{-1} for each copper dose. The study was carried out in pots containing 4.0 kg of soil, and a seedling of grapevine per pot was grown for 60 days. After that, we measured root and shoot dry matter, Cu and Zn content in roots and shoots, chlorophyll *a* fluorescence, photosynthetic pigments, and peroxidase and superoxide dismutase activity. Young grapevines showed high Cu and Zn concentrations in the roots, decreasing translocation to the shoots. However, at the highest doses of Cu and Zn, we observed decrease in plant growth and in photochemical efficiency associated with the decrease in photosynthetic pigment content. Furthermore, the activity of antioxidant enzymes increased in intermediate doses of Zn, which indicates activation of the antioxidant system. However, the stress condition in treatments with high levels of Cu and Zn was not reversed.

(4168 - 501) Immobilization of agricultural phosphorus in Midwestern floodplain soils in the U.S.

Yuji Arai[1]; Mary R. Arenberg[1]
University of Illinois at Urbana-Champaign[1]

Nutrient losses from the Mississippi watershed are exacerbating the growth of the hypoxic zone in the Gulf of Mexico. Located within the highly agricultural Piatt County, IL, Allerton Park encompasses a riparian forest that receives an influx of phosphorus (P) via surface runoff and leaching during spring flooding. The objective of this study is to investigate the ability of the forest soil to buffer agricultural P losses through immobilization using experimental biogeochemistry, ^{31}P-nuclear magnetic resonance (^{31}P-NMR) spectroscopy and P K-edge XANES analysis. If P is effectively sequestered, it may also lead to improved tree growth in woody biomass. To analyze the system's response to flooding, samples were collected within the bottomland and surrounding upland of the forest in April. Organic P, microbial P, phosphatase activity, and total P were quantified to assess P mineralization-immobilization dynamics. First, total P ranged from 338 to 819 mg kg^{-1}, averaging at 580 mg kg^{-1}, in the bottomland and from 113 to 370 mg kg^{-1}, averaging at 245 mg kg^{-1}, in the upland. Next, organic P spanned from 90 to 457 mg kg^{-1}in the bottomland, comprising an average of 45% of total P, and ranged from 42 to 191 mg kg^{-1}in the upland, comprising an average of 36% of total P. Furthermore, microbial P averaged 5.23 µg g^{-1} in the bottomland and 2.75 µg g^{-1} in the upland. Finally, acidic phosphatase activity averaged 13 µmol PNP/g·hr in the bottomland and 11 µmol PNP/g·hr in the upland while alkaline phosphatase activity averaged 24 µmol PNP/g·hr in the bottomland and 8 µmol PNP/g·hr in the upland. Greater concentrations of total P, organic P, and microbial P in the bottomland compared to the upland suggest that the floodplain immobilizes agricultural P. This observation is further evidenced by a higher organic P percentage in the bottomland. Nevertheless, greater alkaline phosphatase activity was observed in the bottomland than upland, which needs to be further researched but may be explained by the influx of nitrogen fertilizer in the floodplain. Overall, greater P immobilization in the bottomland indicates the floodplain's capacity to buffer agricultural P in the early spring.

(8596 - 2833) Impact of soil sterilization on mercury contents in a Latosol grown with common beans

Francielle Roberta Dias de Lima[1]; Aline Oliveira Silva[1]; Isabela Cristina Filardi Vasques[1]; Mateus Moreira Engelhardt[1]; Gabriel Caixeta Martins[1]; Rayner Hugo Cassa Louzada dos Reis[1]; Jakeline Rosa Oliveira[1]; Ediu Carlos da Silva Júnior[1]; Luiz Roberto Guimarães Guilherme[1]; João José Granate de Sá e Melo Marques[1]
Universidade Federal de Lavras[1]

Mercury is a potentially toxic trace element. Its soil availability depends largely on its chemical specie, which is a function of soil attributes such as cation exchange capacity (CEC), pH, redox potential and microbial activity. The objective of the present study was to investigate the effect of soil sterilization on Hg retention when cultivated *Phaseolus vulgaris* (common beans). The experiment was carried out in a greenhouse with a typical Dystrophic Red-Yellow Latosol (LVAd): pH (H_2O) = 4.9; T = 6.1 $cmol/dm^3$; and OM = 21 g/kg; And a typical clayey Dystroferric Red Latosol (LVdf), pH (H_2O) = 4.4; T = 11.7 $cmol/dm^3$; and OM = 40 g/kg, where common beans were sown. Three kilograms of both soils were sterilizated and, posteriorly

kept at rest for 21 days, with daily stirring. It is expected that sterilizating may have deeply impacted de soil biota, which plays a major role in Hg chemistry. Afterwards, two experiments were carried out in pots with 500 cm^3 of soil that received application of $HgCl_2$ at concentrations 0 and 80 mg of Hg per kg of dry soil, for 21 days. The treatments were natural soil (NS) at concentrations 0 and 80 mg/kg and sterilizated, sterile soil (SS) at concentrations 0 and 80 mg/kg, for each soil class. We had four treatments and three replicates in a completely randomized design. The Hg content was determined using the USEPA 3051A method with atomic absorption spectrophotometer with hydride generation using the certified reference material NIST SRM 2710a - Montana Soil and blanks as quality controls. The method detection limit (MDL) was 0.14 mg/kg. The recovery rate of the CRM was 70.4 %. Data were submitted to variance analysis ($p < 0.05$) and Tukey test ($p < 0.05$). Mercury in the treatments without addition of Hg, i.e. native Hg, was below the MDL. For the treatments where Hg was applied, the mean values of Hg were 19.3 and 1.7 mg/kg for LVAd and LVdf, respectively and for SS were 33.8 and 22.8 mg/kg for LVAd and LVdf, respectively. The portion of the Hg lost in unsterilized soil was 28.8 μ kg^{-1} h^{-1} and 41.9 μ kg^{-1} h^{-1} for LVAd and LVdf, respectively. The high levels of Hg in SS can be attributed to the soil microbiota removal, since it participates in the transformations of the biogeochemical cycle of Hg, reducing Hg^{2+} to Hg^0, which is volatile at room temperature. The reduction of the microbial community through the soil sterilization process directly affects the Hg levels in the soil.

(4759 - 1132) Influence of Aluminum and Arsenic in Fe and Al (hydr)oxides mineralogy

Isabela Cristina Filardi Vasques[1]; Renato Welmer Veloso[2]; Vanessa de Paula Ferreira[3]; Jaime Wilson Vargas de Mello[4]
UFLA[1]; IFRO[2]; UFV[3]; UFV, INCTacqua[4]

Studies on co-precipitation and adsorption of As onto Fe and Al (hydr)oxides are of major environmental interest, considering their abundance in oxisoils. This study addressed the co-precipitation of Fe and Al (hydr)oxides in the presence of arsenate and arsenite at different Fe:Al molar ratios. High concentrations of soluble of As were considered in order to simulate highly contaminated environments. Some adaptations were considered in order to simulate the treatment of acid mine drainage contaminated with As. Sulfates salts were used as source of Fe (II), Fe (III) and Al at three Fe:Al molar ratios: 100:0, 80:20 and 60:40. Suitable amounts of these salts were added to vessels with different solutions containing As (V) and (III) and then, the pH was buffered to induce (hydr)oxides precipitation. Mineralogical phases in precipitates were identified by X-ray diffraction and by Scanning Electron Microscopy Coupled to Energy Dispersive X-ray Spectroscopy (SEM/EDS). At the absence of Al, maghemite and magnetite were identified in Fe (II) treatments, but only at 50 mg L^{-1} of As. At higher As concentrations (500 mg L^{-1}), lepidocrocite and goethite were identified in the absence of Al, as well as at the 80:20 Fe:Al molar ratio. Isomorphic substitution in these Fe (hydr)oxides is also considered as widely reported in the literature. The Al segregation as gibbsite was only detected at 60:40 Fe:Al molar ratio. In Fe (III) treatments, hematite was only identified in absence of Al and at 50 mg L^{-1} of As. In the presence of Al and high As, ferrihydrite and gibbsite were identified by XRD. It can be considered that higher concentrations of Al and As slow down phase transformation. It is worth of note the characteristic peak of hematite even better defined in the presence of 50 mg L^{-1} than in absence of As. The SEM analyses showed that As is evenly associated to Fe (hydr)oxides. However, at higher concentration of As there is no oxygen or aluminum associated to Fe and As in some particles. This suggests the formation of compounds such as ferric arsenate not detected by X Ray. The presence of aluminum and arsenic arise considerable influence in Fe and Al (hydr)oxides mineralogy. It is suggested that phase transformation of ferrihydrite to hematite is delayed by the presence of tese elements. In general As precipitates evenly associated to Al and Fe (hydr)oxides, but at a 20:1 (Fe+Al):As molar ratio it segregates as ferric arsenate.

(5163 - 475) Influence of mercury concentrations on ph in tropical soils of different textures

Jakeline R. de Oliveira[1]; Geila S. Carvalho[1]; Jade G. Alacoque[1]; João José Marques[1]
Universidade Federal de Lavras[1]

Soil pH determines mercury speciation and, in the long run, its accumulation in the soil. The aim of this work was to study changes in the pH of tropical soils contaminated with $HgCl_2$. The experimental design was completely randomized in a factorial scheme 6 x 5, corresponding to four mineral soil textural classes (sand, loam, clay, heavy clay), an organic soil, and pure zeolite at five equilibrium solutions (1:10) with 0, 0.1, 0.4, 1.2, and 2.4 mg/L of Hg, as $HgCl_2$, with three replicates. The soils were collected in areas with no anthropogenic action and were then dried and passed through a 2 mm sieve. For the experiment, 1.5 g of soil were weighed and placed in plastic tubes; 15 mL of 15 mmol/L NaCl solution were added along with the concentrations of Hg. The samples were vigorously shaken with a glass rod for 1 min. and remained standing for one hour. The pH readings were performed on the supernatant. Data were submitted to analysis of variance and the comparison of means by the Skott-Knott test. There was a significant interaction between soils and Hg concentrations for soil pH. It was observed that, at the zero concentration of of Hg, the soil with the lowest pH (4.6) was the organic soil; and the zeolite showed the highest pH (8.8). The same pattern was kept until the concentration of 0.4 mg/L Hg. At the concentration of 1.2 mg/L of Hg, the lowest pH value (4.5) was obtained in the sandy soil. The increase of the Hg concentration in the solution up to 2.4 mg/L altered the soil pH values; the sandy and the organic soil had the lowest values, 4.7 and 4.6, respectively. Concentrations of Hg in the equilibrium solution above 0.4 mg/L altered the pH values of soils regardless of their textural class. The results suggest a possible specific sorption mechanism for Hg adsorption in these soils.

(7443 - 2204) Inorganic and organic phosphorus in sediments in the Walnut Creek watershed of central Iowa, USA

Suroso Rahutomo[1]; John L. Kovar[2]; Michael L. Thompson[3]
Indonesian Oil Palm Research Institute[1]; USDA Agricultural Research Service[2]; Iowa State University[3]

The dynamics of phosphorus (P) reactions in stream water are important because of their potential to trigger eutrophication. This study aimed to explore the nature of P in sediments associated with Walnut Creek in central Iowa, USA. The Walnut Creek watershed supports row crop production, grazing, and riparian buffer zones. The alluvial cross section is composed of a sequence of sediments that contribute differentially to the amounts and forms of P entering the stream. Twenty-five sediment samples collected near Walnut Creek (classified as bank, in-stream, and floodplain deposits) were sequentially extracted for P. Across all 25 samples, the inorganic P (*Pi*)

fractions followed the order: Fe-bound *Pi* > Ca-bound *Pi* > reductant-soluble *Pi* > Al-bound *Pi* > soluble and loosely bound *Pi*. For the organic (*Po*) fractions, the order was nonlabile *Po* > fulvic acid-bound *Po* > humic acid-bound *Po* > labile *Po* > moderately labile *Po*. The ranges of total P (TP), Mehlich-3-extractable P ($P\text{-}M_3$), and ammonium oxalate-extractable P (P_{ox}) were 386 to 1,134, 5 to 85, and 60 to 823 mg kg^{-1}, respectively. Among the sample groups, the highest concentrations of TP, $P\text{-}M_3$, and P_{ox} were in the in-stream deposits. Total P was significantly correlated with Fe oxides, clay, and soil organic matter, especially in the bank and floodplain deposits. Because of the potential release of P from these sediments, we can speculate that changes in land use within the riparian areas may, at least initially, have little direct effect on soluble or particulate P concentrations in Walnut Creek. Still, if P inputs from eroded bank sediments are reduced, whether by riparian management, stream bank stabilization, or some other practice, it is likely that P loads in Walnut Creek can be gradually reduced as well.

(9531 - 1200) Ions mobility in oxisol cultived with maize irrigated with swine wastewater treated in anaerobic biodigester

Sarah Mello Leite Moretti[1]; Edna Ivani Bertoncini[2]; Cassio Hamilton Abreu-Junior[1]

University of São Paulo, Center for Nuclear Energy in Agriculture[1]; São Paulo's Agency for Agribusiness Technology, Secretariat of Agriculture and Food Supply of São Paulo[2]

The daily volume of liquid swine manure generated from the pig stalls cleaning is high and its agricultural use can represent important source of nutrients and water. However, this waste presents high organic load, heavy metals presence and ions that can be accumulated in soil and leached. This study aimed evaluate ions contents in soil solution amended with swine wastewater (SWB), 1:50 (v/v) diluted swine wastewater (SWBD) and the conventional management. The field experiment was conducted in clayey Oxisol, using an experimental design in completely randomized blocks with three replications. Winter and summer maize crops were cultivated, evaluating the following treatments: T1-control; T2-mineral fertilization without irrigation, T3-irrigation with SWB, T4-irrigation with SWBD, T5-mineral fertilization and irrigation with water. Maize irrigation was performed considering the crop water requirement and soil matric potential measured by tensiometers installed in each plot. After each harvest, it was evaluated ions mobility by saturation paste method in two soil depths (0-0.20 m and 0.20-0.40 m). The SWB use increased K^+, Na^+ Ca^{+2}, $N\text{-}NO_3^-$ and $N\text{-}NH_4^+$ contents in both soil depths, after winter and summer maize cultivation, when compared to others treatments, except to Na^+ contents that in summer conditions was equal to T4 and T5 treatments. Also, in summer it was observed that the $N\text{-}NO_3^-$ content in subsurface was higher than surface irrigated with SWB, indicating for both ions their leaching. It is emphasized that NO_3^- contents in soil solution of all treatments were higher than limits established for groundwater by São Paulo State legislation, which is equal to 10 mg L^{-1}. After two maize cultivation irrigated with 250 mm of treated swine wastewater, it was observed that SWB can supply some nutrients for plants, however, these ions leaching could represent groundwater contaminations risks. Thus, agricultural use criteria should be established, mainly, considering possible leaching of K^+, Na^+, $N\text{-}NH_4^+$ e $N\text{-}NO_3^-$ when swine wastes are used in agricultural soils.

(1174 - 2463) Kinetics and Adsorption parameters related to Ciprofloxacin adsorption on a volcanic ash derived soil: Effect of organic matter

Cristian Urdiales[1]; Mauricio Varas[1]; Jonathan Suazo[2]; Carmen Pizarro[3]; Mauricio Escudey[3]

Pontificia Universidad Católica de Chile[1]; Universidad de la Frontera[2]; Universidad de Santiago de Chile[3]

To fight diseases and improve animal growth, fluoroquinolones family antibiotics are prescribed for veterinary use and administered through the feed. Antibiotics are not fully metabolized in the gastrointestinal tract, being the soil one of their final destination through manure amendments. Volcanic ash derived soils present a high organic matter (OM) content which may play a significant role in the soil-antibiotic interaction. To establish the importance of (OM) the Ciprofloxacin (CIP) adsorption on Santa Barbara soil (SB, Andisol) with and without OM was studied. The OM was removed with hydrogen peroxide (30% v/v); the treatment efficiency was established by following the variation of the isoelectric point (IEP) of sample determined from electrophoretic mobility studies carried out in a Zeta Meter 4.0 equipment using 10-20 mg of sample suspended in 200 mL of 10^{-3}M KNO_3 solution. Adsorption kinetics study was performed by determining Ciprofloxacin concentration in KNO_3 solutions, after suspending 500 mg of soil sample in 10 mL of a $5.0x10^{-1}$ mmol L^{-1} Ciprofloxacin solution, using batch assays, ranging from 5 to 120 min. The Ciprofloxacin equilibrium concentration (Ce) was determined by square wave voltammetry, through Potential (E) vs Current (I) measurements, using a Ce x Ip (current pick) calibration curve. Different kinetic models were applied to the experimental data, the pseudo-second-order model best fits the experimental results being the calculated C*m* value close to that experimentally obtained. The IEP was used to establish the equilibrium concentration range where CIP adsorption proceeds through the formation of mono or multilayers. The Langmuir-Freundlich model fits the adsorption isotherms data better than Langmuir and Freundlich models do. The CIP adsorption in SB is higher than in SB without organic matter showing the importance of Ciprofloxacin interaction with carboxyl, phenyl, o-alkyl OM functional groups during the adsorption process, evidencing the role of OM not only in the soil-antibiotic interaction but also the OM importance in the transport in depth of Ci in volcanic soils.

Keywords: Ciprofloxacin, adsorption, isotherms

(8638 - 352) Land use effect on stream water quality, an case study in an agricultural watershed of Central Hokkaido, Japan.

Ryusuke Hatano[1]; Mako Abe[1]; Kanta Kuramochi[1]

Hokkaido University[1]

Nutrient management in agricultural field and land use proportion are main factors to keep water quality. Silicon (Si) is important element for diatoms feeding fishes. Unbalance between Si and nitrogen (N) or phosphorus (P) induces eutrophication, and the molar ratios of Si/N less than 2.7 and Si/P less than 54.3 in water are critical level for diatoms growth. Organic soil is low in Si supply. Land use should be considered soil characteristics. Purpose of this research was to clarify the influence of land use and soil type on stream water quality. Ishikari

river watershed is the second largest in Japan and the largest in Hokkaido (14,330km^2 in area and 268km in length). Climate is semi boreal with deep snow in winter (November to April), mean annual precipitation is 1,126 mm and mean annual temperature is 8.9ºC. Land use is composed of forests (63%) , arable lands (31%), and urban area (3%). Soil type is composed of forest soils (68%) in hilly and mountain sides, and lowland soils (23%) and peat soils (5%) along the stream. Water sampling was carried out at 20 points from upstream to downstream of the main stream of Ishikari river at three times in 2016, on May 18 to 20 (seeding period after snow melting season), August 10 to 12 (crop growing season), and November 9 to 11 (winter season), and water quality was analyzed. In May and August, stream nutrient loads were positively correlated with proportions of paddy field and upland field, and negatively correlated with forest proportion, but not significantly correlated with urban proportion. In November, there was no significant correlation between land use proportions and the stream loads. Stream loads of SS, TP, TN and TOC were significantly increased to downstream in May than in August and November, due to surface runoff with snowmelt as well as agricultural activities. In August, stream loads of NO_3^-, NO_2^-, SO_4^{2-}, HCO_3^-, Ca^{2+}, Mg^{2+} and SiO_2 significantly increased with upland proportion. Molar ratios of Si/N and Si/P less than threshold of eutrophication (2.7 and 54.3, respectively) were found from middle stream in May and from upper stream in May and August, respectively. This may be ascribed by the peat soils distributed along the stream from the middle stream to downstream, which have a low Si supply power and a high N and P release with peat decomposition. Reducing fertilizer application, drainage and tillage in peat land is important to conserve the water quality in global warming.

(1725 - 2003) Leaching of hexazinone + diuron in different Brazilian cerrado soils

Kerwin Araujo Costa[1]; Rafael Ramos Bertuani[1]; Larissa Pinto Seiberti[1]; Douglas Gomes Viana[1]; Amanda Duim Ferreira[1]; Kamila Cabral Mielke[1]; Fábio Ribeiro Pires[1]; João Carlos Madalão[1]; Paulo Henrique Ramos Cabral[2]; Adriano Jakelaitis[2]
Universidade Federal do Espirito Santo[1]; Instituto Federal Goiano - Campus Rio Verde[2]

The expansion of agribusiness in Brazil has boosted the use of agrochemicals, but when applied improperly, such compounds represent a high risk of environmental contamination. The herbicide movement and its interaction in the sorption and desorption processes are still poorly understood in Brazilian soil and climate conditions. Therefore, it was evaluated the leaching of the hexazinone + diuron herbicide in soils of the sugarcane region of southwestern Goiás. Samples of five soils collected at depths of 0.0 to 0.2 m were used. Soil A was collected in an area with conventional cultivation history, soils B, C and D with no till system and soil E collected in a native forest. The soils were packed in polyvinyl chloride columns 0.5 m long, then the 700 g ha^{-1} dose of the active ingredient hexazinone + diuron was applied to the top of the columns. Twelve hours after application of the herbicide, a single 60 mm rain slide was simulated. After this step, the columns remained in the upright position for 72 hours. For the confirmation of herbicide leaching in each treatment, soil samples were collected at depths of 0.0 – 0.5 - 0.1 - 0.15- 0.2 – 0.25 – 0.3 – 0.35 – 0.4 – 0.45 – 0.5 m. Each fraction was placed in a pot, where the bioindicator Cucumis sativus was planted. At 21 days after emergence, phytotoxicity scores were given, and the dry matter of the aerial part of the bioindicator was quantified. Data from the biological analyzes related to herbicide leaching were submitted to analysis of variance and regression. Soil A is characterized by low clay content, Cation Exchange Capacity and Organic Matter (OM), due to this fact, hexazinone + diuron leached OMre in this soil. In soil B the herbicide was detected up to the depth of 0.2 m, however, at this depth the phytotoxicity symptoms in the bioindicator plants were lower, and also the dry matter of the bioindicator was higher in those depths, compared to the soil A. The hexazinone + diuron leached less in soil C, being detected in the depths of 0.0 – 0.5 m ; 0.5 - 0.1 m. In soil D, the leaching was high despite the good contents of OM and Cation Exchange Capacity, possibly due to the high pH value. In the soil E the hexazinone + diuron leached to the depth of 0.15 m, that is to say, in this soil the leaching was intermediate between the other soils.

Keywords: Herbicide, phytotoxicity, bioassay

(4979 - 2564) Lead accumulation in different plant species cultivated in a contaminated soil

Letícia Cristina Freitas Silva[1]; Helen Carla Santana Amorim[1]; Felipe Zablith[1]; Maurício Paulo Ferreira Fontes[1]; Ivo Ribeiro da Silva[1]; Leonardus Vergutz[1]
UFV[1]

Lead (Pb) pollution is one of the most concerning problems to environmental and human health in developing countries. The irregular disposal of lead mining and smelting residues heavily increases Pb concentration in soils, damaging agricultural activities and limiting the land use. Cultivating fast-growing and accumulator plant species in contaminated sites is an alternative to reduce Pb levels in soils and mitigate its impacts in the environment. Therefore, the main objective of this study is to assess the Pb accumulation in different plant species cultivated in a highly contaminated site by lead smelter particulate material. Soil samples (0-5 cm and 5-15 cm) from a Typic Hapludert were collected near to an inactive lead smelter in Santo Amaro, Bahia, Brazil. The soil samples were physically, chemically and mineralogically characterized, and used in a glasshouse experiment. The current work is part of a bigger Pb bioavailability experiment; it was mounted in a randomized block design, in a factorial scheme (2x(1+3)) corresponding to the two soil depths, three plant species (*Eucalyptus urograndis*, *Brachiaria brizantha* cv. Marandu or *Brassica juncea* L.), and a control treatment without plant. Six repetitions of each treatment were assembled. Each plastic pot was filled with 2.5 kg of soil, received seeds or seedling of each plant specie, and basic phosphorus fertilization (300 mg dm^{-3} of P). After 14 weeks, the experiment was unmounted; soil samples had their total Pb content determined through microwave digestion (USEPA 3052), roots and shoots were harvested, washed, dried at 65°C for 48 hours, weighed, and had the dry matter recorded. The dried plant material was submitted to acid digestion (5 ml of HNO_3 + 2 ml of H_2O_2) to determine the total Pb content. Differences in total Pb content in plant material were tested using ANOVA followed by Tukey ($p<0.05$). Pb content in the 0-5 cm soil depth is 2122 ppm, and 1313 ppm for the 5-15 cm depth. Pb is mostly accumulated in the roots of the three plant species for both soil depths. *Brassica juncea* is the plant specie that most accumulates Pb in roots despite of the total Pb content in soil (41 mg kg^{-1} and 38 mg kg^{-1} of dry matter for the 0-5 and 5-15 cm depths, respectively) and in the shoot for the 5-15 cm soil depth (7.78 mg kg^{-1} of dry matter). Due to its high potential to accumulate Pb, *Brassica juncea* may be used in remediation of Pb contaminated soils.

(2780 - 2139) Lead fractions in a contaminated soil cultivated with different plant species

Helen Carla Santana Amorim[1]; Felipe Zablith[1]; Mauricio Paulo Ferreira Fontes[1]; Ivo Ribeiro da Silva[1]; Leonardus Vergutz[1]
Universidade Federal de Viçosa[1]

Poorly regulated lead (Pb) mining and smelting operations have led to an increased contamination of soil and water in the last decades. Although roughly immobile in soils, Pb may become soluble due to acidification processes occurred in the rhizosphere of the plants, enter in the food web via plant uptake, and damage environmental and human health. By assessing Pb forms in soils under bulk and rhizosphere conditions is possible to predict the fate of the contaminant in the environment. The main goal of this study is to assess the Pb fractions in a soil contaminated by lead smelter particulate material, under bulk and rhizosphere conditions. The current work is part of a bigger Pb bioavailability experiment; soil samples (0-5 cm and 5-15 cm) from a Typic Hapludert were collected near to an inactive lead smelter in Santo Amaro, Bahia, Brazil. The soil samples were physically, chemically and mineralogically characterized, and had the Pb fractions determined by a modified BCR sequential extraction procedure (SEP). Four fractions were obtained in this procedure: F1 (water soluble, exchangeable and bound to carbonates), F2 (bound to amorphous Fe- and Mn- (hydr)oxides), F3 (bound to organic matter), and F4 (residual, bound to Fe- and Al-(hydr)oxides). A pot experiment was mounted in a randomized block design, in a factorial scheme 2x(1+3) corresponding to the two soil depths, three plant species (*Eucalyptus urograndis*, *Brachiaria brizantha* cv. Marandu or *Brassica juncea* L.), a control treatment without plant, and six repetitions. Each pot was filled with 2.5 kg of soil, received seeds or seedling of each plant species, and 300 mg dm^{-3} of P. After 14 weeks, the experiment was unmounted; rhizosphere soil samples were collected near to the plant species' roots, and a soil sample from the control treatment was considered the bulk soil. Pb fractions were determined in the bulk and rhizosphere soil samples by the BCR procedure. Differences in Pb fractions were tested using ANOVA followed by Tukey ($p<0.05$). In the original and cultivated soil samples, for both soil depths, Pb fractions decreased in the order: F2 > F4 > F3 > F1. In the 0-5 cm soil depth, there is no difference between the Pb fractions in the original, bulk and rhizosphere soils. In the 5-15 cm soil depth, all three rhizosphere soils showed a decrease in the residual fraction compared to the original soil, indicating that the presence of plants and its rhizospheres may alter previous stable Pb forms.

(1524 - 1696) Long-term effect of the application of correctives on soil acidity

Jocelina Paranhos Rosa de Vargas[1]; Danilo Rheinheimer dos Santos[1]; Marília Camotti Bastos[2]; Vanessa dos Santos Dias[1]; Pedro Bolzan Parisi[1]
Universidade Federal de Santa Maria[1]; Université de Lorraine[2]

The main interest of the soils acidity correction is to neutralize the exchangeable Al^{3+}, since the presence of this form of Al in the soil causes restriction of root growth and consequently the decrease of the productivity of sensitive crops. Thus, monitoring the advance of attributes related to soil acidity in depth in cultivated areas is fundamental to assist in the decision of reapplication of acidity corrective forms. The aim of this study was to quantify the chemical changes in the soil caused by lime application calcitic and dolomitic, in a superficial and incorporated form after 141 months of its application. The experiment was installed in 2004 under native field in an Typic Hapludalf. The statistical design was a two-factor type with two types of application forms (incorporated and superficial) three types of correctives (control, calcareous calcitic and dolomitic. In July 2016, soil samples were collected at depths of 0 to 60 cm. In the soil layer of 0 to 10 cm the soil samples were collected every 1 cm, in the layer of 10 to 25 cm the soil samples were collected every 2.5 cm and in the layer of 25 to 60 cm the samples of were collected every 5 cm. The analysis performed were: values of pH in water in the ratio 1: 1, TSM and Ca, Mg and Al exchangeable. From these results the saturation by Al and bases was calculated. The simple deposition of the dolomitic corrective on the surface of the soil, twelve years after the application, allowed changes in the attributes related to soil acidity in the profile, similar to the incorporation. The use of the calcitic corrective provided more significant alterations in the attributes related to soil acidity in the profile compared to the dolomite, following its greater solubility in relation to dolomite. Almost twelve years after the natural acidity correction of the soil following the recommendations of the Soil Chemistry and Fertility Commission -RS / SC (2016), a slight reacidification of the soil of the 0-5 cm layer is observed, whose aluminum saturation is still less than 5% in the first 10 cm. Even almost twelve years after the corrective application, superficial or incorporated, still significant migration of the alkalinizing front in the soil profile to depths greater than 20 cm is perceived.

(2425 - 757) Monitoring of heavy metals content in arable soils and plants in Central Black Earht Regions of Russia

Lukin Sergei[1]
Belgorod State University[1]

In the Russian Federation carrying out the state agro environmental monitoring of agricultural lands is the purpose of agrochemical service subordinated to the Ministry of Agriculture. The objective of our researches consisted in carrying out ecological assessment of content of heavy metals (Cd, Cr, Cu, Ni, Zn) in the agrocenosis of a forest-steppe zone of a south-west part of Central Chernozems areas where the soil generally represented by Luvic Chernozems. Studies were conducted on 20 reperny sites representing the field or the site of the field with 4 to 40 hectares. The main source of most heavy metals entering the agrocenosis are organic fertilizers. For example, the cattle manure moist contains an average of zinc - 18.9, copper -5.7, nickel -2.77, chromium -2.39, cadmium -0.084 mg/kg. In the course of the research it was established that the average gross content in the arable layer (0-20 cm) of leached zinc was 37.1, nickel - 24.9, chromium - 21.0, copper -0.11, cadmium -0.08mg/kg. The average gross content in the arable layer (0-20 cm) of Luvic Chernozems zinc is 37.1, nickel -24.9, chromium -21.0, cadmium - 0.32mg/kg. The average content of mobile forms of zinc was of 0.74, nickel - 0.63, chromium - 0.44, copper -0.11, nickel -0.08 mg/kg. The average content of zinc in beans of soybean was 34.4, copper - 11.7, nickel -5.15, chromium - 0.42, cadmium -0.072mg/kg of absolutely dry matter. The content of zinc, copper, nickel and chromium in the soybean straw was lower than in beans, with values respectively of 6.12, 3.58, 0.70, 0.38 mg/kg. The cadmium content in the straw was of 0.083mg/kg which is higher than in bean. Soy is one of those crops that characterized by high accumulation.

(8417 - 1392) Morphopedologic characterization of landscapes under direct and indirect influence of vulcanic flows and water quality in the hydrographic basin of Ribeirão Areado, alto São Francisco-MG, Brazil

Juberto Babilônia de Sousa[1]; Flavio Rodrigues do Nascimento[2]; Celia Alves de Souza[3]
Instituto Federal de Educação, Ciência e Tecnologia do Estado de Mato

Grosso – IFMT, Campus Cáceres, Brasil[1]; Universidade Federal do Ceará - UFC, Fortaleza, Brasil, departamento de geografia[2]; Universidade do Estado de Mato grosso – UNEMAT, Cáceres, Brasil, departamento de geografia[3]

The objective of this study was to determine in the landscape units developed or influenced by volcanic tuffs, their pedological characteristics and the chemical functioning, in order to interpret the influences on the surface water quality. With the superposition of geological, geomorphological and pedological maps, units of relatively homogeneous landscapes were delimited. Morphological descriptions were carried out and samples of nine soils and rocks profiles were collected for physico-chemical analysis. Fifteen water points were collected to determine their chemical qualities, in the dry and rainy periods. The results showed three morphopedic compartments. The compartment I is represented by the tabular planing surface, rocks of the Areado Group and volcanic tuffs of Mata da Corda Group. Association of Latosol-Yellow Dystrophic (ferric) in relief of flat slopes occurs, Disrupting Tb Disruption Tb Cambisol in relief of well-marked ruptures. The compartment II consists of the dissected surface with a strong degree of rock carving of the Areado Group. The association of Red and Yellow Distrophic Latosol (ferric) and Eutrophic Red-Yellow Argisol in relief of short and smooth undulating slopes, Tb Distrophic Hash Cambisol and Lithographic Distrophic Neosol in relief with more severe ruptures occurs. The compartment III is composed of bottom of valleys embedded with wavy tops and rocks of the Bambuí Group. There is an association of Eutrophic Red-Yellow Argisol in short and smooth undulating slopes, Dystrophic Red-Yellow Latosol (ferric) in slopes of flat and long tops, and Haplotype Tb Dystrophic Cambisol in slopes with pointed tops. The morphological and physico-chemical characteristics of the soils associated to the local climate, relief and geology conditioned different degrees of weathering /pedogenesis of the profiles with influences on the chemical functionality of the morpho-pathological units in sample areas of the basin. The chemical composition of the water showed a different behavior in the two analyzed periods, with a higher concentration of chemical elements during the dry season. Concentrations of the chemical elements in the water were above the values considered normal by the Brazilian legislation, suggesting a possible chemical contamination of the surface waters of the basin, which leads to contamination of the environment and, above all, to a possible public health problem for the residents in the basin.

(3498 - 465) Natural levels of heavy metals in different soil types from Paraná 3 Watershed, Brazil

Juliane Maria Bergamin Bocardi[1]; Sueli Pércio Quinaia[1]; Adelmo Lowe Pletsch[2]; Fábio Luiz Fronza[2]

UNICENTRO - Universidade Estadual do Centro-Oeste[1]; UTFPR - Universidade Tecnológica Federal do Paraná[2]

Natural background concentrations of heavy metals in the soil refer to the levels of these elements in the environment, under natural conditions, on which they depend on pedogenetic processes and degree of soil development. The area of study covered the region located in the west of the Paraná State, the Paraná 3 Watershed (PW3). A total of 73 composed samples were obtained, of surfasse soils from Conservation Area and Forests Remnants of the 28 cities that are partially or totally inside the PW3. The soils of PW3 include two distinct lithologic groups, in which it was possible to identify six soil types: Red Latosol, Red Nitosol, Regolithic Neosol, Haplic Gleysol, Rendzic Chernosol and Red Alfisol. The heavy metals of the soil samples were extracted by partial digestion with concentrated nitric and hydrochloric acids (3:1), according to the procedures described in USEPA 3051A. The determination of the contents of the heavy metals (Ag, Ba, Cd, Cr, Cu, Fe, Ni, Pb, and Zn) was performed by Coupled Plasma-Optical Emission Spectrometry (ICP-OES) Emission Spectroscopy with Induced Plasma (ICP-OES) and analyzed by soil types. The concentration of most of the elements varied considerably between the different soil types. In the Regolithic Neosols, there were higher medians in the contents of the Ba, Cu, Ni and Zn when compared to the Red Latosols and Red Nitosols (types that predominated in this study). These results may be associated with the nature and thickness of these soils. The Haplic Gleysol had lowest Fe contents, related to the reduction reactions, typical of flooded soils, favoring the formation of more soluble forms of Fe. The Rendzic Chernosols showed that for a large part of the elements (Ba, Cd, Cu, Ni and Zn) their concentrations medians were higher than the other soils types. On the other hand, all elements determined in the Red Alfisol, had in lower concentrations than the other soils types. These results were associated with the parental material. In general, the levels of heavy metals (Ag, Ba, Cd, Cr, Cu, Fe, Ni, Pb, and Zn) presented significant differences among the found soil types, being possible to relate these contents to the main pedological characteristics of each order. The results of this research represent the study area in terms of geological and soil type variations and reflect the natural levels of heavy metals that can serve as reference parameters in other environmental studies.

(3400 - 1142) Nature of boron and minerals in a Japanese hot spring area

Kazuki Kobayashi[1]; Yohey Hashimoto[1]

Tokyo University of Agriculture and Technology[1]

Boron (B) is recognized as one of the pollutants because of its dose-dependent toxicity. The discharged water from some hot springs in Japan contains high levels of boron (B) that exceeds an effluent standard criterion of 10 mg L^{-1} (Water Pollution Prevention Act, Japan). Boron in the aqueous environment is often associated with aluminum and iron (oxy)hydroxides, calcitic minerals and phyllosilicates, depending on their abundance and chemical properties of water. Elucidation of B behavior in the natural environment is critical for a better water management and remediation strategy in the hot spring area. The aim of this study was to investigate the concentration gradient of B and mineralogy of sediment from the gushing point of hot spring to the downstream of water passage. Discharged water and river sediment samples were collected from the upstream (gushing point) to downstream of river in Matsushiro, Japan. Ionic concentrations of water and mineralogical properties of solids were determined in relation to B. The B concentration in the discharged water was 174 mg L^{-1} at the gushing point of hot spring and decreased to 15.3 mg L^{-1} at the sampling point at 300 m downstream. The decrease of dissolved B concentration toward the downstream indicates that B is (ad)sorbed on or incorporated in minerals. Iron (Fe) and calcium (Ca) concentrations in the discharged water were 14.4 and 832 mg L^{-1} at the gushing point, respectively, and decreased with increasing the distance from the gushing point. In particular, the concentration of dissolved Fe decreased rapidly to 0.09 mg L^{-1} at a distance of 20 m from the gushing point. Color of the sediment samples were gradually changed from brown to white with distance from the gushing point. The XRD data showed that the white-color sediment contained calcites, whereas the minerals in the brown-color sediment consisted mostly of amorphous compounds that were identified as ferric oxides by synchrotron-based scanning transmission X-ray microscope. These Ca and Fe minerals formed in the path of water stream may retain B and decreased dissolved B concentrations.

Keywords: hot spring; drainage; sediment; natural attenuation

Financial support: This research was financially supported by an Environmental Research and Technology Development Fund (5-1606) from the Ministry of the Environment, Japan.

(8847 - 1608) Nitrate leaching in a maize-cover crop rotation in Mediterranean Central Chile.

Alicia Galdames[1]; Manuel Casanova[1]; Yasna Tapia[1]; Ranvir Singh[2]; Miguel Quemada[3]; Osvaldo Salazar[1]
Departamento de Ingeniería y Suelos, Facultad de Ciencias Agronómicas, Universidad de Chile[1]; Institute of Agriculture and Environment, Massey University, Palmerston North 4410, New Zealand[2]; Departamento Producción Agraria, Universidad Politécnica de Madrid, 28040, Spain[3]

In Mediterranean climate regions of the world, the irrigated maize fields with high nitrogen (N) fertilization doses represent a high risk of diffuse nitrate-N (NO_3-N) pollution of receiving water bodies. We, in a large soil leaching columns experiment, studied the losses of NO_3-N from maize cultivation on a coarse-textured soil (Entic Haploxeroll) in Mediterranean Chile. The combined effects of cover crops (CC) and inorganic N fertilisation rates were evaluated on NO_3-N leaching in soil percolation from the soil columns. The study was conducted in a temperature-controlled glasshouse (25°C), on undisturbed soil columns packed in PVC tubes (0.2 m diameter, 0.5 m long), at the Antumapu Experimental Station (33°34'S, 70°38'W). A total of 52 soil columns (13 treatments x 4 replicates) were established and monitored over a period of 2 years (August 2015 to January 2018) to evaluate NO_3-N leaching from: 1) continuous fallow (F) compared with a continuous CC (*Lolium multiflorum* or *Trifolium repens*), with 0 or 150 kg N ha^{-1} applied; and 2) maize-F and maize-CC rotations with two different N doses (250 or 400 kg N ha^{-1}) for the maize and CC (*L. multiflorum* and/or *T. repens*). We found that N-NO_3 concentration in the soil percolation for the continuous *T. repens* was on average 15 mg N-NO_3 L^{-1}, a two-fold higher than the average N-NO_3 concentration in the soil solution for the continuous *L. multiflorum* with 7 mg L^{-1}. Moreover, *L. multiflorum* tended to display higher biomass than *T. repens*. These results highlight that *L. multiflorum* grass species takes up more NO_3-N from the soil solution, resulting into the lowest concentration of NO_3-N leaching in the soil percolation. The presence of the legume (*T. repens*) increased the NO_3-N concentration in the soil solution through N-fixation, hence increased the availability and leaching of NO_3-N in the soil. As expected, excessive N fertilizer application (400 kg N ha^{-1}) increased the NO_3-N concentrations in the soil percolation. The maize cultivation with excessive N fertilization and *T. repens* as a CC resulted into the highest concentration (32 mg N-NO_3 L^{-1}), while the maize cultivation with optimal N fertilization (250 kg N ha^{-1}) and *L. multiflorum* as a CC resulted into the lowest NO_3-N concentration (13 mg N-NO_3 L^{-1}) leaching from the soil columns. It is concluded that the *L. multiflorum* takes up more N from the soil solution, resulting into the lowest concentration of NO_3-N leaching in the soil percolation solution.

(9453 - 1492) Nutrients enrichment in soils irrigated with treated wastewater

Riat, Martha Cecilia[1]; Cremona, María Victoria[2]; Tanzer, Laura[3]; Velasco, Virginia[4]; Sánchez, Matías[1]; Magnin, Santiago[3]
UNRN[1]; INTA EEA Bariloche[2]; DPA Río Negro[3]; INTA AER Jacobacci[4]

The use of treated wastewater in irrigation is considered an interesting alternative to avoid disposal into water bodies. Water reuse becomes more critical in arid areas where water scarcity obliges to do an efficient use of it. Nevertheless, irrigation with water containing high levels of salts and nutrient contents involves environmental risks that should be contemplated. We conducted this research with treated wastewater coming from the sludge treatment plant of Ingeniero Jacobacci (Río Negro-Argentina, 41°19'19.51"S – 69°30'36.88"), placed in an arid zone with 150 mm of mean annual precipitation . The experiment consisted in a split plot design, comparing the effect of irrigation with well water-WW and treated wastewater-TW, on the soil of a natural vegetation and an alfalfa crop. We took soil samples every 20 cm up to 80 cm depth, at the beginning of the experiment and 9 months after start of irrigation, when crops were fully developed. Apart from other parameters not reported here, we analyzed ammonia- NH_4^+ and nitrate- NO_3^- (Bremner) and available phosphorus-P (Olsen) in all soil samples. We also evaluated dry matter production. We performed an ANOVA with the two types of water as the main factor of interest. Differences of soil nutrients concentration between sample dates were analyzed. In both types of vegetation, soils irrigated with WW showed a reduction of NO_3^- (on average for all depths: -4.2±2) and on P (-4.6±3), and showed similar values of NH_4^+(0.6±0.6) , in agreement with the high demand of the growing vegetation. In plots with TW, differential nutrient contents were in all cases positive (NH_4^+ 10.1± 4.4; NO_3^- 8.8±5.2; P 15.7±3.7), and significantly higher than plots with WW ($p<0.05$), showing an increasing nutrient load with this treatment. Maximum absolute values were found in TW treatment: 12 -NH_4^+, 30 -NO_3^- and 34 –P mg/kg. Dry matter production was similar in both treatments in alfalfa (circa 23000 kgMS/ha), and it was higher in TW than in WW (17000 vs 6600 kgMS/ha) in natural vegetation. Although the maximum values observed do not represent environmental risks yet, a clear trend to a soil nutrient load in treatments with TW irrigation was made evident. These experiments will provide the information needed to develop a precise crop and water management that seek to transform this nutrient load into dry matter production. Anyway, these data show that a rigorous monitoring of environmental impacts is also needed.

(8118 - 409) Pesticides and Soil

Rojas-Cabezas Edgar[1]
Colegio de Ingenieros Agrónomos de Costa Rica[1]

A high percentage of the pesticides that are applied in agronomic systems do not reach the target organisms, and even a large portion of those that do reach their target organism reach the environment before undergoing physical-chemical transformations. Once the pesticides are incorporated into the environment, they can be transformed in a variety of ways: chemical decomposition, photochemical decomposition, microbial decomposition, volatilization, and movement and physiological decomposition. There are different processes that determine the degree to which these pesticides pollute the environment, the most prominent ones being accumulation, degradation, transport, and microbiological. The vast majority of these processes occur in the soil and are explained as follows: a) Accumulation processes: ion exchange, hydrogen bonds, replacement (chelation), charge transfer, physical forces, hydrophobia. b)Degradation processes: hydrolysis, degradation, hydroxylation, condensation, redox, photodecomposition. c)Transport processes: drag, diffusion, evaporation, leaching.

d)Microbiological processes. Persistence: All pesticides remain in the environment for different periods of time, which are determined by: a)Pesticide-related factors: chemical structure, volatility, solubility, adsorption, formulation, dose, pH. b)Soil characteristics: 1.Clays: Parent material, lamellar load, Cation exchange. 2.Organic matter: exchange capacity, pH, structure, microorganisms. b) Environment-related factors: temperature, precipitation, vegetation cover. c)Other aspects: secondary metabolites, influence on microflora and microfauna, risk of contamination of groundwater. The environmental and edaphic contamination generated by pesticides can be prevented or reduced by applying concepts such as: integrated control, minimum doses, equipment calibration, pesticide selection and rotation of ingredients. Once the environmental/edaphic soil contamination processes have occurred in a severe way, some practices can help to reduce the problem. In recent years, the pesticide industry has made efforts to avoid or reduce environmental/edaphic soil pollution, directing many of its resources to concepts such as: new ingredients, changes in action mechanisms, new formulations, changes in inert ingredients, dose reduction, application technologies, and elimination of uses and ingredients.

(2676 - 2219) Phytolith production in forage grasses grown in soils contaminated with nickel

Enilson de Barros Silva[1]; Múcio Mágno de Melo Farnezi[1]
Universidade Federal dos Vales do Jequitinhonha e Mucuri[1]

Phytoliths production is directly related to the plant species and the availability of silicic acid in the soil solution. The vegetables absorb the silica when it is in the form of monomeric silicic acid. The polymerization process, acid is transformed into gel and opaque, being deposited in plant tissues as phytoliths. Phytoliths can play an important role in agricultural activities and the preservation of the planet, reducing the problems of plant poisoning in soils contaminated with heavy metals. The species of the family Gramineae presents great capacity to accumulate silica, forming substantial quantities of phytoliths in tissue. The objective of this work is to evaluate the phytoliths production in three forage grasses cultivated in soils contaminated with nickel. The experiment was conducted in a greenhouse in Diamantina (18º14' S, 43º36' W; 1.250 m a.s.l.), Minas Gerais, Brazil. The experiment was carried out in a completely randomized design in the 3 x 3 x 4 factorial scheme, with three soil types classified as Typic Quartzipsamment (TQ), Xantic Hapludox (XH) and Rhodic Hapludox (RH), three forage grasses *Urochloa decumbens* cv. 'Basilisk', *Urochloa brizantha* cv. 'Marandu' and *Megathyrsus maximum* cv. 'Mombaça' and four soil Ni doses (0, 20, 40, and 120 mg kg^{-1}) as pure nickel chloride for analysis with three replicates. At 120 days, the dry weight of shoots of the grasses was influenced by the increasing Ni doses applied to the soil with increase in the first Ni doses in the soil and subsequent decrease with the elevation of these doses. The evaluated cultivars presented a positive response to the increase of Ni doses applied to the soil, presenting a quadratic response to the increase of Ni concentration in the three evaluated soils. The positive response was observed in the growth of the cultivars up to the 40 mg kg^{-1} dose applied to the soil. The cultivars showed good phytolith production capacity with a reduction of production at the dose of 20 mg kg^{-1} with subsequent increase with increase of the Ni concentration in the three types of soil. The sequestration of Ni in phytoliths is of great relevance, since it may explain the non-detection of phytotoxic effects of these metals on the grass, besides excluding them from the trophic web. The high production of biomass and phytoliths by the evaluated forage grasses potentiates them for use in cropping systems in soils contaminated with nickel.

(7813 - 2277) Phytoremediation of Cadmium by Khaya ivorensis A. Chev. Critical level of toxicity and factors of bioaccumulation and translocation.

Cândido Ferreira de Oliveira Neto[1]; Josilene do Carmo Mescouto de Sousa[1]; Thays Correa Costa[1]; Jessica Taynara da Silva Martins[1]; Liliane Correa Machado[1]; Denilson Pontes Ferreira[1]; Vitor Resende do Nascimento[1]; Susana Silva Conceição[1]; Ana Ecídia de Araújo Brito[1]; Waldemar Viana de Andrade Júnior[1]
Universidade Federal Rural da Amazônia (UFRA)[1]

Soil contamination by cadmium represents a potential agricultural, food-producing, and environmental hazard throughout the world. Faced with the problems caused by this and other metals it is necessary to remove or stabilize the same of the soil, so that there is no contamination of the ecosystems. One of the options for recovering the activity and the diversity of these environments is phytoremediation. With this, the objective of this work was to evaluate the growth responses, physiological and biochemical characteristics of plants of Khaya ivorensis A. Chev. submitted to different doses of $CdCl_2$. The experiment was conducted at the Federal Rural University of Amazonia (UFRA), Belém campus, from December 2015 to April 2016. A completely randomized experimental design with 5 treatments (Control, 10 $ClCd_2$ mg/L^{-1} , 20 $ClCd_2$ mg/L^{-1}, 30 $ClCd_2$ mg/L^{-1}, 40 $ClCd_2$ mg/L^{-1}) and 7 replicates. With increasing doses of the metal, the Khaya ivorensis A. Chev. plants, presented as a response a decline in the biometric, physiological and biochemical parameters, but did not cause the death of the plants. The treatment with the dose of 10 $ClCd_2$ mg/L_{-1} obtained the highest values for both the translocation factor and the bioaccumulation factor, none of the treatments presented a critical level of toxicity. The Khaya ivorensis A. Chev species proved to be an excellent alternative for the phytoremediation method in areas contaminated with cadmium.

(3183 - 3103) Phytoremediation of contaminated soil with 2,4-D + picloram in eastern Amazon

Jéssica Paloma Pinheiro da Silva[1]; Douglas Pereira Ferreira[2]; Sandra Andréa Santos da Silva[1]; Samia Cristina de Lima Lisboa[1]; Rainerio Meireles da Silva[1]
UFPA[1]; UEPA[2]

The residual effect presented by part of registered herbicide have caused a series of modifications for the environment. For face the contamilation of soil by xenobiotic compounds, an of strategies used is the phytoremediation, which use plants for the extraction/softening of polluting compound. The object this research is evaluate the potential of capim-Braquiarão and capim-Mombaça, largely used in Amazon region, in phytoremediating treated soil with 2,4-D+picloram herbicide, using the radish like bioindicator plant. The experiment was driven in vegetation house, in design fully in two stage. In the first stage the treatment were compounds by cultivation of capim-Braquirão and capim-Mombaça treated with and whitout the dose of herbicide, with five repetition in each treatment. In the second stage, the treatment consisted in cultivation of radish Crimson Gigante in: soil free of herbicide residue; contaminated soil with herbicide with previous cultivation of species capim-Braquiarão; contaminated soil with herbicide with previous cultivation of species capim-Mombaça; and contaminated soil with herbicide without the previous cultivation

of gramidea, with five repetiton each treatment. Vases was used with 8 dm³ and without hole, which received the treatment with 2,4-D+picloram herbicide, of individual form in surface of each vase, in pre-emergency, fifteen days after application proceeded itself the seeding of gramíneas. At fifty days after seeding, the forages were harvested and evaluated their phytoremadiator potential. This was segregated in part area and root, analyzing the parameter of fresh biomass (g), dry biomass (g) and height (cm) of segregated parts for each treatment. After the withdrawal of phytoremediation plants, it was accomplished the transplant, in each vase, of radish. At five, ten, fifteen and twenty days after the emergency (DAE) was evaluated the visual phytotoxicity of radish plants and at twenty DAE it determined itself the accumulation of green and dry material (g), height of plant (cm), the analyzes were used following the same analyze procedure of forages. The results demonstrated that the evaluated gamineas present phytoremediator characteristic for auxinic herbicides, with highlight at capim-Braquiarão. The radish present itself as bioindicator potential of presence from 2,4-D+picloram herbicide, presenting pronounced symptoms at five DAE, when cultivated in contaminated soil without previous acting of gramíneas.

(8343 - 1223) Planosols developed under rainfall gradient in the Brazilian semi-arid region

Sebastiana Maely Saraiva[1]; Vânia da Silva Fraga[2]; José Coelho de Araújo Filho[3]; Roseilton Fernandes dos Santos[2]; Raphael Moreira Beirigo[2]; Faed Ribeiro Batista[1]
[1]; UFPB[2]; EMBRAPA[3]

In regions with limits imposed by climatic conditions, such as in the arid and semi-arid regions, soils are poorly developed in the pedogenetic point of view and are generally shallow to little deep. The objective of this work was to evaluate the influence of the rainfall gradient on the and development of three Planosols, in diferente soil forming enviroments, in the state of Paraíba, considering three climatic subtypes according to the annual average: very dry (≤ 400 mm), dry ≥ 400 and ≤ 600 mm) and sub-humid (≥ 600 mm). In each climatic subtype, where trenches were open for sampling of soil, which were characterized as their physical properties (particle size distribution, clay dispersed in water, soil and particle density, flocculation degree and porosity). and chemical (Ca, Mg, Na and K, Al, H + Al, COT, P and pH). It was not possible to observe the relationship between soil depth and the climatic conditions because they are soils formed from rocks of differential resistance to weathering. On the other hand, rainfall was important in the formation of diagnostic horizons (Bt), with clay content proportional to rainfall; there was no clear influence of climate on the availability of nutrients. In some horizons of the studied soils, high levels of salinity were verified in the deeper horizons (B and C), with predominance of Na. This element in high concentrations can impair the productive capacity of soils, as it promotes clay dispersion, pore obstruction and makes it difficult to infiltrate water and air in soils, besides the toxic effects on plants. Considering the values of CTC it is possible to verify that a behavior related to the humidity conditions of each environment, with lower value present in the soil of the subhumid condition, this possibly is due to the base leaching promoted by the higher precipitation indices. The imperfect drainage conditions, due to the presence of impermeable layers especially in arid or semi-arid regions, with low rainfall and high evapotranspiration contribute to increase the concentration of soluble salts in the soil solution (salinity) and, or increased sodicity (PST), interfering with the normal development of plants. The Planosols studied have a salic character, that is, electrical conductivity greater than 7 dS / m within 120 cm of the soil surface.

(5943 - 2908) Principal Component Analysis for urban groundwater characterization

Camila Marcon de Carvalho Leite[1]; Edson Wendland[1]
Sao Carlos School of Engineering (University of Sao Paulo)[1]

Groundwater for public supply is a usual alternative, which has grown worldwide. However, different land uses, such as urban, agricultural and manufacturing activities, have modified the chemical properties of groundwater. Quality monitoring and preservation of aquifers are indispensable, in order to maintain their sustainability.This work assesses the chemical characteristics variation of groundwater from 27 wells used for public supply located in the northeast of Guarani Aquifer System, in São Carlos(SP), Brazil.Specifically, we aimed to identify parameters affected by human activities.For the chemical characterization, the following parameters were analyzed: pH, electrical conductivity, redox potential, temperature, major ions and metals in groundwater samples collected from pumping wells, according to Standard Methods for the Examination of Water and Wastewater (APHA, AWWA).A set of quantitative analytical data from the Guarani Aquifer System was processed by descriptive statistical analysis and a multivariate statistical method; Principal Component Analysis (PCA), in order to investigate the groundwater composition.The experimental matrix consisted of 25 physical and chemical variables, determined in 27 groundwater samples. PCA allowed finding out associations between variables, thus reducing the dimensionality of the data table in a 2D matrix.The samples were distributed in two main groups in a Principal Component Analysis (PCA) describing 62.7% of the total samples variability.In the first group, 14 groundwater samples were assigned to 38.7% of the variability, related to geochemical evolution processes, which are characterized by: bicarbonate, calcium, dissolved organic carbon, pH, electrical conductivity, sodium, temperature and magnesium. The second group (5 samples) represents 24% of the variability and consists of chloride, nitrate, Eh, potassium, sulfate and fluoride, which may be associated to anthropogenic origins.It was observed nitrate in 6 samples varying from 0.26 to 2.68 $mg.L^{-1}$ of $N\text{-}NO_3$. Although the concentrations are below the maximum value allowed by CONAMA 357/2005 standard (10 $mg.L^{-1}$), it is important to identify their source since groundwater in a confined aquifer should not be in contact with human sources of contamination.This preliminary groundwater characterization may assist the water resources management by the local Water Supply Company and support future studies on the identification of environmental contamination sources.

(4749 - 398) Quality reference values for trace elements in soils of Alta Floresta – Mato Grosso, Brazil

Jessica Borges da Veiga[1]; Maria Aparecida Pereira Pierangeli[1]; Marco Antônio Camillo de Carvalho[1]; Antonio Carlos Silveiro da Silva[1]
Universidade do estado de Mato Grosso, UNEMAT[1]

Differences between quality reference values (QRV), established at the state and regional level, have been described in the literature. In this context, the objective was to quantify the natural concentrations and establish QRV for As, Cd, Cu, Fe, Mn, Pb and Zn in typical soils of Alta Floresta, Mato Grosso, Brazil. It was collected twenty soil samples in native forest area with minimal human influence, the layer of 0.00 to 0.20 m. The digestion of the soil samples was based on the SW-846 3050B method, and the determination was carried out by ICP-AES. The results were submitted to descriptive analysis and agglomerative hierarchical cluster analysis (AHA). The QRV, in mg kg^{-1}, obtained from

the 75th percentile were: Fe (26172), Mn (348), Zn (17.3), Pb (<5.5), As (<2.3), Cu (<9.0), Cd (<0.14). These values are below those obtained for some Brazilian and international soil. However, by the AHA, Alta Floresta soils were similar to the national soil. The low contents of As, Pb, Cu, Zn, and Cd are due to soil formation factors of the region: developed on granitic-gneiss rocks, shales, amphibolites and many weathered granites, whose soils evolved due to laterization and podzolization processes. These results confirm the overestimation or underestimation of trace elements at the state and regional level. In this regard, regionalized studies are required to define QRV in order to mitigate these problems.

(6824 - 895) Quantification of nonpoint phosphorus losses derived from soluble fertilizer and cow manure in the Uruguayan Santa Lucía River Basin

Florencia De Lucca Agrelo[1]; Carlos H. Perdomo[1]

Facultad de Agronomía, Universidad de la República[1]

The concentration of specialized dairy-farming systems in the Uruguayan Santa Lucía River Basin has led to an increase in the nutrient concentrations of water bodies, mainly phosphorus (P), accelerating the process of water eutrophication. It has been estimated than more of 80% of P inputs to watercourses and lakes come from nonpoint sources, associated with the P transport by water runoff. Several indexes have been developed to quantify P losses from nonpoint sources, such as the Phosphorus Index (PI). This index estimates P losses from agricultural fields in both the particulate and dissolved forms. Nevertheless, it has been observed that under No Till, where erosion is under control, and with surface fertilizations, dissolved P losses acquire greater relevance. The quantification of these losses under field conditions would contribute to the development of the PI for Uruguay, and made possible to prioritize the application of management practices to the zones of greatest risk of P exportation, resulting in a greater resource use efficiency. The objective of this work is to quantify and compare P losses from soluble phosphate fertilizers and cow manure, both applied on the soil surface without incorporation. These losses will be assessed using runoff plots under natural rainfall conditions. The treatments consist of similar P rates applied as soluble P fertilizer and cow manure, and a control treatment without fertilization. The generated information will be used to design primary P loss reduction systems applicable to management units previously identified as having a high risk of P exportation.

Keywords: eutrophication; nonpoint source pollution; runoff

(7883 - 2572) Rare earth elements in soil correctives and P-containing fertilizers marketed in Brazil

Fernando Bruno Vieira Da Silva[1]; Clístenes Williams Araújo Do Nascimento[1]; Paula Renata Muniz Araújo[1]

Federal Rural University Of Pernambuco[1]

The mineral exploration of rare earth elements (REEs) and their entry into the soil by pollution or fertilizer application has generated concern about possible environmental impacts and human health. In this sense, we evaluated 60 samples of agricultural inputs (limestone, gypsum and phosphate fertilizers) marketed in Brazil in order to characterize their contents, signature and solubility of REEs. The fertilizers from igneous origin presenting the largest accumulation of REEs. Regardless of origin, the accumulations of the light REEs (Ce, La, Nd, Pr, Sm and Eu) were larger than the heavy ones (Y, Dy, Gd, Er, Yb, Ho, Tb and Lu). The solubility of fertilizers produced from sedimentary sources was greater than that of igneous sources. The mean annual REEs contribution of SSP and organo-mineral + phosphate rock (both of igneous origin) to soils was > 4000 t $year^{-1}$ and the highest additions were for Ce, La, Nd and Y. The limestone contributed 250 t of Gd, more than any other source. Thus, phosphate fertilization and liming were considered to be significant sources of REEs and soils receiving continuously high doses of these inputs are likely to be enriched in REEs.

(4246 - 642) Sequential extraction of metals in soil and sediments with intensive agricultural activity within the basin of la Villa River-Panama

Adolfo Santo P[1]; Jose E Villarreal[2]; Neldis Basllesteros[3]; Jhon Villalaz[1]

Instituto de Investigación Agropecuaria de panama[1]; Instituto de Investigación Agropecuaria de panama[2]; Universidad Catolica Santa Maria La Antigua[3]

The present study was carried out within the basin of the La Villa river (provinces of Herrera and Los Santos). In these lands historically, a great agricultural activity has been developed, standing out the production of corn, tomatoes, melons, watermelon, beans, chili peppers, sugarcane, beef cattle and milk. They are lands subjected to an intensive use of agrochemicals and influenced by discharges of products of some industrial and agroindustry companies located within the basin. The objective of the study was to determine the environmental risk represented by the concentrations of trace metals in soil and sediments in areas with intensive agricultural activity within the La Villa river basin. 21 samples of soil and sediments were taken from farms of farmers in the rainy season (June-November 2016) and 20 in the dry season (January-April 2017). The total trace metal concentration was determined by extraction with HNO_3 + HCl using continuous source atomic absorption spectrophotometer. The content of Zn, Fe, Mn, Cu, Ni, Pb, Cd, As and Cr was sequentially extracted following the procedure of Keller and Védy to determine to which phase the heavy metal (hydrosoluble, exchangeable, associated with oxides of Fe and Mn, to the organic matter and residual) is bound. Using the procedure of comparison of means of Student's T, the results of the sequential extraction found in both periods were compared according to location within the basin (high, medium and low basin) with a 95% probability. In general, the total concentration was below the levels considered toxic at all sites. When sequencing the Cd, Pb and As showed higher concentrations in the fractions that have greater bioavailability as they are: soluble in water and interchangeable, for the other metals there was a predominance of the residual fraction, showing greater stability and lower risk of Water contamination. When comparing means, in general, the values were kept above 90% probability of staying less or equal to the average value of each fraction, both in rainy and dry seasons. Only the Cr, Ni and As, presented levels of probability above 40% of becoming higher than the average found in the water soluble and interchangeable fractions.

(6067 - 628) Sharing of fungal species in areas affected by iron tailings after disruption of Fundão dam in Mariana, MG, Brazil

Isabelle Gonçalves de Oliveira Prado[1]; Marliane de Cássia Soares da Silva[1]; Betania Guilhermina Pedrosa[1]; Cynthia Canêdo da Silva[1];

Catarina Megumi Kasuya[1]
Universidade Federal de Viçosa[1]

Fungi are involved in the physical, chemical and biological process in the soil. Therefore, the evaluation of fungi community along the time can be a biological indicator of recovery process, like in areas affected by iron mining disaster, occurred in Mariana, MG, Brazil, in Nov/2015. So, we evaluated the fungi richness in four areas: undisturbed forest (UND-as control) and 3 areas under different stages of recovery (REC1, 2 and 3). Soil samples were collected in Feb/2016 (1st) and Sep/2016 (2nd). These samples were used for routine chemical and molecular analysis. Fungi community profiles were evaluated after total DNA extraction and sequencing of ITS1 region by Illumina Mi-Seq. The results of this sequencing were performed using the QIIME Software, according to BMP protocol, UPARSE method and UNITE database. Venn diagrams were performed in JVENN software to display list of fungi species. Canonical Correspondence Analysis (CCA) was used to analyze the abundance of species joining soil chemical parameters, in different periods of collection and areas. In both period of collection, UND presented highest fungi richness, may be by the absence of disturbance. During 1st collection, in REC1 there was no vegetation and lowest fungi richness. In REC2 and REC3 the revegetation processes have been introduced and intermediate fungi richness was observed. In the 2nd collection, REC1 presented the spontaneous plants growth and it was observed an increase in fungi richness. In REC3, fungi richness was also increased, while in REC2 and UND it was maintained. The fungi richness in the core portion remained constant, but the shared species tended to increase in the 2nd collection, due to the better vegetation covering after 6 months. The CCA showed difference between the UND and REC areas in both collections. REC areas was more influenced by pH, base saturation and P and UND areas by organic matter, K, Mg, Ca and cation exchange capacity. We can concluded that revegetation process has provided an increase in the fungi richness in the recovery areas, but it is distant from the UND by chemical parameters vision. Future functional analyzes of fungi species can elucidate their activities in these environments and follow the change of chemical parameters along the recovery process.

(3181 - 618) Soil phosphorus vertical mobilization in a Regosol from the semiarid region of Paraiba, Brazil

Kalline de Almeida Alves Carneiro[1]; Marianne Costa de Azevedo[1]; Bruno de Oliveira Dias[1]; Vânia da Silva Fraga[1]; Ignacio Hernán Salcedo[1]; Tancredo Augusto Feitosa de Souza[1]
Universidade Federal da Paraíba[1]

In sandy soils, phosphorus vertical mobilization (PVM) could be very dangerous for environment and water quality. We hypothesized that in a sandy soil, as a Regosol, with high contents of soil phosphorus available in water (Pw), soil P leaching could be promoted by soil P mobilization through its transport from soil surface to deepest layers. Our aim here, was to evaluatedsoil PVM in a sandy soil using soil columns (10 cm depth) during steady saturated water flow, and correlated PVM with soil Fe and Al oxides contents and forms.Our soil samples were collected in four different areas in field conditions. The soil was classified as a Regosol, and the studied areas were characterized as smallholder farming systems.We analyzed and extracted the soil phosphorus available in water and the forms of Fe and Al oxides with high and low crystallinity. The application of miscible displacement technique to soils was used to promote soil P leaching, and the P was quantified by colorimetry. In our field study, we have detected three soil conditions: a) high contents of P_w(20.20 mg kg^{-1}); b) medium contents of P_w (14.00 mg kg^{-1}); and c) low contents of Pw (<12 mg kg^{-1}). We found that the area with the highest P_w content showed the highest P loss. In the other hand, the lowest P loss was found in soil samples from areas that showed low content of $P_w$associated with the highest contents of $Al_2O_{3(ox)}$, $Al_2O_{3(dit)}$, $Fe_2O_{3(ox)}$ and $Fe_2O_{3(dit)}$ (0.98, 0.60, 0.44 and 0.60 g kg^{-1}, respectively) and high crystallinity. There is no significant different between areas with medium and low P_w content for PVM. We also observed that where the contents of Fe and Al oxides were high, there were influence of these oxides on P adsorption resulting in a low P loss. Also, in our study we can assume that there are two main ways where phosphorus vertical mobilization could be influenced by $Fe_{(ox)}/Fe_{(dit)}$ratio and $Al_{(ox)}/Al_{(dit)}$ ratio. Frist, we found higher P loss in soil conditions with high $Fe_{(ox)}/Fe_{(dit)}$ratio (8.34 dag kg^{-1}), when compared with soil conditions with low $Fe_{(ox)}/Fe_{(dit)}$ratio (4.84 dag kg^{-1}); and second, we found higher P loss in soil conditions with low $Al_{(ox)}/Al_{(dit)}$ ratio (4.84 dag kg^{-1}), when compared with soil conditions with high $Al_{(ox)}/Al_{(dit)}$ ratio (13.27dag kg^{-1}). So, we conclude that (1) there are a strong relationship with high contents of P_w with high rates of PVM; and (2) the forms of Fe and Al oxides with low crystallinity can influence PVM in a Regosol.

(6911 - 2243) Soil-mimicking hybrid composites based on clay, polymer and nitrogen-fixing bacteria for the development of remediation systems of degraded soil

Tulio Lerma[1]; Manuel Palencia[2]; Enrique Combatt[3]
1- GI-CAT, Department of Chemistry, Universidad del Valle, Cali, 25360, Colombia; 2-Mindtech Research Group (Mindtech-RG), Mindtech S.A.S, Cali, 25360, Colombia[1]; GI-CAT, Department of Chemistry, Universidad del Valle, Cali, 25360, Colombia[2]; Department of Agricultural Engineering and Rural Development, Universidad de Cordoba, Montería, 230002, Colombia.[3]

The constant deterioration of the soil as a consequence of natural and anthropogenic processes causes the loss of the clayey fraction and humified organic matter, leading inevitably to the formation of nutrient-poor soils with low fertility and low agricultural productivity. It is suggested by us that an efficient and easy restoration of soils can be possible by addition of materials structurally and functionally like to soil particles. Thus, the objective of this work was to develop soil-mimicking materials from polymer-clay hybrid composites in conjunction with nitrogen-fixing bacteria for the development of remediation systems of degraded soils. For this, montmorillonite was chemically modified with trichlorovinylsilane in order to produce surface activation of clay to promote the covalent links of poly(acrylic acid) which is a soil polymer conditioner. Acrylic acid was polymerized by free radical polymerization in the presence of modified clay and using ammonium persulfate as initiator. Units of sorbitol and citric acid were chemically incorporated in the polymer matrix by sequential esterification. Later, the bacterium *Azotobacter chroococcum* (nitrogen-fixing bacterium) was inoculated in the matrix previously hydrated by direct swelling with water. Finally, system was dried and activated to verify the bacterial reactivation. Parallel experiments were performed without the use of microorganisms, without esterification and in absence of clay-polymer composites. The material obtained was characterized by elemental analysis, thermal analysis, infrared spectroscopy and scanning electron microscopy. In addition, absorption water capacity, capacity of cationic exchange, capacity of buffering and ability of microorganisms to be metabolically

activated by addition of water were analyzed. From of results, it is concluded that through the proposed methodology it is possible to synthesize soil-mimicking hybrid systems, in structure and functionality, using as model the supramolecular ensemble clay-humin-humic acids. In addition, it is demonstrate that this artificial system can be used as potential suitable means for the development of microorganisms that promote plant growth, such as *Azotobacter chroococcum*.

Luiz de Queiroz College of Agriculture, 11 Pádua Dias Ave., Piracicaba, 13418-900, Brazil[1]; Federal Rural University of Pernambuco, n/n Manuel de Medeiros St., Recife, 52171-900, Brazil[2]

Vegetables have different abilities to uptake and accumulate potentially toxic elements (PTEs). Soil attributes and the farming system (conventional or organic) play an important role in the PTEs' phytoavailability and influence the risk for human health. Our aims in this study were to: (i) determine the levels of Ba, Cu, Mn, Ni and Zn in soils and in vegetables produced under organic and conventional systems; (ii) investigate the transfer of PTEs to plants through soil-plant transfer factors; and (iii) estimate the human health risks associated to consumption of these vegetables as affected by farming systems. Samples of edible parts of organically and conventionally produced lettuce (*Lactuca sativa*), onion (*Allium sepa*), bell pepper (*Capsicum annuum*) and tomato (*Solanun lycopersicum*) were collected in the state of Pernambuco (Brazil). Soil samples were collected from the uppermost soil layer (0 – 20 cm). PTEs in plants were extracted through HNO_3 and H_2O_2 digestion. The pseudototal fraction of the PTEs in soils was extracted by a 1:3 $HCl:HNO_3$ (v/v) solution; reactive fraction was extracted by 0.43 mol L^{-1} HNO_3, and DTPA extracted the available contents of PTEs. The ratio of the content of PTEs in the soil samples (pseudototal, reactive and available fractions) and the total PTEs concentration in vegetables were used to estimate the transfer factors. Soil-plant transfer factors and risk concentration were calculated to assess the interaction of PTEs concentrations in plant and soil with human health risk. In general, vegetables accumulated Zn and Cu, and excluded Ba, Mn and Ni. Lettuce leaves presented the highest ability to accumulate PTEs. Contents of PTEs were higher in vegetables grown on conventional as compared to organic farming. Soil-plant transfer factors obtained from different soil extractants had contrasting results when organic and conventional systems were compared. The use of human risk assessment provides good information to complement the traditional environmental studies based on the PTEs concentrations in plants and soils. Regardless of the scenario considered, children and adults in contact to vegetables from the organic system had a lower health risk than individuals exposed to lettuce leaves conventionally produced.

(1495 - 1217) Sorption of clomazone by soils formed on calcite and calcite-dolomite bedrock (Piva Mountain)

Petar Raičević[1]; Lazar Kaluđerović[1]; Zorica Tomić[1]; Rada Đurović-Pejčev[2]; Jovica Vasin[3]; Snežana Jakšić[3]; Aleksandar Đorđević[1]

Department of Soil Management, Faculty of Agriculture, University of Belgrade, Nemanjina 6, Belgrade 11000, Serbia;[1]; Laboratory of Chemistry, Institute of Pesticides and Environmental Protection, Belgrade 11000, Republic of Serbia[2]; Laboratory for Soil and Agroecology, Institute of Fields and Vegetable Crops, Maksima Gorkog 30, Novi Sad 21000, Serbia[3]

This paper provides preliminary information about the sorption of the pesticide clomazone by two different soil types, calcomelanosol (Mollic Leptosols, Barni Do locality) and calcocambisol (Cambisols, Babići locality). These two types of the soil represent two phases in soil evolution on carbonaceous geological substrate. Clomazone sorption was examined using batch adsorption method. Clomazone isotherms for all samples showed non-linearity. All samples showed L-type adsorption isotherms. Mineral composition of the clay fraction was examined using XRD diffraction method. Results indicated that difference in sorption rate could be explained with mineral composition of the clay fraction in soil. In the clay fraction of all samples (>0,002), high content of the kaolinite and vermiculite was established, as well as small amount of smectite and mixed layered silicates. Better adsorption of clomazone on the sorption centers of the sample 26, when compared with samples 29A and 29B was indicated by the higher log *Kf* value. This Freundlich coefficient was 0.562 in sample 26, while in the samples 29A and 29B was 0.357 and 0.512, respectively. Batch adsorption experiment showed that the mineral composition of the clay fraction affect clomazone sorption in the soil. Based on the analysis of the mineral composition and based on the batch adsorption analysis, it can be concluded that the sorption of clomazone in these samples depends primarily on the content of the smectite and decreases in the order 26 > 29B > 29A, as well as the content of smectite in these samples. Transformation of micas led to the release of K^+, and dissolution of calcite led to the release of Ca^{2+}. Exchange of K^+ ions with Ca^{2+} ions in the interlayer space led to the transformation of micas to vermiculite, mineral that usually doesn't occur as typical in the soils formed on carbonaceous geological substrate.

(1918 - 3076) Spatial econometric modeling of soils with high cadmium content in cocoa producing areas of Yacopí, Colombia

Heidy Soledad Rodríguez Albarrcín[1]; Aquiles Enrique Darghan Contreras[1]

Facultad de Ciencias Agrarias, Universidad Nacional de Colombia sede Bogotá[1]

Cadmium (Cd) is a highly toxic heavy metal that causes harmful effects in soils, plants, microorganisms and humans. Plants take cadmium from available forms of this element in the soil. In Latin America, Cd contents have been reported in cocoa beans superior to those allowed by international standards in processed products, which generates monitoring alerts in order to assure the safety of the product. Based on a preliminary study on cocoa production systems in a region of Colombian Andean zone in which the soil levels of total Cd, available Cd, and Cd in plant tissue were characterized; the relationship of the element and some chemical properties of the soil with the plant contents was evaluated by spatial econometrical models, and areas with higher concentrations were identified, showing high Cd contents in the locations with the highest pH (4.9 - 6.7) and higher Zn concentration (59 - 119 ppm). Four farms with Cd in cocoa beans contents higher than 3 mg / kg were selected over these zones, and the total Cd (extracted with aqua regia), and available Cd (extracted

DTPA) at two depths of the soil, 0-30 and 60-100 cm, was determined, and the available fractions of the element at 0-30 cm, making use of sequential extraction techniques. It was observed that when going from the depth of 0-30 cm to 30-60 cm the levels of the element (available and total) were reduced, and it was found by spatial econometric modeling with delay in explanatory variables that up to 30 cm of depth the contents of almond Cd was statistically associated to Cd in leaves, litter, total and available, as well as the pH of the soil. In reference to fractionation, the almond Cd showed high correlations with respect to the interchangeable Cd (r = 0.78), Cd associated with carbonates (r = 0.71), Cd in manganese oxides (r = 0.65), residual Cd (r = 0.62) and Cd in organic matter (r = 0.45). More than 90% of the total Cd is distributed in the fractions easily and moderately available for the plant, finding high correlations between the available Cd, exchangeable (r = 0.9), in carbonates (r = 0.94), in manganese oxides (r = 0.87) and organic matter (r = 0.8). Soils with the highest total Cd content are mainly associated with carbonates and high concentrations of Cd in the parent material, which suggests an adequate management of fertilization based on a preliminary soil study to avoid increasing Cd concentrations.

(5809 - 2637) Sulfonamide and fluoroquinolone electro-oxidation and their vinculation with kinetic and computational parameters.

Danilo Ramos[1]; Camila Canales[1]; Angélica Fierro[1]; Mónica Antilén[1]
Pontificia Universidad Católica de Chile[1]

In the livestock industry, a big quantity of antibacterials belonging to the group of fluoroquinolones and sulfonamides has been used, with the aim of treating diseases in animals. In this context, these drugs are not completely absorbed by the organism, they are excreted in the feces, reaching the agricultural soils and observing an important presence in the environment, without losing their pharmacological activity. Due to the above, this work aims to establish the connection between computational parameters and a kinetics-electrochemical study of a group of sulfonamides (sulfachloropyridazine, sulfadiazine, sulfamethazine, sulfamerazine, sulfamethoxazole and sulfathiazole) and fluoroquinolones (ciprofloxacin, danofloxacin, enrofloxacin, norfloxacin and sarafloxacin), in order to understand adsorption processes on the organic fraction of volcanic soils. The use of cyclic voltammetry as electrochemical technique allows us to find the optimal working pH (7.0), since it requires a lower overpotential to carry out the oxidation reaction of antibiotics. In relation to the electrochemical study, it was determined that the oxidation reaction for these molecules corresponds to an irreversible process controlled by diffusion, in all cases. In this way, through the analysis of the slope between the peak current (Ip) versus the square root of scan rate ($v^{1/2}$), as suggested by the Randles-Sevcik equation for an irreversible process controlled by diffusion, it is possible to obtain the number of electrons transferred in the whole reaction. Then, an antimicrobial was selected from each family to determine the analytical parameters such as the average calibration curve, R^2, limit of detection (LD) and limit of quantification (LQ). Parallel to this, the HOMO-LUMO gap was obtained using quantum calculations, observing a clear difference between fluoroquinolones and sulfonamides, being the last one with greater magnitude between 2 and 3 eV of difference as well as a wide difference between the dipolar moments presented by each family of antimicrobials. Comparing the results obtained from both studies it can be seen that each drug has a similar dipole moment for each family due to the conformational structure. This latter observation has a close relation with the peak oxidation potentials due to the electron-availability of the molecule to carry out the oxidation reaction.

(3776 - 1571) Sulfur supply on growth of lettuce plants exposed to barium toxicity

Arnon Afonso de Souza Cardoso[1]; Ana Paula Pereira Nunes[1]; Éder Rodrigues Batista[1]; Lorena Carmen Hernandez Nataren[1]; Márcio Felipe Pinheiro Neri Nunes[1]; Valdemar Faquin[1]; Maria Ligia de Souza Silva[1]
Federal University of Lavras[1]

Barium (Ba) is a non-essential element for plants, but it can accumulate to toxic levels. Availability of Ba in soil can be reduced by sulfur (S), through barium sulfate formation. Thus, we aimed to evaluate S supply on growth of lettuce (*Lactuca sativa* L.) under barium toxicity. Plants were grown in pots (2.5 dm^3) with Oxisol under greenhouse conditions. Soil received combinations of five Ba rates (0; 150; 300; 450 and 600 mg dm^{-3}) with three S rates (0; 40 and 80 mg dm^{-3}), in randomized block design, with four replications and two plants per pot. At 30 days after transplanting, plants were harvested for shoot and root dry matter evaluation. Shoot and root dry matter shown linear reduction with increasing Ba rates. Inhibition on dry matter production by Ba levels was stronger in plants with lower S supply, mainly with application of 600 mg dm^{-3} of Ba. S supply alleviated toxic effect of Ba on dry matter production, mostly with S rate of 80 mg dm^{-3}. When 600 mg dm^{-3} of Ba was added in soil, we observed increase of 80% in shoot dry matter production of plants grown under 80 mg dm^{-3} of S compared with plants without S addition. S supply attenuate toxicity of Ba on lettuce growth, and can used as alternative management for soils contaminated with high levels of Ba.

(4757 - 936) The chemistry of legacy phosphorus in US Mid-Atlantic agricultural soils

Kathryn D. Szerlag[1]; Donald L. Sparks[1]
University of Delaware[1]

Phosphorus is an essential plant nutrient and is applied to agricultural soils as fertilizer or manure to promote optimal crop yield. Unfortunately, phosphorus loss to both fresh and salt water ecosystems can be extremely detrimental to aquatic life and water quality due to eutrophication caused by nutrient enrichment. By determining the phosphorus species present in soils, we are able to better understand phosphorus availability to plants and environmental susceptibility to nutrient enrichment. Although phosphorus in soil has been extensively researched, little direct evidence exists for the solid phase species of phosphorus that occur. Direct speciation of phosphorus will allow for improvement in fertilizer recommendations, updated best management practices, and informed remediation strategies to prevent phosphorus losses to aquatic environments. Until the recent application of synchrotron based light sources to investigate phosphorus in soils, there has not been a direct method to accurately determine phosphorous speciation. This research utilizes multiple tools including stirred-flow methods to analyses phosphorous release kinetics, and synchrotron based techniques to directly investigate the chemical forms and stability of legacy phosphorus (in excess of 800 mg/kg) from agricultural soils located on the Delmarva peninsula (Delaware, USA). Mineralogical characterization (XRD) of the soils will be presented. Soils will also be subjected to the Hedley sequential extraction to

investigate phosphorus contributions from different pools, such as metal oxide or phyllosilicate associated phosphorus. Phosphorus K-edge X-ray absorption near edge structure (XANES) data from bulk soils will be presented. High resolution, micro X-ray fluorescence (m-XRF) mapping of phosphorus "hot spots" within the soil sample and their association with iron, calcium, and aluminum will also be presented. Micro XANES (m-XANES) will probe these "hot spots" to directly determine phosphorus speciation. By using these methods, we will be able to determine the types of phosphorus (i.e., surface adsorption or precipitation) occurring within the soil, which ultimately dictate phosphorus availability and mobility to both crops and the environment.

Keywords: legacy phosphorus, eutrophication, phosphorus speciation

(5026 - 609) The effects of growth stage and iron oxides deposited on rhizosphere soil on the accumulation of cadmium by rice grains of different genotypes

Chien-Hui Syu[1]; Pin-Ming Chen[2]; Yu-Cheng Lai[2]; Kai-Wei Juang[2]
Agricultural Chemistry Division, Taiwan Agricultural Research Institute, Council of Agriculture, Executive Yuan, Taiwan[1]; Department of Agronomy, National Chiayi University, Chiayi City, Taiwan[2]

Rice consumption is a major pathway of cadmium (Cd) exposure to the human for the population of Asia, and the intake of Cd through the food chain may lead to serious health effects such as cancer and kidney problems. Therefore, developing the suitable practical countermeasures to reduce the Cd uptake by paddy rice is an important and urgent task nowadays. This study investigates the effects of growth stage and iron oxides deposited on rhizosphere soil on the accumulation of cadmium by rice grains of different genotypes. Twenty-seven cultivars commonly planted in Taiwan including 6 indica and 21 japonica rice were used in a field experiment. The sample of rice plants and rhizosphere soils were collected at grain-filling and mature stages, and the amounts of Cd and iron (Fe) in iron oxides of rhizosphere soil and iron plaque, and those elements in rice plants (root, shoot and brown rice) were measured. The results showed that the average Cd concentration in brown rice for indica rice was higher than that for japonica rice. Around half of the used rice genotypes including 5 indica and 8 japonica rice were found accumulating Cd in brown rice exceeding the tolerable level 0.4 mg kg^{-1}. And there was the significant positive correlation between the Cd concentrations in brown rice and the raises of Cd concentration in the shoot from grain-filling to mature stages. This suggested that the growth period from grain-filling to completely mature was the key stage for accumulating Cd in brown rice. In addition, the relative tendency of Cd sequestration toward rhizosphere soil was negatively correlated with the Cd concentrations in brown rice; however, the root surface to form iron plaque showed stronger affinity to soil-available Cd than did the iron oxides deposited on rhizosphere soil. Consequently, the rice genotypes with higher iron oxides deposited on rhizosphere soil would have less Cd accumulation in rice grains. Moreover, the enhancement of iron oxide deposits on the rhizosphere soil at grain-filling stage could be as a practical countermeasure to reduce Cd accumulation in rice grains grown in Cd-contaminated soils.

(1782 - 1471) The impact of redox potential and salinity on As cycling and mobility in goethite systems

Joshua Z. Sanchez[1]; Jason W. Stuckey[2]; Donald L. Sparks[1]
University of Delaware[1]; Multnomah University[2]

Climate change and subsequent sea level rise (SLR) are global issues, especially since population and industry are heavily concentrated in coastal areas. Contaminated soils are commonly located along the shorelines, which can be problematic due to future flooding events caused by storm surges and SLR. Soil contaminants, such as arsenic (As), may be desorbed and released into solution as a result of flooding and/or salinization of the current freshwater conditions. Previous findings by our group from an As-contaminated field site (Wilmington, DE) suggested freshwater facilitated higher mobilization of As from contaminated soils than seawater. However, geochemical controls governing As cycling in variable saline and brackish water environments are largely unknown and warrant further research. To address this knowledge gap, model systems consisting of goethite (a common soil mineral), arsenate [As(V)], and arsenite [As(III)] were reacted in state-of-the-art microcosms over salinity and redox gradients to probe As cycling processes. In order to determine As distribution independent of redox potential, separate batch sorption experiments as a function of As concentration, salinity, or pH were first carried out. Sorption data revealed that seawater systems retained more As(V) on the solid phase at a higher pH compared to freshwater systems. Utilizing the microcosm experimental setup, redox potential was abiotically decreased from +200 to -300 mV while collecting slurry samples every 100 mV. Solid phase samples were analyzed via As and Fe K-edge XANES and EXAFS spectroscopy to determine As/Fe speciation, goethite structure, and local As bonding environment. Results from this study will improve the current understanding of As cycling and contribute to As management strategies in coastal communities with SLR impacted soils.

(2772 - 2601) The influence of different mining compounds on phytotoxicity of Cu in field-collected soils

Pedro Mondaca[1]; Carlos Guzmán[2]; Alexander Neaman[1]
Pontificia Universidad Católica de Valparaíso[1]; Universidad de Castilla-La Mancha[2]

Environmental problems historically associated with Cu mining are widely known. Particularly, smelter dust and tailing sand are common Cu-rich particles in mining areas of central Chile. Previous studies demonstrated that Cu has higher solubility in soils spiked with smelter dust, in comparison with soils spiked with tailing sand. However, this difference could be masked in the field if Cu reaches an equilibrium state with the soil through aging processes. Thus, this study aimed to (1) elucidate the long-term behavior of Cu from smelter dust and from tailing sand in soils, and (2) compare the phytotoxicity of these two mining compounds in historically contaminated soils. Thereby, 21 agricultural topsoils contaminated with smelter dust and 21 agricultural topsoils contaminated with tailing sand were collected in a semiarid region of central Chile. All soils were historically contaminated (more than five decades). Physicochemical characteristics were determined by using routine methods. Additionally, total and soluble concentration of Cu, Zn, Pb, and As were determined by atomic absorption spectrometry (AAS). Besides, phytotoxicity of each soil was assessed through a bioassay with ryegrass (*Lolium perenne* L.). After 21 days of growth on each soil, shoot length of ryegrass was measured and the aerial part was harvested and used to determine foliar Cu content. Laboratory analyses showed that soil total Cu and soil soluble Cu were statistically similar in both areas. However, shoot length of ryegrass did show differences between two studied areas. Specifically, regression analyses revealed that shoot length of ryegrass decrease in function of the total Cu concentration in soils contaminated with smelter dust, but this correlation was not significant in soils contaminated with tailing sand. In soils contaminated with smelter dust, it was possible to determine EC_{10}, EC_{25}, and EC_{50} of total Cu in the soil of 336 mg

kg^{-1}, 429 mg kg^{-1}, and 533 mg kg^{-1}, respectively, using the shoot length as a response variable. These results suggest that Cu phytotoxicity thresholds based only on the soil total Cu concentration can overestimate environmental risks. In consequence, this study conclude that it is crucial to distinguish the type of mining compound in soils contaminated by Cu mining industry in Chile.
Keywords: Copper, smelter, bioavailbility, effective concentration.

(6291 - 668) The potential use of *Lolium perenne* L. as cover crop in alleviating Copper toxicity in vineyard soils.

Gustavo Brunetto[1]; Stefano Cesco[2]; Tanja Mimmo[2]; Youry Pii[2]; Fabio Valentinuzzi[2]; George Wellington Bastos de Melo[3]; Carlos Alberto Ceretta[1]; Lessandro De Conti[4]

Universidade Federal de Santa Maria[1]; Libera Università di Bolzano[2]; Embrapa Uva e Vinho[3]; Instituto Federal Farroupilha[4]

High levels of copper (Cu) in agricultural soils can cause toxicity to commercial crops as grapevines. The use of Cu tolerant cover crops might help alleviating Cu toxicity of the commercial crop via different rhizosphere processes. Thus, this study aimed at assessing the mechanisms involved in the mitigation of Cu phytotoxicity. Seedlings of *Lolium perenne* L. were hydroponically grown in controlled conditions with 4 different levels of Cu (0.2, 5, 25 e 50 µM) for 14 days. Furthermore, iron (Fe) was supplied as either Fe-EDTA or Fe-EDDHA. The pattern of root exudates has been determined during plant growth. At harvest, roots and shoots were separated assessing both fresh and dry weight and their nutrient content. Root morphology parameters were measured and root content of organic acids and total phenols was also determined. Results showed that the release of total phenols and chelating compounds and the root content of total phenols increased with increasing Cu concentration. Lolium plants showed slight Cu toxicity symptoms at the highest dose diagnosed by the reduction in dry matter yield and morphological changes in the roots (reduced root lenght and volume). Copper was mainly accumulated in roots, yet lolium plants were also able to translocate significant Cu concentrations to the shoots. The source of Fe had a small influence on plant growth parameters, nutrient accumulation and root exudation being restricted to the highest Cu concentration (50 µM). At this Cu level, FeEDTA presented lower Cu concentration in both shoots and roots: most likely part of the Fe chelate (EDTA) interacted with Cu complexing Cu^{2+} and consequently reducing its bioavailability. These results highlight the importance of the nutrient source affecting not only the uptake and accumulation of the nutrient itslef but also of other nutrients. In conclusion, our results suggest that *Lolim perenne* expresses two different mechanisms to alleviate Cu toxicity of the neighbouring plants by a) promoting Cu translocation and its compartmentalization at the shoot level and b) reducing Cu bioavailability as a consequence of the release of Cu-complexing exudates.
Keywords: copper toxicity; cover crops; rhizosphere; root exudates.

(7161 - 1724) Toxicity of pesticide used in the forest system in the survival of the species *Folsomia candida*

André Junior Ogliari[1]; Carolina Riviera Duarte Maluche Baretta[1]; Isabela Aparecida Giordani[1]; Elizeu Moizés Bonfim[1]; Talyta Zortéa[2]

Universidade Comunitária Regional de Chapecó - UNOCHAPECÓ[1]; Universidade Tecnológica Federal do Parana – UTFPR[2]

The demand for wood products in Brazil has led to the expansion of silviculture, making it necessary to use pesticides in monocultures to avoid pests that may affect the development and survival of seedlings (LE et al., 2012). It is not known the real impact caused by the use of pesticides on the terrestrial biota, or even on organisms that play important roles in the decomposition of organic matter, such as the springtails (DAMÉ et al., 1996). This study aimed to evaluate the toxicological potential of a pesticide used in a forest system, on the survival of the specimens *Folsomia candida*. The experiment was conducted in a completely randomized design using Tropical Artificial Soil (TAS) as a standard soil, composed of sand, coconut fiber and kaolin. The lethality test was performed with the specimens *F. candida*, which followed the recommendations of ISO 11267 (1999), with six replicates for each concentration of the Comet® (pyraclostrobin) defensive, based on the application recommendations for forest species (0, 58, 140, 350, 525 and 875 µL). Each experimental unit received 30g of contaminated soil and ten individuals aged 10-12 days. The tests were maintained at temperature 20±2 °C and photoperiod of 12:12h (light/dark). The survival assessment was performed at 28 days. The results were submitted to analysis of variance (ANOVA One-way), followed by the Dunnett test ($p < 0.05$). Acute toxicity (lethality) tests met the validation criteria in accordance with the respective guideline. The survival of springtails in the control was greater than 80% and the coefficient of variation was less than 30% (CV = 12.5%). The survival of *F. candida* was not significantly affected by the tested concentrations of the Comet®. There are no other studies testing the toxicity of pyraclostrobin, the active ingredient of Comet®, in *F. candida*. We suggest to extend the study to the effect of the product in natural soil, to prove the effects obtained in artificial soil. Toxicological assays with aquatic invertebrates and fish indicated a highly toxic potential of this fungicide for such organisms (BRINGOLF, et al., 2007; ZHANG et al., 2017). It is concluded that the commercial product Comet®, was not able to cause toxicological effects in the survival of organisms of the species *Folsomia candida* in the concentrations tested.
Keywords: terrestrial ecotoxicology; *Folsomia candida*; pesticides.

(1963 - 2694) Trace elements in sediments and water quality of rivers affected by the rupture of Fundão Dam

Fábio Fernandes Maia[1]; Jaime Wilson Vargas de Mello[1]; Renato Welmer Veloso[2]

Universidade Federal de Viçosa[1]; Instituto Federal de Rondônia[2]

The Doce River is formed by the confluence of Carmo and Piranga rivers. It crosses the east of Minas Gerais and the Espírito Santo states, passing through cities where it plays important role maintaining the riparian ecosystems and water supply. In November 2015, the Fundão tailing dam, located at Mariana City in Minas Gerais state, ruptured and released around 40 million m^3 of iron ore tailings in Carmo River. It caused environmental impacts and compromised the water supply for many cities. The objective of this study was to evaluate the water quality, the trace elements contents in sediments, as well as to investigate the mobility of these elements in the rivers Carmo and Doce. Water and sediment samples were collected at 8 sites in these rivers. Dissolved oxygen, pH, true color, turbidity, *Escherichia coli*, total suspended solids and As, Cd, Co, Cr, Cu, Mn, Ni, Pb and Zn concentrations were assessed in water samples. In the sediments were quantified the contents of As, Cd, Co, Cr, Cu, Hg, Mn, Mo, Ni, Pb, V and Zn. Acid digestion as requested by USEPA methods SW-846 3015A and SW-846 3051A were used to obtain the concentrations of the elements in the water and in the sediments, respectively. Exchangeable, reducible, oxidizable and residual fractions of the chemical elements in the sediments were evaluated by sequential extraction by BCR protocol. For the two rivers evaluated, the values

obtained for pH, true color and total suspended solids were in agreement with the tolerance range established by the Brazilian environmental rules. However, the values of dissolved oxygen, turbidity and *E. coli* were above the established limits. The soluble As in both rivers were also above the established threshold for fishing and aquaculture, but within the tolerance range for irrigation and water supply. Soluble Mn exceeded the maximum value in two sites collected at Doce River and soluble Zn in only one site of Carmo River. These result indicated local contaminations of these elements. The sediments of Carmo and Doce rivers presented similar chemical composition for the analyzed elements. High levels of Cd compared to the investigation value (VI) were detected in sediments. Additionally, Hg levels were above the prevention value (VP). Most of the elements in the sediments, excepted Mn, were associated to the residual fraction. The data indicates the low mobility of these elements, due to its association in the minerals crystalline network.

Keywords: Mariana City, Doce River; water pollution; acid digestion; sequential extraction

(2707 - 971) Transfer Factors by Cadmium, Lead and Cobalt from Soil to Tomato Plants Cultivated in Nova Friburgo Region – Rio de Janeiro

Fábio Freire de Sousa[1]; Margarida Goréte Ferreira do Carmo[1]; Erica Souto Abreu Lima[1]; Nelson Moura Brasil do Amaral Sobrinho[1]
UFRRJ[1]

Indiscriminate use of agrochemicals to increase productivity coupled with inadequate soil management in agricultural areas, can be considered one of the main sources of input of heavy metals into soil and food chain. This study aims to identify soil contamination by Cd, Pb and Co and the main factors that were contributed to the transfer of these elements to the tomato plants (Solanum lycopersicum). The experiment was carried out in a family farm, in Barracão dos Mendes watershed, Nova Friburgo-RJ. The EPA 3050B methodology was applied for quantification of pseudototals metals levels in soil and agrochemical samples, and the EPA 3050 methodology for plant samples analysis. The pollution index (PI) was calculated for Cd, Pb and Co in relation to reference values established for the hillslope region ("Região Serrana") of the State (Matos, 2016). Pollution index data, slope and topographic wetness index (TWI) obtained by the program ArcGis 10.1 and SAGA 2.5, respectively, were submitted to statistical analysis using the program SAS (2010). It was observed that highest IP values were found for Cd, with a maximum value of 39.63 and mean of 10.36. Lead showed maximum IP values of 3.43 and for Co the value was 2.65. These results demonstrate an enrichment of these metals in tomato growing areas. Regards to the accumulated content in tomato plants, the maximum values was obtaining for Co (11.29 mg plant^{-1}), Pb (3.13 mg plant^{-1}) and Cd (0.22 mg plant^{-1}), thereby, the metal accumulated in foliar tissues represented the greater part of the total accumulated in the tomato plants. Through principal components analysis, it was verified that Cd, Co and Pb contents presented a close relation with Fe and Al contents and with the slope. Highlighting strong influence of the relief and the transport of soil particles, exposing the subsurface layers of the soil more rich in oxides, hydroxides and oxyhydroxides of iron and aluminum present in the source material. These factors associated to the anthropogenic contribution, mainly due to excessive use of agrochemicals over the years, contributed to the accumulation of these metals in tomato plants. Slope and TWI variables were important tools for understanding the factors that contributed to the increase heavy metals levels in soil and tomato plants.

(3527 - 783) Urban impacts over the sediment pollution in Lake Guaíba, Southern Brazil

Leonardo Capeleto de Andrade[1]; Lawrence Morris[2]; Flávio Anastácio de Oliveira Camargo[1]
UFRGS[1]; UGA[2]

The high population density in metropolis leads to socio-environmental impacts that directly affect local water resources. Urban lakes are important to the maintenance of anthropic ecosystems and the quality of life of the population; however, they suffer major impacts from development in surrounding areas. Lake Guaíba has historical, economic and cultural importance to Porto Alegre, Southern Brazil, and its metropolitan region. With a large drainage area, Lake Guaíba accumulates impacts of different water bodies. Currently, the lake has multiple uses such as water supply source (to almost 2 million people), effluent dilution, navigation, recreation, and fishing. Guaíba is a large urban lake, fed by rivers (Jacuí, Sinos, Caí, and Gravataí) wide spread through a large part of the state, suffering many impacts. The aim of this study was evaluate the urban impacts of the metropolitan region over the pollution of sediments in Lake Guaíba. The sediment was sampled in different parts of, including the lake margins, the region near to Jacuí's Delta (forming rivers meeting), besides the historical monitoring results by municipality department. Sediment samples were dried and sieved. The samples were evaluated for: electrical conductivity, pH, densities, particle-size, organic carbon, phosphorus, nitrogen; and pseudo-total metals. The historical pollution from tributaries can be verified by the increasing (in monitoring results) of metals Zn, Cu, Pb, Cr, Ni, and Hg in the surface sediment near to Jacuí's Delta. Near to this region Cu and Ni concentrations exceeded the Brazilian guiding values for sediments. Sediment in the margins of Lake Guaíba presents indications of pollution with Pb, Cu, Cr, Ni, TOC, TKN, and P, mainly derived from urban streams that flow into the lake. The sites with more heavy metals (Zn, Cu, Ni, and Pb), C, N, and P concentrations were the places near to polluted urban streams outflows. These parameters have direct and indirect connection with the urban pollution commonly present in metropolitan regions. Metals and other pollutants enter the aquatic environment from various ways and sources (natural and anthropogenic), such as runoff, sewage, atmospheric deposition, and vehicular traffic. The quality of sediments in Lake Guaíba is linked with the tributaries and streams that flow to the lake. In order to solve these environmental liabilities, public actions should not focus only on the lake, but also in control the sources of this pollution.

(4124 - 2381) Variable surface charge Humic acid-ferrihydrite composite: Influence of electrolytes on Ciprofloxacin adsorption process

Monica Antilen[1]; Loreto Villacura[2]; Manuel Gacitua[2]; Carmen Pizarro[2]; Mauricio Escudey[2]
Pontificia Universidad Catolica de Chile[1]; Universidad de Santiago de Chile[2]

Impacts arising from antimicrobial-compounds present on environmental matrices, like soils and water, have become a worldwide concern. Synthetic humic acid/iron oxide composites (HA/FeO) combining the multifunctionality of humic acid with the adsorption potential of iron oxides (associated to its structural and superficial characteristics), will present enhanced antibiotics adsorption capacity than what has been previously reported. However, it is important to consider the composition of the soil-solution, which could interfere in the process of adsorption-removal of these antimicrobial-compounds. In this work the objective is to evaluate the influence of the electrolyte, in the efficiency of the adsorbents, through the evaluation of their effect on ciprofloxacine adsorption dynamics, through adsorption kinetics and adsorption

isotherms assays, employing a methodology previously developed. The adsorption isotherms of ciprofloxacin on different adsorbents, carried out in KNO_3 and phosphate buffer solution show differences, both in their form and in the maximum adsorption registered, evidenced through different adsorption models (Langmuir, Freundlich and Langmuir-Freundlich). These results can be explained considering the surface charge of the adsorbents (measured through electrophoretic migration), which indicates the importance of the electrostatic interactions in the adsorption mechanisms.

Keywords: Phosphate, Humic Acids, Ferrihydrite, electrophoretic migration

C2.3 - Soil biology

C2.3.1 - Soil microbiological processes and nutrient cycling under crop rotation

(8824 - 1927) Acacia changes litter and soil microbial indicators associated with C and N cycling in intercropped Eucalyptus plantations

Bruna A. B. Lopes[1]; Arthur P. A. Pereira[1]; Maurício R. G. Zagatto[1]; Carolina B. Brandani[1]; Denise de L. Mescolotti[1]; Simone R. Cotta[1]; José L. M. Gonçalves[1]; Elke J. B. N. Cardoso[1]

ESALQ/USP[1]

Forest management strategies, like intercropping Eucalyptus plantations with nitrogen-fixing Acacia can improve C and N inputs, stimulating biogeochemical cycling and nutrient availability in the soil. However, our knowledge on the participation of the microbiota in specific parts of these processes is still incipient. In an effort to understand the C and N dynamics going on in pure and intercropped *Eucalyptus grandis* and *Acacia mangium* plantations, we decided to characterize the microbial and enzymatic activity in soil and litter and the metabolic profile of the soil microbial community, looking for correlations between them. We collected bulk soil samples (0-20 cm) from a field experiment with four treatments, pure *E. grandis* (E) and *A. mangium* (A) plantations, pure *E. grandis* with N fertilizer (E+N) and an intercrop of *E. grandis* and *A. mangium,* 27 and 39 months after planting. The soil organic fraction (OF) presented a higher mass in A and E+A, with a greater N and C content. Microbial C was significantly lower in the E and E+N and higher in the A and E+A stands, at 27 months after planting, with a higher *q*Mic-C index. The metabolic quotient (qCO_2) increased with time and in both epochs, and there was a tendency for higher values in E and E+N. Urease and amidase activity were always significantly higher in the E and E+N treatments and there were no significant differences between treatments regarding the degradation potential of the evaluated C substrates by the microbiota. However, we verified significant differences in the amounts consumed of some of the C sources when comparing periods, mainly in the A (16 sources) and E+A (5 sources) treatments. A canonical redundancy analysis showed interactions between litter and soil attributes and some soil microbial attributes, separating A and E+A from the others, in both periods. These results allow us to infer that C and N accumulations in OM fractions of intercropped plantations are due mostly to a great stimulation of all microbial processes by Acacia trees. This phenomenon is of utmost importance in areas with sandy soils containing extremely low levels of organic matter, because it improves nutrient availability in the soil and results in better tree nutrition.

(9336 - 308) Acid phosphatase activity and removing and replaced the rainforests with pine forests, anual or perennial crops

Arzuaga, Silvia Amanda[1]; Toledo, diana Marcela[1]; Contreras Leiva, Stella Maris[1]; Vazquez, Sara[1]

Universidad Nacional del Nordeste[1]

The objective of this research was to assess the effects of removed the rainforests and replaced with pine forests, anual or perennial crops on the acid phosphatase activity and its relationship with the organic carbon and available phosphorus. The assay was performed in Oxisols soils in the province of Misiones, northeast of the Argentine Republic. The experimental design was completely randomized, with four treatments: subtropical rainforest (Sv), pine forests (*Pinus sp.*) of 17 years (Pi), corn crop under conventional tillage (*Zea mayz*) (Mz) and tea cultivation (*Camellia sinensis*) (Tea). Twelve plots were located per treatment and samples were taken of the following depths: 0-0.10, 0.10-0.20 and 0.20-0.30 m. Texture, pH, acid phosphatase activity (APA), soil organic carbon (CO) and available phosphorus (P) were determined. The results were analyzed through an ANOVA, a Duncan test ($P \leq 0.05$) and a Pearson's correlation test ($P \leq 0.05$). These soils showed acid reaction and their clay content was over 710 g kg^{-1}.The APA was higher in Sv, in the three studied depths with mean values of 671.26; 265.72 and 186.33 mg of p-nitrophenol $kg^{-1}h^{-1}$ ($P<0.0001$). The lowest APA was found in tea at all depths with means of 197.31; 125.87 and 84.36 mg of p-nitrophenol $kg^{-1}h^{-1}$ ($P<0.0001$). The CO was higher in soils under Sv in the three depths, with no significant differences between the cultivated soils. The P of surface was higher in pristine soils ($P<0.0001$), while in the second and third depth the availability of this nutrient was higher in the Sv and Pi treatments. APA and CO correlated positively and significantly at the three depths, characterized in depth of 0 to 0.10 m with an r: 0.77 and a $P<0.0001$; at higher CO increased phosphatase activity. Acid phosphatase activity and P correlated positively and significantly only at the first depth (R: 0.36; P=0.02). The soils under Sv presented the highest values of APA, and then in decreasing order Pi, Mz and Tea. When replacing the forest by afforestation with pine, tea crops or maize crops, there was a decrease in CO, P and APA indicating a degradation of the soil.

(5749 - 2501) *Acidobacteria* community responses to nitrogen dose and form in Chinese fir plantations in southern China

Caixia Liu[1]; Yuhong Dong[1]; Lingyu Hou[1]; Nan Deng[1]; Ruzhen Jiao[1]

Research Institute of Forestry, the Chinese Academy of Forestry, Beijing, China[1]

Acidobacteria is a new bacterial group, identified by molecular research, that is widely distributed and has specific ecological functions in forest soil. In this study, we investigated *Acidobacteria* response to N input, and the effects were related to N form and dose. The experimental design included two N forms (NH_4^+-N and NO_3^--N) and five levels of N deposition (0, 20, 40, 60, 80 kg N ha^{-1}) for 2 years. Research into the *Acidobacteria* community was conducted using 16Sr RNA gene-based high-throughput pyrosequencing methods. *Acidobacteria* OTUs and N had a negative relationship in 0–60 kg $ha^{-1}y^{-1}$; however, at N doses beyond a certain size, nitrogen might promote an increase in *Acidobacteria* OTUs. The *Acidobacteria* relative abundance under NH_4^+-N treatment was higher than under NO_3^--N treatment. *Acidobacteria* relative abundance decreased with increasing of NH_4^+-N dose, but increased with increasing NO_3^--N dose. Overall, 13 different *Acidobacteria* subgroups were identified, with Gp1, Gp2 and Gp3 being dominant. Significant differences in *Acidobacteria* distribution were primarily caused by N

input and pH value. The environmental factors of N were all negatively related to *Acidobacteria* distribution in low N dose treatments (0–20 kg $ha^{-1}y^{-1}$), but were positively related in response to N dose treatments (40–80 kg $ha^{-1}y^{-1}$).

Keywords: Keywords: *Acidobacteria*, subgroup, ammonium, nitrate, N dose, forest soil

(5144 - 1535) Agricultural soils zoomed in: response of nitrogen-cycling microorganisms and nitrous oxide emissions to stabilized N-fertilizers

Micaela Tosi[1]; Shannon Brown[1]; Claudia Wagner-Riddle[1]; Kari Dunfield[1]

School of Environmental Sciences, University of Guelph, 50 Stone Rd., Guelph, Ontario, N1G 2W1, Canada[1]

In agroecosystems, the efficient use of fertilizers is key to optimizing productivity and reducing nutrient losses that can be detrimental for the environment. Soil microbial communities play a major role regulating nutrient fate, like emissions of the greenhouse gas nitrous oxide (N_2O) through denitrification. Stabilized N-fertilizers are a strategy to reduce losses by inhibiting specific microbial groups, but not enough studies have followed their effect on soil microorganisms once they are applied in the field. To fulfill this gap, our study follows the response of soil N-cycling microorganisms to a stabilized fertilizer and relates it to *in situ* N_2O emissions. The study was carried out in experimental corn plots located in SE Ontario, Canada, where N_2O was monitored continuously by tunable-diode laser absorption spectroscopy. Corn was side-dress fertilized with urea-ammonium nitrate with or without Agrotain Plus®, a stabilizer inhibiting urease activity and ammonia-oxidation. In 3 transects per plot, 10 samples (0-10 cm) were taken between the application line and the crop, homogenized and immediately froze. We sampled 10 d before and 2, 6, 9, 13, 16, 20 and 23 d after fertilization. Soil DNA and RNA were extracted to quantify, using qPCR, genes targeting total bacteria (16S rRNA) and N-cycling functional groups: ureolytic (*ureC*), ammonia-oxidizers (bacterial and archaeal *amoA*), nitrite-reducers (*nirK* and *nirS*) and N_2O-reducers (clade I and II *nosZ*). Preliminary results showed responses in gene abundance 9 d after fertilization. Among direct targets of the stabilizer, only ammonia-oxidizing bacteria and archaea were affected (37.8% and 56.6% lower than the control, respectively). Similarly, the stabilizer caused a reduction in total bacteria (-41.2%) and denitrifiers, both nitrite-reducers (~-46%) and N_2O-reducers (~-43%). Differences in day 9 were caused by an increase in the non-stabilized treatment but, overall, both treatments had similar dynamics over time. The stabilizer did not prevent an initial N_2O flux but did reduce emissions during days 4-9. This shift between N_2O and microbial data suggests a delayed effect on microbial abundance, which might be preceded by changes in microbial activity, or even an artifact caused by N flowing towards the sampling spot. Through microbial communities, we can understand the mechanisms underlying different agricultural practices and optimize their benefits for plant productivity and environmental health.

Keywords: Agroecosystems; soil microbiome; quantitative PCR; denitrification; ecosystem services.

(2913 - 1456) Agronomic efficiency of nitrogen-fixing bacteria in symbiosis with cowpea

Márcia Rufini[1]; Dâmiany Pádua Oliveira[1]; Fábio Aurélio Dias Martins[2]; Jacqueline Savana da Silva[1]; Thiago de Assis Pereira[1]; Priscilla Aguida Cassiano de Oliveira[1]; Otacílio Gomes Filho[3]; Polyanna Mara de Oliveira[3]; Abner José de Carvalho[4]; Fatima Maria de Souza Moreira[1]

Federal University of Lavras[1]; Agricultural Research Company of Minas Gerais, Epamig Sul[2]; Agricultural Research Company of Minas Gerais, Epamig Norte[3]; State University of Montes Claros, Campus Janaúba[4]

The cowpea (*Vigna unguiculata* L. Walp) has great social and economic importance in the North and Northeast regions of Brazil, with increasing expansion to the Central-West region. Currently, Brazilian bean exports have been mainly cowpea, destined for the markets of India, Egypt and Pakistan. As it is a culture with high nutritional value and versatile, it presents potential of growth in the country. Therefore, studies of an efficient symbiosis with nitrogen fixing nodulating bacteria (NFNB) are essential, aiming at good yields and reduction of production costs and environmental impacts. Thus, the objective of this work was to evaluate the efficiency of NFNB strains in the biological nitrogen fixation in symbiosis with cowpea cultivated in Northern Minas Gerais, Brazil. Two field experiments were installed in Janaúba and Jaíba, in a conventional system and under conventional sprinkler irrigation. A randomized block experimental design was used with four replications and seven treatments: three efficient strains in test (*Bradyrhizobium* sp. UFLA 03-153, *B. brasilense* UFLA 03-320 and UFLA 03-321), two controls with approved strains as inoculant for the crop (*Bradyrhizobium* sp. UFLA 03-84 and *B. elkanii* INPA 03-11B) and two controls without inoculation with or without fertilization with mineral N (70 kg ha^{-1} N). The inoculant was prepared with peat, inoculating 250g of the inoculant for each 10kg of seeds and observing the legal minimum number of viable cells per seed. The cultivar of cowpea used was BRS Itaim and the sowing density was 15 seeds per meter. All plots received phosphate and potassium fertilization based on 70 kg ha^{-1} P_2O_5 and 40 kg ha^{-1} K_2O. The analyzed variables were: number and dry matter of nodules, shoot dry matter, grain yield, production components, N content and accumulation in shoot and grain. A variance analysis was performed using the statistical software Sisvar. Despite the smaller number of nodules, the productivity of Jaíba was three times higher than that of Janaúba. There was a significant effect of the treatments only for grain yield. In this case, the strains UFLA 03-320 (1088 kg ha^{-1}), UFLA 03-321 (956 kg ha^{-1}) and UFLA 03-84 (960 kg ha^{-1}) were similar to fertilization with mineral N (1020 kg ha^{-1}), surpassing the others. These results suggest an efficient symbiosis of some strains tested in cowpea and further tests will be carried out aiming at its recommendation and approval to be used as inoculants.

(3316 - 2555) ***Are soil microbial community associated with irrigation management practices? - A potato production case study.***

Thiago Gumiere[1]; Silvio J. Gumiere[2]; Guillaume Létourneau[2]; Jean-Pascal Matteau[2]; Alain N. Rousseau[1]

Institut National de la Recherche Scientifique[1]; Laval University[2]

In agriculture, water consumption for crop production represents 69% of all water use. Therefore, precision irrigation systems based on soil water content have been developed to reduce crop water requirements. However, the impact of different water contents on soil organisms, such as the microbial community, remains unclear. Here, we evaluated the effect of four irrigation management practices (wet,

optimal, dry and very dry) on the soil microbial community across three potato cultivars and two soil types (silt and sand). The results have indicated that irrigation management practices and microbial community composition were correlated. For silt and sand, irrigation management practices could explain 15.39% and 12.65% of the community structure, respectively (PERMANOVA, p<0.001). From the wet irrigation practice to the very-dry irrigation practice, we observed a decreasing pattern in the relative abundance of the phyla bacteria *Actinobacteria*, *Proteobacteria* and *Gemmatimonadetes*. Other phyla bacteria, such as *Acidobacteria*, *Chloroflexi* and *Firmicutes*, and also *Thaumarchaeota* (Archaea phyla), showed an opposite pattern, with higher relative abundance for the dry and very-dry management practices. We also observed differences in the predictive functionality analyses for the different irrigation practices. For example, the wet-irrigation practice showed the lower prediction for the gene *AmoCAB* (Nitrification process), and higher prediction for the gene *CysND* (Assimilatory sulfate reduction process). Regardless of soil type and potato cultivar, the irrigation management practice affected both the composition and the predicted functionality of the soil microbial community. These findings could be useful to further advance our understanding of microbial community dynamics under different irrigation practices. We believe the findings of this study have the potential to lead to the development of an innovative irrigation paradigm in potato production based on soil microbial community knowledge.

(8414 - 3222) Association between soil biological attributes and coffee yield in the Cerrado Region of Minas Gerais State

Osnar Obede da Silva Aragão[1]; Silvia Maria de Oliveira Longatti[1]; Polyana Santos de Castro Caputo[1]; Diego Henrique Oliveira Araújo[1]; Márcia Rufini[1]; Gladyston Rodrigues Carvalho[2]; Fatima Maria de Souza Moreira[1]

Federal University of Lavras, Department of Soil Science, Lavras, 37200-000, Brazil, (osnar.silva@gmail.com)[1]; Agricultural Research Company of Minas Gerais, west.[2]

Microbiological indicators can be useful for predicting the rates and the direction of changes in soil quality. The evaluation of these indicators can guide farmers in their decision about how to manage their production systems, resulting in higher soil quality and, consequently, in better crop yield. Among these is the coffee production system, which has high economic and social importance in Brazil. Coffee is a major crop in the state of Minas Gerais, one of the greatest producers in the country. The objective of this work was to evaluate the relationship between soil biological indicators and yield of different coffee cultivars in the cerrado region of Minas Gerais state, Brazil. The work was carried out with soil samples collected in the mesoregion of Alto Paranaíba (18 ° 59 '26 "S and 46 ° 58' 9.5" W). In the sampling area, six plots with different yields were selected, each with two cultivars: Catuai 99 (E and A), Catuaí 144 (C and R), and Rubi (F and M). The E, C and F plots presented the highest yields and the A, R and M plots, the lowest yields. Crop productivity was calculated as the average productivity from years 2014/2015, 2015/2016, and 2016/2017. The experimental procedure consisted in the collection of five composite samples in each plot, and each of these composite samples was formed by pooling four subsamples taken at a depth of 0-10 cm in the projection of the plant crown. The following microbiological attributes were evaluated: microbial biomass carbon (MBC), basal respiration, and fluorescein diacetate hydrolysis (FDA). The data were submitted to normality tests before the analysis of variance, and the means were compared by the Scott-Knott test at the 5% significance level. The statistical analysis was carried out with the Sisvar program. The MBC was significantly different between plots with the same cultivar. It was 57.5% superior in plot E compared to plot A, 43.3% superior in C compared to R, and 32.3% superior in F compared to M. No significant differences in basal respiration were observed. For the FDA, a significant difference was observed only between plots F and M, with an enzymatic activity 42.8% superior in F. Among the microbiological indicators evaluated, the MBC presented a higher correlation and better discrimination of areas with different coffee yields.

(1562 - 193) Breaking paradigms for agricultural sustainability utilizing plant-growth promoting bacteria and their metabolites: perspectives for the next decade

Mariangela Hungria[1]; Marco Antonio Nogueira[1]

Embrapa Soja[1]

The high cost of chemical fertilizers, in addition to a general view of long-term sustainability, of mitigation in the emission of greenhouse gases and of improvement of soil quality, have opened many opportunities for research with plant-growth promoting bacteria (PGPB), including traditional symbiotic rhizobia, phytohormones producers, and via other microbial processes. We have performed field trials in which we identified two new *Bradyrhizobium* strains for the soybean (*Glycine max* (L.) Merr.) crop with an excellent performance in the main producing areas of Brazil, that should fully supply the N-requirements of highly-productive genotypes; in addition, we have broken paradigms of autoregulation of nodulation by the host legume, defining strategies to increase soybean nodulation. Co-inoculation of rhizobia and *Azospirillum*, as well as the addition of microbial metabolites in both soybean and common bean (*Phaseolus vulgaris* L.) have consistently resulted in grain yield gains, indicating that combinations of microbes and microbial molecules are far better than single inoculations. For cereals, the inoculation with strains of *Azospirillum brasilense* selected by our research group has consistently improved root growth and yield. In addition, we have detected benefits from inoculation of *Azospirillum* that go beyond phytohormone production and nitrogen fixation, including the expression of plant genes related to tolerance to abiotic and biotic stresses, that impact plant performance under water, saline and temperature stresses. Interestingly, co-inoculation of selected strains of *A. brasilense* and *Rhizobium tropici* improved maize (*Zea mays* L.) growth in comparison to single inoculation with *Azospirillum*. Two *A. brasilense* strains and other PGPB have been selected and promoted growth of *Brachiaria* (=*Urochloa*), and their use can boost the recovery of degraded pastures. Our results indicate that microbes and microbial molecules have residual benefits, and instead of using inoculants for single crops, one should consider the whole cropping system. Our field trials evaluating the partial or full replacement of N-fertilizers using our selected elite strains result in estimates that 80 million tons of CO_2-equivalents can be mitigated annually considering the soybean, common bean, maize and brachiaria production.

(4921 - 533) Changes in activity of soil microbial community is altered due to plant invasion on the ecosystems of eastern Slovakia

Lenka Bobuľská[1]; Lenka Demková[1]

Department of Ecology, Faculty of Humanities and Natural Sciences,

University of Prešov[1]

Invasive species are a major threat to community composition and ecosystem processes worldwide. Recent studies on invasive species have revealed a wide variety of their impact on soil ecosystems, native plants and soil organisms, including microbial population and its composition. Soil microbial community is an important component of ecosystem response to environmental changes, yet is little know about how microbial activity, structure and function respond to disturbances. The study assessed the effect of *Heracleum mantegazzianum* and *Heliantus tuberosus* invading eastern sites of Slovakia on soil microbial indices. Obtained data were compared with non-invaded adjacent sites (grasslands). Microbial properties such as soil respiration and soil enzyme activities (urease, acid phosphatase, alkaline phosphatase, FDA and beta-glucosidase) were determined. Additionally, soil organic carbon, soil moisture and soil reaction were also performed. Both plant species showed very similar values of microbial properties. Activity of soil microbial community differed between soils under invasive species and those under native plants. In contrast, invaders did not changed the rate of soil organic carbon that is relatively stable soil parameter and soil reaction showed higher values compared to the sites under non-invaded species. Microbial parameter that was most effected by invasive species was acid and alkaline phosphatase that may be also explained by soil reaction changes as phosphatases are very sensitive to soil pH variations. There are several studies focusing on soil biological activity of invasive species and assessing their global impact on ecosystems. Some paper confirm the negative influence on activity and composition of microbial community, the others state that microbial community is unaltered by plant invasion. Therefore, the reaching of general conclusion is vague and there is more need for detailed explanation of processes in the soil ecosystems.

(1502 - 919) Co-inoculation of *Rhizobium* and *Bradyrhizobium* on common beans (*Phaseolus vulgaris*) enhances plant growth and nodulation

Rafael de Almeida Leite[1]; Adelson Paulo Araújo[1]; Ederson da Conceição Jesus[2]

UFRRJ[1]; Embrapa[2]

The common bean (*Phaseolus vulgaris* L.) is known to nodulate with a wide range of rhizobia. Amongst these, Bradyrhizobia is a group that induces the formation of inefficient nodules. Nevertheless, strains of this genus have been previously reported as able to enhance the performance of the symbiosis when co-inoculated with efficient rhizobia strains. Our objective was to evaluate whether the co-inoculation of Bradyrhizobia and *Rhizobium* can improve plant growth and nodulation of common bean plants, testing the consistency of these reports. A Leonard jars experiment was carried out to assess the effects of different strains of *Bradyrhizobium* on plant growth promotion when co-inoculated with the reference strain CIAT 899 of *Rhizobium tropici*. The inoculant was grown in YMB medium. Common bean seeds (cultivar Pérola) were surface sterilized and pre-germinated. Two plants were grown per jar, and each received a dose of 10^8 colony-forming unities per seed of the respective strain. Plants were harvested 42 days after seeding, and shoot, root, and nodule dry weight and number were assessed. Co-inoculated plants showed an overall increase in growth and nodulation. One of the *Bradyrhizobium* co-inoculated strains led to a significant increase in shoot biomass (stem and leaf) and root biomass, when compared with the efficient CIAT 899 strain alone, reaching a 63% increase in total shoot biomass. One of the strain combinations effectively induced the formation of more nodules, with an increase of 50% compared to the CIAT 899 strain alone. Two of the strains combinations accumulated 45 to 55% more nodule dry mass. This data shows a positive effect of the co-inoculation *Rhizobium-Bradyrhizobium* on plant growth and nodulation of common beans. The mechanism behind this effect remains to be unveiled.

(3444 - 2125) Common bean genotypes respond to inoculation with rhizobia strains selected for efficiency in biological n_2 fixation

Jacqueline Savana da Silva[1]; Damiany Pádua Oliveira[1]; Márcia Rufini[1]; Fábio Aurélio Dias Martins[2]; Thiago de Assis Pereira[1]; Maria Vitória Batista Duque Guttierrez Baptista[1]; Celso Leandro da Silva Junior[1]; Antônio Edrey de Castro[1]; Messias José Bastos de Andrade[1]; Fatima Maria de Souza Moreira[1]

Universidade Federal de Lavras[1]; Empresa de Pesquisa Agropecuária de Minas Gerais[2]

The use of plant genotypes efficient in establishing symbiosis with rhizobia on a property is a relevant strategy for capturing and utilizing the N_2 fixed. For its part, the genotype of the rhizobia may affect the response of the host plant. With the use of responsive cultivars and efficient strains, satisfactory yields that are equivalent to or even better than those obtained from nitrogen fertilization can be expected. Knowledge of these factors can therefore guide not only breeding programs involved with biological nitrogen fixation (BNF), but also direct farmers in determining what plant material and nitrogen source to be adopted in the crop. Thus, the aim of this study was to verify the performance of commercial genotypes of common bean (BRSMG Uai, BRSMG Madrepérola, and Pérola) not inoculated, inoculated with a recommended strain (CIAT 899 of *Rhizobium tropici*) or with a strain in the selection phase (UFLA 04-195 of *Rhizobium* sp.), or receiving mineral fertilization with 80 kg ha^{-1} of urea N. The experiment was conducted in the field in the 2017 winter crop season in the municipality of Patos de Minas, MG, Brazil. A randomized block experimental design was used in a 3x4 factorial arrangement (cultivars x N sources), with four replications. All the plots received base phosphate and potassium fertilization according to soil analysis. The inoculant was prepared with sterilized peat at the ratio of 3:2 of peat and cultures prepared in liquid 79 medium, adopting the rate of 25 g of inoculant per kilogram of seed. Nodulation, plant biomass, and N concentration and accumulation in the shoots were evaluated at flowering. Grain yield and productivity of primary components were determined at maturity. All the data were subjected to analysis of variance (ANOVA) and, when necessary, the data were transformed in $(x+0.5)^{0.5}$. In the cases of significant effect of the treatments, the Scott-Knott test was used to cluster the levels of the factors. In terms of yield, the cv. BRSMG UAI responds more to nitrogen fertilization than to BNF. The cvs. Madrepérola and Pérola are as responsive to inoculation as to mineral fertilization, with high and equal yields obtained from both N sources (introduced rhizobia and mineral N). The strain UFLA 04-195 shows satisfactory performance in the three cultivars tested and is as efficient as the strain CIAT 899. For that reason and other good results, the strain has potential for recommendation as an inoculant for common bean.

(3087 - 716) Correction of soil acidity with the use of dairy industry residues

Edenara De Marco[1]; Danilo Dufech Castilhos[1]; Thaís Thürmer[1]; Matheus Schneider Klaus[1]

Universidade Federal de Pelotas[1]

The dairy industry generates waste that, without due mitigation, has the potential to generate environmental impacts. The disposal of organic waste to the soil has as purpose a form of disposal of material, aiming at reducing environmental contamination. This practice can consider the waste as a raw material potencial, which, if well managed, benefits the properties of the soil. The objective of the present work is to evaluate the alteration in pH of the soil after application of increasing doses of sludge from the dairy industry. The biological sludge of the dairy industry had the following characteristics: Neutralizing capacity 16,4%; Organic C 380 g kg^{-1}; N 66,3 g kg^{-1}; P 34 g kg^{-1}; K 2,2 g kg^{-1}; Ca 35,9 g kg^{-1} and Mg 2,9 g kg^{-1}. The soil used in this study, classified as Albaqualf soil (Planosol), presented: pH in water 4,0; Organic matter 2,62%; Clay 21%; S 38,2 mg dm^{-3}; P (Mehlich) 11,5 mg dm^{-3}; K 21 mg dm^{-3}; Al 3,7 cmol dm^{-3}; H + Al 17,3 $cmol_c$ dm^{-3}; $CTC_{affective}$ 5,5 $cmol_c$ dm^{-3} and SMP 4,8. The experiment was conducted in the Laboratory of Soil Microbiology of the Federal University of Pelotas, arranged in a completely randomized design, with three replications. An experimental unit was used 500g of soil disposed in a polyethylene bag. The recommended dose of 36 Mg ha^{-1} of sludge from the dairy industry was defined by the need for N, as recommended by the Commission on Soil Chemistry and Fertility - RS/SC (2016) for maize. From this dose different percentages were established that determined the following treatments: 1- 0 Mg ha^{-1}; 2- 18 Mg ha^{-1}; 3- 36 Mg ha^{-1}; 4- 42 Mg ha^{-1}; 5- 108 Mg ha^{-1}; 6- 144 Mg ha^{-1}. The samples were collected at 16, 22, 29, 39 and 51 days of incubation. Data were submitted to analysis of variance at 5%, and regression analysis was performed. There was a quadratic behavior at all doses throughout collection times. All treatments that received sludge from the dairy industry showed a corrective effect on soil acidity, the treatment 6 had a higher effect, raising pH to 4,82 at 16 and 22 days of incubation. From the 39 days of incubation, the pH value decay was observed in all treatments, demonstrating the loss of the corrective potential of the sludge from the dairy industry. It can be concluded that the sludge from the dairy industry does not have sufficient neutralization potential to raise the pH to an ideal value for the development of plants, requiring limestone complementation.

(6651 - 2079) Cover crops diversity improves soil microbilogy on crop rotations systems

Bruno Poloto Lopes[1]; Carlos Felipe dos Santos Cordeiro[1]; Leonardo Vesco Galdi[1]; Fábio Fernando Araújo[1]; Fábio Rafael Echer[1]

Universidade do Oeste Paulista (UNOESTE)[1]

Diversification of plant species, whether cultivated or under cover crops, in a production system affect soil properties, especially soil microbiology. The objective of this study was to evaluate the effect of different crop rotation systems on soil microbial activity. The experiment was carried in the field in Presidente Bernardes-SP, Brazil, in a completely block randomized design, with five replications. The treatments consisted of single or intercropping of cover crops cultivated in the 2017 winter: 1) black oats (*Avena strigosa*) and lupine (*Lupinus albus*); 2) black oats, lupine (*Lupinus albus*), Mombaça (*Panicum maximum jacq.*) and stylosanthes (*Stylosanthes macrocephala*; 3) Mombaça (*Panicum maximum jacq.*); 4) Mombaça (*Panicum maximum jacq.*) and stylosanthes and 5) fallow. The soil for the microbiological analysis was sampled at of 0-10 cm depth, on 10/10/2017 (120 days after cover crops sowing), and the evaluated characteristics were: activity of the enzyme dehydrogenase, soil respiration, microbial biomass nitrogen, microbial biomass carbon, remaining shoot dry matter and root dry matter weight (0-20 cm). The means of the treatments were compared by the Tukey's test (P<0.05). The dry matter weight of the remaining straw was higher in the Mombaça and stylosanthes treatments (4.4 Mg ha^{-1}); (4.2 Mg ha^{-1}) and in the consortium oats, lupine, Mombaça and stylosanthes (3.9 Mg ha^{-1}) compared to the fallow (1.6 Mg ha^{-1}). The root dry matter mass was higher in the treatments with cover crops (1.7 Mg ha^{-1}), compared to the fallow (0.8 Mg ha^{-1}). The enzyme dehydrogenase showed higher activity in the oat and lupine consortium (3.9 ug TTF g^{-1} soil) compared to the fallow (1.8 ug TTF g^{-1} soil). On the other hand, soil respiration was higher in the fallow and Mombaça (4.9 and 3.8 mg CO_2 kg^{-1} of soil day^{-1}, respectively), compared to the oat and lupine consortium (2.4 mg CO_2 kg^{-1} of day^{-1} soil). Nitrogen and carbon from microbial biomass were higher in the soil cultivated with oats, lupine, Mombaça and stylosanthes (20.8 and 422 mg kg^{-1}) compared to fallow (6.9 and 141 mg kg^{-1}). In conclusion, increasing the diversity of cover species in the rotational systems improves the biological activity of the soil.

Keywords: straw, microorganisms, crop rotation.

(9680 - 1361) Dark septate fungi inoculation and fertilization with organic nitrogen source benefit the growth of tomato plants

Jerri Zilli[1]; Carlos Vergara[2]; Karla Emanuelle Campos Araujo[2]; Segundo Urquiaga[1]; Nivaldo Schultz[2]; Fabiano de Carvalho Balieiro[3]; Peter Soares Medeiros[2]; Leandro Azevedo Santos[2]; Gustavo Ribeiro Xavier[1]

Embrapa Agrobiologia[1]; Universidade Federal Rural do Rio de Janeiro[2]; Embrapa Solos[3]

Dark septate endophytic (DSE) fungi can be used as plant growth promoter. However, several ecological functions of DSE fungi need further clarification. The present study investigated the effects of DSE fungi inoculation on nutrient accumulation and growth of tomato plants fertilized with organic and inorganic N sources. Experiment was carried out under greenhouse conditions in a randomized blocks design, with five replicates of tomato seedlings. Tomato seedlings (cv. Santa Clara I-5300) inoculated with DSE fungi (isolates A101and A105) and without DSE fungi (control) were transplanted to pots filled with 12 kg of soil which had previously received finely ground plant material (Canavalia ensiformis [L.]) or ammonium sulfate. Growth indicators and nutrient content in the plants were quantified 50 days after transplanting. The treatment inoculated with DSE fungi and supplied with an organic N source showed significantly higher N, P, K, Ca, and Mg content, plant height, and shoot dry matter increased. In contrast, no positive effects were observed in the presence of an inorganic N source. Inoculation with A101and A105 promoted the growth of tomato using organic N source.

(7281 - 1951) Density and diversity of edaphic mites de in an integrated crop-livestock system after 15 years under different grazing intensities

Hazael Soranzo de Almeida[1]; Ângela Denise Hübert Neufeld Vieira[2]; Lisiane Sobucki[1]; Paulo César de Faccio Carvalho[3]; Rodrigo Josemar Seminoti Jacques[1]

Universidade Federal de Santa Maria[1]; Universidade Regional Integrada do Alto Uruguai e das Missões[2]; Federal University of Rio Grande do Sul[3]

Integrated crop-livestock systems (ICLS) when correctly managed, they are examples of an intense and sustainable agriculture. However, the excessive weight on the soil of the animal in the grazing may damage chemistry, physics and biologic proprieties of soil and environment quality. The edaphic mites behave such as organic waste transformers and regulators of soil biota. Furthermore, they are sensitive bioindicators and may indicate changes to soil quality. The aim of study was to evaluate the density and diversity of edaphic mites in an integrated crop-livestock system after 15 years under different grazing intensities. The experiment was conducted in a Rhodic ferralsol clayic over a 15-year period in a 23-ha area, characterized by the crop succession *Glycine max* (summer grain production) and *Avena strigosa + Lolium multiflorum* (winter pasture). The treatments consisted of four grazing height: 10-cm (intense), 20 and 30-cm (moderate), 40-cm (light) and no grazing (control plots). A randomized block experimental design was used, with three replicates per treatment. The size of the plots with grazing varied from 0.9 to 3.6 ha. The entire plots had continuous grazing in winter and three tester animals, resulting in the different grazing heights tested. Four samplings were performed between 2014 and 2016, two following the grazing season and two following the soybean harvest. The soil samples (0-3 cm) were collected in five points per plot and packed in plastic bags with a Sand Auger. In the mites extraction of soil was used a Berlese funnel – Tullgren tool modified. Incandescent bulbs of 25W provided the illumination for 96 hours. For counting and identifying of mites were used a stereomicroscope microscope and classification keys. The density after grazing of collected mites was 5.790, 10.001, 3.500, 3.633 e 9.827, after soya grazing was 2.225, 3.534, 1.699, 1.981 e 2.679 for the grass heights of 10, 20, 30, 40 cm and without grazing area, respectively. For the collecting after grazing were find, the orders Gamasida and Oribatida at all pasture heights. Actinedida and Acarida occurred exclusively at a height of 30-cm. With the exception of the height of 30 cm, the others presented the same order diversity. The highest density occurred in the period after grazing.

(7117 - 466) Differential biological activity along a soil sequence used for coffee cultivation in the Brazilian Cerrado

Cátia Aparecida Simon[1]; Armando Cavalcante Franco Dias[2]; Dorotéia Alves Ferreira[2]; Gabriel Nuto Nóbrega[1]; Luis Norberto Pascoal[3]; Isabela Pascoal Becker[3]; Tiago Osório Ferreira[1]; Fernando Dini Andreote[1]
Department of Soil Science, "Luiz de Queiroz" College of Agriculture, University of São Paulo (ESALQ/USP), Piracicaba, SP, Brazil.[1]; Andrios Assistance and Training in Soil Microbiology, Piracicaba, SP, Brazil.[2]; Bioterra Academy, Daterra Sustainable Coffee, Patrocínio, MG, Brazil.[3]

The biological attributes in soils are highly connected to the soil structure, soil usage and crop management. The natural variance of such attributes is poorly understood, especially the correlation between soil type and biological indicators, such as enzymatic activities. By using such approach in cropped areas, we can gain insights on the role of crop management upon the functionality of soil biology. The challenges to use indicators of soil biology quality or proxies of soil biology functionality have been recently advanced, by the validation of enzymatic activity as a reliable marker for broad scale studies. Here we used this approach, by analyzing the natural variation in the activity of arylsulfatase along a soil sequence (Anionic Acrudox-Typic Acraquox -Plinthic Acrudox) in 220,30ha, under a coffee (*Coffea arabica* L.) field newly installed, in the South of Minas Gerais State, Brazil (the Brazilian Cerrado). Three soil samplings were performed (September/2016, January and July/2017), when 74 sampling sites (geographically determined) were assessed by the collection of soil samples from the 0-10 cm layer. The data were interpolated in order to map the biological activity of soils along the soil sequence. Results revealed a higher activity of arylsulfatase in the Anionic Acrudox in September/2016 and January/2017 (98.0 and 86.6 mg p-nitrophenol.kg^{-1} of soil.h^{-1}, respectively), replaced by the higher values found in the Plinthic Acrudox during July/2017 (165.00 to 182.00 mg p-nitrophenol.kg^{-1} of soil.h^{-1}). These values can be related to the organic matter content of the soil, in which the area constituted by Plinthic Acrudox showed higher content of organic matter (values between 3.70 and 7.40 %) when compared with Anionic Acrudox (values between 2.80 to 4.90 %). However, the shift in the activity ranking was also correlated to the implementation of the new coffee plantation, established in the area of Anionic Acrudox previously to the last sampling. A continuous monitoring of this area will shed light on the effect of coffee cultivation upon the biological activity of soils, supporting innovative management strategies in the field.

(9258 - 727) Does agricultural development increase microbial diversity and decrease soil carbon in Zambia?

Toru Hamamoto[1]; Meki Chirwa[2]; Imasiku Nyambe[2]; Yoshitaka Uchida[1]
Hokkaido University[1]; University of Zambia[2]

Changes in soil biological community structures due to the cultivation of natural lands into agricultural lands can cause some changes in soil's functions. However, little is known about the effect of land use changes on soil microbial community structure in sub-Saharan Africa. Therefore, the aim of this research was to investigate the relationships among soil characteristics and soil animal/microbial communities during the conversion of natural ecosystems into cultivated lands in Zambia, and to link soil carbon (C) dynamics to the changes in soil biodiversity. We sampled soils from four different land use types within a farm located in central Zambia, namely, native forest, grassland, watermelon farm, and maize farm. Fourteen different types of soil animals were collected by pitfall traps. Crop pests such as crickets were observed only in the maize sites. Decomposers such as earthworms mostly existed in the forest and grassland sites. Decomposers' presence or absence may influence the contribution of soil animals to soil C stock process. Soil DNA was extracted from soils sampled at each site to investigate the soil bacterial communities and their relationships with soil chemical properties. In results, *Gammaproteobacteria* had a higher relative abundance in the maize sites (15%) and *Bacilli* had a higher relative abundance in the forest sites (20%). The increase in *Gammaproteobacteria* at these sites may be explained by lower C in the maize farm site. According to previous studies, dissolved organic matter inputs drive high rates of soil respiration in the soil bacterial community, particularly among members of *Gammaproteobacteria*. Therefore, the lower soil C levels in the maize sites may have been due to increased soil microbial respiration rates with cultivation. Comparison of the Shannon diversity indices based on the soil microbial classes indicated that microbial diversity was relatively higher in maize sites (2.4) compared to other sites. This indicates that the cultivation of natural soils does not necessarily reduce the diversity of soil microbes (1.6 and 1.8 in the forest and grassland, respectively). In conclusion, changes from national ecosystems to cropland in Zambia changed the soil animal communities and increased soil bacterial diversities. The changes potentially influence C dynamics in soils. This basic information may further develop to investigate the biological indicators for the

sustainable development of sub-Saharan African soils.

(6307 - 1738) Domestic sewage application effects on microbiological characteristics of a latosol cultivated with Solanum lycopersicum.

Giovana Fornaciari Moreira[1]; Victor Barros Damacena[2]
Instituto Federal do mato grosso - campus Caceres/ professor Olegário baldo[1]; IFMT campus caceres[2]

The lack of water in Brazil is not about its supply, the problem goes beyond and is related to the inequalities of distribution and its quality. The pressure about the use of the water resources is enhanced with linear and increasing growth of the Brazilian population. For that matter, the reuse of domestic sewage holds high potential as a source of water and nutritional and organic matter, in addition to minimizing the release of liquid waste without direct treatment in water courses. Considering this, this study aimed to investigate the effects of domestic sewage application on microbiological characteristics of a latosol cultivated with Solanum lycopersicum. The research was conducted in an experimental area of 882 m², with geographic coordinates of 15º 31 '22 "S and 58º 15' 57" W (230 m altitude), in S. J. dos Quatro Marcos - MT (Brazil). On this experiment, 35 plots were used, in which the treatments were summarized in the application of domestic sewage (DS) and water supply (WS), with five different proportions: T1- 100% DS and 0% WS, T2-75 % DS and 25% WS, T3-50% DS and 50% WS, T4- 25% DS and 75% WS and T5-0% DS and 100% WS. Soil samples were collected in the 35 plots after harvesting S. lycopersicum in the 0 to 20 cm, 20 to 40 cm and 40 to 60 cm layers for microbiological analysis at the laboratory. These were then weighed (10g), filled into 90 mL vials of 8.5% saline solution (NaCl), shaken manually and withdrawn a 1 mL aliquot of the material into which cultivation medium (petrifilm plates). The plates were incubated in an oven to 44.5 °C for 48 hours. Subsequently, they were taken to the colonies counting of thermotolerant and total coliforms using a magnifying glass. To detect and quantify the helminth eggs, 100 g of the homogenized soil sample was used. Hereupon it was immersed in a sedimentation cup, containing water at 45 ºC. The material was sedimented for 24 hours, followed by centrifugation at 2000 rpm for two minutes. Sample slides were prepared, stained with aqueous iodine (Lugol's iodine) and checked under microscopy. The experiment was set up in a randomized block design with five treatments and seven replications. The results showed that the system favored removals of more than 70% of the characteristics of total and thermotolerant coliforms; and higher levels of thermotolerant coliforms and helminth eggs in the soil occurred in the highest proportions of domestic sewage (Treatment 1 and Treatment 2).

(5235 - 2102) Earthworms intestinal bacteria strains in sugar cane crops

María Cristina Picon[1]; Ernestina Susana Teisaire[2]
Fundación Miguel Lillo[1]; Universidad Nacional de Tucumán[2]

Earthworms play an important role in soil ecology; they act on its physical, chemical and biological properties, such as: texture, organic matter decomposition and biochemical regulation cycles. These actions are favored by the microbial activity of the communities that inhabit the digestive tube of these organisms. However, since there is a lack of taxonomic information about these organisms, we will try to determine communities of the intestinal microflora of the earthworm species that are found in sugar cane crops in the province of Tucumán. For that purpose, collections were made in May 2012 in a sugar cane field in Chicligasta, located in National Route 38 km 745. The material was obtained by dissection of the earthworms, previously identified, and the microorganisms were extracted from the intestine by dissection and posterior maceration in saline solution. The strains were isolated and identified by classical biochemical techniques according to Bergey's manual and the use of molecular techniques with 16S gene sequencing. The following earthworms and the microorganisms associated to each one were identified: Family Glossoscolecidae: - a) *Pontoscolex corethrurus: Bacillus circulans, Paenibacillus lautus, Bacillus sp., Micrococcus sp., Micrococcus lateus y Lysinibacillus boronitolerans; -b) Enantiodrilus borellii: Micrococcus luteus, Bacillus sp., Bacillus cereus, Bacillus thuringensis, Micrococcus luteus, Pseudomonas nitroreducens, Brevibacterium casei, Bacillus sp, Micrococcus sp., Bacillus thuringiensis, Pseudomonas sp., Bacillus megaterium y Lysinibacillus sp*. Family Megascolecidae: - *c) Metaphire californica: Micrococcus luteus, Bacillus sp., Bacillus cereus y Bacillus thuringensis;* These results show a tendency in both species of Glossoscolecidae to the presence of a greater diversity of bacteria strains, which will indirectly affect the different functions as growth-promoting plant, such as phosphorus solubilization, auxin production, gibberellins and siderophores and nitrogen fixation.
Keywords: Earthworms Bacteria Intestinal

(2130 - 3145) Effect of *Azospirillum brasiliense* associated with organic fertilization on off-season maize crop in the region of Parecis - MT

Michael Ortigara Goulart[1]; Andre Tavares de Vasconcelos[1]; Guilherme Bariviera[1]; Leilane Marisa Hunhoff[1]; Marcela Vieira Paulo[1]; Roberto Antonio Savelli Martinez[1]; Bianca Nathiele Favetti Chagas[1]
University of the State of Mato Grosso[1]

Corn is one of the world's top agricultural products, as well as being a highly nutritious crop. Aiming for a more sustainable agriculture with less dependence on mineral fertilizers, which can be attributed to contamination of groundwater by eutrophication and a rise in agricultural production costs, some practices such as organic fertilization and inoculation by beneficial microorganisms are important. They are used as conservationist production tools However, there is little information on the joint use of organic fertilizers and *Azospirillum brasiliense* on that crop. Thus, to evaluate the effect of the interaction of the fertilization with the inoculation of *A. brasiliense* on the agronomic characteristics of maize cultivated in the off-season in the region of Parecis – MT an experiment was implemented. The experimental design of a randomized complete block design in a 2 x 5 factorial scheme with 4 replicates, two doses of chicken litter (0 and 2.5 tons ha^{-1}), combined with five commercial doses of *A. brasiliense* (0; 10; 15; 20 and 25 ml kg^{-1} of seeds) was used. The corn hybrid used was Formula Viptera, spaced of 50 cm between lines, with a population of 50 thousand plants per hectare. The number of spikes per meter, length and diameter of spikes, productivity, as well as the chlorophyll content in V6, V7, V8 and VT were evaluated. There was an important interaction for the ear corn length and productivity. Spikes diameter were not influenced by the factors studied. For the chlorophyll content, only in V6 the chicken litter dose presented statistical difference. The inoculation of *A. brasiliense* promoted an increase of 11.58% on corn ear length using a dose of 13.61 ml of the commercial product, when compared to the control without application in the absence of chicken litter. The inoculation of *A. brasiliense* did not promote productivity increase in the presence of the chicken litter; however, in the absence of the organic compound there was a linear increase as the inoculant dose increased.

Keywords: inoculation; chicken litter; productive characteristics

(8616 - 1183) Effect of different carbon substrates and phosphorus addition on microbial carbon use efficiency, gross nitrogen mineralization and N_2O emission from a grassland soil

Kazi R. Mehnaz[1]; Paola E. Corneo[1]; Claudia Keitel[1]; Feike A. Dijkstra[1]
Sydney Institute of Agriculture, School of Life and Environmental Sciences, The University of Sydney, 380 Werombi Rd, Brownlow Hill, NSW 2570, Australia[1]

The quantity and chemical composition of soil organic carbon (C) are the primary factors controlling the growth and activity of soil microorganisms. However, availability of phosphorus (P) can also limit microbial activity in soil because of its high requirement for nucleic acids, phospholipids and ATP synthesis. Little is known about the effect of P availability relative to the availability of C varying in chemical composition on soil microbial activity. In this study, we assessed the effect of different C substrates (glucose, oxalic acid and phenol), with and without P on microbial C use efficiency (CUE), microbial respiration, gross nitrogen (N) mineralization and nitrous oxide (N_2O) emission from a grassland soil. Soils were treated with 20 atom% ^{13}C-labeled glucose, oxalic acid or phenol (50 mg C kg^{-1}) with and without P (5 mg P kg^{-1}) after the addition of labelled (30 atom% $^{15}N\text{-}NH_4^+$) and nonlabelled ($^{14}N\text{-}NO_3^-$) N (15 mg N kg^{-1}), and incubated for 20 days at 25% (g/g) soil water content. Gas samples were collected at day 0, 1, 2, 8 and 20 of incubation to assess the carbon dioxide (CO_2) and N_2O emission rates. Another set of similarly treated soil was also incubated for 20 days in a closed jar containing sodium hydroxide to capture CO_2 and later being analyzed for total C and ^{13}C. Microbial CUE of the different C compounds added was assessed by following the ^{13}C tracer into microbial biomass and respiration. Furthermore, similarly treated soil was incubated with and without addition of ^{18}O-labeled water for 48 hours to determine microbial CUE based on incorporation of ^{18}O into microbial DNA (a substrate independent method). Gross rates of N mineralization were measured during a 48 hr incubation of similarly treated soil using the ^{15}N isotope pool dilution technique. Microbial biomass ^{13}C and ^{15}N and soil ^{15}N recovery were measured after 48 hr and 20 days of incubation. Samples still need to be analyzed but we hypothesize that the variation in recalcitrance among C substrates will change the efficiency of microbial C utilization and thus respiration, and the differences in degradation of C substrates will also affect gross N mineralization and N_2O emission from heterotrophic denitrification. We also hypothesize that the alleviation of P limitation of soil microbes will positively contribute to all microbial processes assessed in this study.

(3365 - 3037) Effect of native arbuscular mycorrhiza isolated from acidic volcanic soils on wheat root traits and phosphorus uptake

Pedro Campos[1]; Paula Aguilera[1]; Natalia Aguilera[1]; Sebastián Meier[2]; Fernando Borie[1]; Alex Seguel[1]
Universidad de La Frontera[1]; INIA Carillanca[2]

Wheat is one of the most important food crops in the world and the annual crop most harvest in Chile. However, wheat production is highly dependent on phosphorus (P) fertilizers. Arbuscular mycorrhizal (AM) symbiosis is most common and widespread mycorrhizal symbiosis, which improves acquisition of soil water and nutrients, particularly P. Nevertheless, there is little information about the effects of different AM species in wheat root physiology and development in order to understand the high variability of growth responses found in the literature. The aim of this work was to study the effect of two mycorrhizal isolated from acidic volcanic soils on biomass production and root development and physiology of wheat plants. A pot and a rhizobox experiment using autoclaved sand:vermiculite (1:1) as substrate were performed using winter wheat (cv. Tukan) inoculated with *Claroideoglomus claroideum* (CC), *Rhizofagus intraradices* (RI) and non-inoculated plants as control. Plants were grown for 33 days under greenhouse conditions and watered with Taylor and Foy nutrient solution with low P supply as needed. At the end of the experiment, roots were scanned and organic acid (OA) exudation were measured through filter disks set over three different points of the root system on plants grown in rhizoboxes. At harvest, yield, soil acid phosphatase, OA exudation in rhizospheric soil and P concentration were measured. Mycorrhizal colonization by CC increased shoot and root biomass and P concentration, root specific area, secondary root number and length compared to non-inoculated plants. In other hand, RI plants presented a smaller root system compared to the control, and lower response on biomass production. Colonization by both fungi decreased acid phosphatase activity, while colonization by RI increased total and localized oxalic acid exudation. Overall, CC was more effective in promoting P acquisition from substrate, mainly because to the higher root development promoted by this isolate. The higher oxalic acid exudation observed by plants colonized by RI could comprehend an important mechanism in soils with high content of residual P. Acknowledgment: FONDECYT project Nº 11160385 (A. Seguel) and CONICYT Scholarship (P. Campos).

(1557 - 1373) Effects of Biofertilizer on the root colonization of soy and corn by arbuscular mycorrhizal fungi

Luis Eduardo Azevedo Marques Lesacano[1]; Tatiane Gonçalves Bordim[2]; Gabriel Ferreira de Paula[3]; Leopoldo Sussumu Matsumoto[3]
Unviersidade Estadual do Norte do Paraná[1]; Universidade Estadal do Norte do Paraná[2]; Universidade Estadual do Norte do Paraná[3]

Exploitation of benefits of arbuscular mycorhyzal (AM) in agriculture has been compromised by lots of agricultural practices which decrease the number of mycorrizal propagules in the soil and the diversity of arbuscular mycorrizal fungi (AMF) species. An alternative is the search for agricultural inputs that stimulates the colonization by the native community of AMF in the soil. Studies conducted in vegetation house have demonstrated that biofertilizers influence positively the mycorrizal colonization. In this context, the objective of this study was to analyze, under field conditions, the influence of continuous application of a liquid biofertilizer in the AFM roots colonization of soy and corn. Trials with two culture were conducted at the North Paraná State University (UENP - Bandeirantes in the harvest 2015/1016, with five treatment (control and increasing doses of foliar application 50, 75, 150 and 225 L ha^{-1}) and four replicates. It was observed that application of the biofertilizer promoted an increase in the mycorrhiza colonization of soybean roots, with percentage values in the control and doses 50, 75, 150 e 225 L ha^{-1} corresponding to 50%, 51% 58%, 61% e 69%, respectively. Unlike soybeans, the application of biofertilizers doses did not change the percentage of mycorrhizal colonization of corn roots, whose values were 60%, 55%, 54% and 55% in the control and dosages 50, 75, 150 and 225 L ha^{-1} respectively,. The increase in mycorrizal colonization of soybean roots suggests a positive effect of the biofertilize in mycorrhizal colonization in roots of this species. The results of this study demonstrate the absence of deleterious effects of this product on the AFM community under experimental conditions

adopted in this study, unlike chemical fertilizers and others agricultural inputs, which may cause a reduction in mycorrhizal inoculum potential and, in the benefits obtained by the plant through AM.

(4807 - 1146) Effects of bokashi fertilizer and rice straw on greenhouse gas emission and rice yield in paddy field

Kazuyuki INUBUSHI[1]; Takashi NAGASAWA[1]; Zanyang Wang[1]; Qian Li[1]
Chiba University[1]

Bokashi fertilizer (bokashi), mixture of organic and inorganic materials and fermented, is used in Japanese paddy field for organic farming. Rice straw is also incorporated to soil after harvesting. These organic materials improve soil fertility. However, applying such organic materials in paddy field may increase CH_4 emission. Therefore, we conducted incubation and pot experiments to see the effects of bokashi and rice straw on greenhouse gas emission. Soil was sampling in paddy field in Chiba, Japan in March. Rice straw was powdered or chopped into 2 - 3cm pieces. Bokashi was made by Kogo Beikoku Co., Ltd. (Mixture ratio; Rice bran: Oilcake: Chicken Manure: Eggshell: Bone mill = 5: 4: 1: 1: 1). We conducted aerobic incubation (4 weeks) and then anaerobic incubation (16 weeks). Six treatments were set up with 2 application timings with or without organic materials (rice straw and/or bokashi). In this experiment, CO_2, N_2O, Soil Microbial Biomass Carbon (MBC) in aerobic incubation and CH_4 in anaerobic incubation were analyzed. In pot experiment, aerobic condition maintained for 3 weeks. Two treatments were set up with 2 application timings with or without organic materials (rice straw and/or bokashi). In this experiment, CO_2, N_2O in aerobic condition and CH_4, Eh, Soil pH, and Soluble Organic Carbon (SOC) after transplanting and flooding were measured, and rice yield were analyzed. In aerobic incubation, CO_2 was produced rapidly in treatments with rice straw. MBC of treatment A (with rice straw and bokashi before aerobic incubation) was the highest during aerobic incubation. In anaerobic incubation, Treatment B (with rice straw before aerobic incubation and bokashi after aerobic incubation) produced more CH_4 than treatment A. In pot experiment, treatment A (with rice straw and bokashi before aerobic period) produced more CO_2 than treatment B (with rice straw before aerobic period and bokashi before flooding and transplanting). After flooding and transplanting, CH_4 emission in treatment B was larger than treatment A before drainage. However, CH_4 emission after drainage in treatment A became larger than treatment B. Incorporated rice straw to soil with bokashi produced more CO_2 than rice straw only. Microbial growth in soil was active by using nutrients of bokashi as nitrogen sources. However incorporation of organic materials increased CH_4 emission, their decomposition in aerobic period decreased early stage of CH_4 emission after flooding.

(5798 - 2733) Effects of long-term cultivation of forages on microbial soil attributes

Guilherme M. Moreira[1]; Guilherme L. S. Xavier[1]; Maria Catarina M. Kasuya[1]; Dilermando M. Fonseca[1]; Ivo R. Silva[1]; Raphael B. A. Fernandes[1]
Universidade Federal de Viçosa, Brazil[1]

Forages are one of the most important cultures cultivated in Brazil, however, the effect of its long-term cultivation on soil microbial attributes remains unclear. This study aimed evaluated the effects of continuous cultivation for > 10 years of forage species on soil microbial attributes. We evaluated the following species: Andropogon (Andropogom gayanus), Tanzania (Panicum maximum vr. Tanzânia), Massai (Panicum maximum cv. Massai), Marandu (Brachiaria brizantha cv. Marandu), Mulato (B. decumbens x B. ruziziensis cv. Mulato), Xaraés (B. brizantha cv. Xaraés), Colonião (Pennisetum americanum x Pennisetum purpureum cv. Paraiso), Mombaça (Panicum maximum vr. Mombaça), Capim gordura (Melinis minutiflora), Amendoim Forrageiro (Arachis pintoi), Ruzizienses (B. ruzizienses), Humidícola (B. humidicola), Cameroon (Pennisetum purpureum cv. Cameronn), Decumbens, (B. decumbens), Tifton (Cynodon dactylon cv. Tifton 85), Pueraria (Pueraria phaseoloides), and Stilosantes (Stylosanthes guianensis). The study was carried out in Universidade Federal of Viçosa, Viçosa, MG, Brazil. Soil microbial quality was evaluated by the microbial biomass carbon (MBC) and nitrogen (MBN) contents, and microbial metabolic quotient (QBIO). Statistical analysis was performed by analysis of variance and post hoc Tukey test ($P<0.05$). The soil MBC contents were higher in Humidicola and Cameroon grasses and lower in Tifton, Amendoim forrageiro and Mulato. The soil MBN contents were increased with Mombaça and Ruziziensis cultivation and reduced with Stilosantes, Tifton and Capim gordura cultivation. The QBIO indicated better microbial habitat in the soil with Andropogom , Massai and Stilosantes, and worse one associated with Amendoim Forrageiro and Xaraés. Differences among forage species were identified in soil contents of MBC and MBN, and the lowest values were observed associated with the soil with Tifton. Results obtained are related to the presence of different groups of microorganisms associated with different forage species, which can affect CBM and NBM contents (eg, the fungal microbiota normally has lower N contents than the bacterial microbiota). Results of QBIO suggest that microbial habitat conditions are probably more related to other soil attributes modified by the plant species than to MBC and MBN contents (with the exception of Amendoim Forrageiro and Xaraés). Data obtained indicate homogeneity in soil microbial quality after long-term cultivation of 16 forage species.

(4239 - 1640) Evaluation of groundnut genotypes for variations in their response to phosphorus sources in three agro-ecological zones of Nigeria

Ado Adamu Yusuf[1]; Jamila Aliyu[2]; Fatima Hassan[3]; Hauwa Abdulkareem Yusuf[4]; Muhyideen Oyekunle[3]
Department of Soil Science, Faculty of Agriculture/Institute for Agricultural Research, Ahmadu Bello University, P.M.B. 1044, Samaru, Zaria, Kaduna State, Nigeria[1]; Department of Soil Science, Faculty of Agriculture/Institute for Agricultural Research, Ahmadu Bello University, P.M.B. 1044, Samaru, Zaria, Kaduna State, Nigeria[2]; Department of Plant Science, Faculty of Agriculture/Institute for Agricultural Research, Ahmadu Bello University, P.M.B. 1044, Samaru, Zaria, Kaduna State, Nigeria[3]; Department of Agricultural Extension and Rural Development, Faculty of Agriculture/Institute for Agricultural Research, Ahmadu Bello University, P.M.B. 1044, Samaru, Zaria, Kaduna State, Nigeria[4]

Groundnut (*Arachis hypogaea* L.) is an important grain legume for yield stabilization in the cereal dominated cropping systems of Nigerian savannas. However, its productivity is limited by low phosphorus (P) content of the soils despite active breeding programme to develop high yielding pest and disease resistant varieties. The pod and haulm yields of 16 groundnut genotypes comprising 7 released, 6 advanced breeding lines, 2 local and 1 non-nodulating were evaluated for their response to 30 kg P/ha as single superphosphate (SSP) fertilizer and Sokoto rock phosphate (SRP) in

three agro-ecological zones – Southern Guinea (SGS), Northern Guinea (NGS) and Sudan savannas (SS) of Nigeria. Soil samples were analyzed for initial characterization of the experimental sites before trial establishment. The trials were laid out in a split-plot design with the P source in the main plot and the genotypes in the sub-plot replicated three times. The combined analysis of variance indicated the significance of the location, P source, genotype and their corresponding interactions on pod yield. Stability and genotype superiority for pod and haulm yields was determined using GGE biplot analysis. According to location by P source interaction, the highest pod yield (3359 kg/ha) was obtained at Samaru in NGS with the application of SSP. The yield of the control treatment in this location (2326 kg/ha) was significantly higher than all the treated plots in the other locations except at Minna (SGS) where the yield was at par with the application of SRP (2349 kg/ha). Among the genotypes, advanced breeding lines for aphid and rosette virus resistance ARRORS ICGX-SM and ARRORS ICGX that received SSP outperformed the remaining 14 in the genotype by P source interaction. Similarly, these genotypes gave the highest pod yield at Samaru in the genotype by location interaction. The higher influence of the NGS location on pod yield was attributed to its higher soil fertility indicators such as organic C, Ca and clay. The non-nodulating genotype ICGL 5 was the least productive due to lack of symbiosis with soil bacteria responsible for fixing atmospheric nitrogen. A polygon view of the GGE biplot analysis indicated that ARRORS ICGX-SM and ARRORS ICGX were the most stable and desirable genotypes in terms of pod yield while these same genotypes together with three released genotypes SAMNUT 10, 21, 23 and a local material, *Mai Bargo* are recommended for haulm production in all the three locations.

(7854 - 1553) Evaluation of soil microbial community changes under different agricultural land uses in eastern montana, USA

Joshua J. Steffan[1]; Eric C. Brevik[1]; Billi Jean Petermann[1]
Dickinson State University[1]

The composition of the soil microbial community within different land uses or land management techniques and systems remains an unanswered question. Scientists increasingly recognize that microbial diversity improves soil structure, nutrient availability, and helps facilitate air and water movement in the soil to keep soils functioning to provide ecosystem services. Thus, it is imperative to further understand the diversity of soil microbial communities under different conditions and their role within those ecosystems. For example, an increased bacterial diversity may indicate active communities, abundant resources, and the ability to support higher trophic level organisms. In this study, three different land management strategies are compared to determine how the microbial communities are responding to these different conditions and how these different microbial communities affect basic physical and chemical soil properties and overall soil health. The study is being conducted in Dawson County in Eastern Montana, USA. The first management site was previously enrolled in the Conservation Reserve Program (CRP) for over thirty years, has been untouched (rested) over that time period, and represents long-term perennial cover. The second site has history similar to site 1, but was converted to no-till production agriculture starting in fall of 2015. The third site also has similar history, but was converted to no-till production agriculture beginning in the fall of 2014 and is grazed by livestock over the winter months following the harvest of the agronomic crop. Soil samples were taken during the spring and fall for the past two years. Herein, we report the results of the soil samples which underwent Phospholipid Fatty Acid Analysis at three soil depths (0-5cm, 5-15cm and 15-30cm). Overall, total microbial biomass and diversity appear to increase in both the no-till management sites compared to continuous CRP land.

(9200 - 2158) Exotic arbuscular mycorrhizal fungi reduce mycorrhizal colonization rate in cowpea plants

Marco Aurélio Gabriel da Silva[1]; Ingrid Alexssandra Neris Lino[2]; Danielle Karla Alves da Silva[3]; Antônio Félix da Costa[4]; Leonor Costa Maia[2]; Adriana Mayumi Yano Melo[3]
Universidade Federal de Uberlândia[1]; Universidade Federal de Pernambuco[2]; Universidade Federal do Vale do São Francisco[3]; Instituto Agronômico de Pernambuco[4]

Arbuscular mycorrhizal fungi (AMF) are obligatory biotrophic that colonizing roots of the majority of land plants. In this associations, fungus transfer nutrients (mainly P) to the plant, and in exchange receives photosynthates. About 80% of land plants form symbiosis with AMF, including cowpea [*Vigna unguiculata* (L.) Walp.], which constitute an important protein resource in the diet of people from developing countries, and it can be naturally colonized by AMF. Considering colonization as a key factor of symbiosis, and that it can be affected by several factors, we aimed to evaluate the effect of inoculation with different exotic AMF in the colonization of cowpea (cv. Miranda IPA 207) and in the sporulation of AMF. The experiment was performed during 70 days in greenhouse using soil-inoculum (containing about 3,000 infective propagules per pot, applied under the seeds) from three AMF isolates - *Acaulospora longula* URM-FMA 07 (AL), *Claroideoglomus etunicatum* URM-FMA 03 (CE) e *Gigaspora albida* URM-FMA 11 (GA). The experimental design was completely randomized with four treatments: T1= Control (uninoculated soil containing only native AMF from field samples), T2= inoculation with AL; T3= inoculation with CE e T4= inoculation with GA, with5 replicates. The data were submitted to the analysis of variances (ANOVA) and the averages were compared by Tukey test (5% of probability). There were no significant differences in the glomerospores number in comparison to the control ($p>0.05$). On the other hand, greater colonization rates (82.4%) were observed in the control plants (native AMF) comparing to plants inoculated with *A. longula* (75%), *C. etunicatum* (67.2%) and *G. albida* (75%). In general, it is known that AMF inoculation contributes to improving mycorrhizal colonization rates, however, in our study, the opposite was observed, and the native AMF were more efficient in colonizing the host than to the AMF introduced. A disturbance in the native AMF community may have been generated by the introduction of the exotic, justifying the reduction in the colonization rates. Futhermore, there may have been a competition effect for the root system between microorganisms. Studies that aim to know the best inoculants for cowpea crops should be continued since inoculation practices alter the mycorrhization of these plants.

France[5]

Most often, it is recognized that mycorrhizae are only occurring in the first layers of soil and decrease drastically with depth. Unfortunately, the vertical distribution of mycorrhizal associations remains poorly understood and very few studies have investigated these symbiosis in very deep layers, the majority of studies focusing on the topsoil. In a context of climate changes that predicts more frequent drought events, it is of great interest to take into account the functioning of the deep roots in relationship with this fungal symbiosis, which could play an important role in water acquisition and in the exploration of the soil with their extraradical hyphae network. In this work, we characterized, in a 5-year-old *Eucalyptus grandis* plantation in Brazil, changes in fungal community within soil profiles and whether these changes are influenced or not by a water stress using a throughfall reduction experiment. This research was conducted at the experimental station of Itatinga (ESALQ-USP, São Paulo state). Root samples were collected between May and June 2015. Fine roots (< 2 mm) were sampled carefully layer per layer during the digging of a pit (1.5 x 4 meters) in order to prevent any contaminations between two consecutive soil depths. Ten soil layers have been sampled from 0 to 4 meter depth. An Illumina sequencing of the Internal Transcribed Spacer (ITS2) was carried out on DNA extracted from root samples to study fungal community composition and diversity. We showed that the fungal communities were dominated by ectomycorrhizal fungi (ECM).The fungus *Pisolithus* represented more than 80% of the fungal community. For the first time, both ECM sequences and ECM root tips were observed along the profiles down to 4 meters. By subsampling the root tips of *Pisolithus*, we showed that *Pisolithus* populations responded strongly both to the depth and to the rainfall reduction. This work represents a step forward in the microbial ecology with the evidence, for the first time, of the occurrence of ECMs down to a depth of 4 meters. These results highlight the importance to work more on this subject and to expand these researches to other tropical perennial plants of major interest in order to evaluate the genericity of our observations made on eucalyptus. One of the challenges for future research will be to take into account the role of deep fine roots in plant nutrition but also in the carbon cycle considering the quantity of C allocated in these assemblages.

(2741 - 534) Indigenous mycorrhizae enhances carbon and nitrogen uptake by sweet sorghum genotypes grown under two divers soil ecological zones

Ibrahim. A. M. Ahmed[1]; Ibrahim Ortaş[2]; Celal Yucel[3]

Department of Soil Science and Plant Nutrition, University of Cukurova, Adana, Turkey. Department of Soil and Environment Sciences, Faculty of Agriculture, University of Khartoum, Khartoum, Sudan.[1]; Department of Soil Science and Plant Nutrition, University of Cukurova, Adana, Turkey[2]; Eastern Mediterranean Agriculture Research Institute, Adana, Turkey.[3]

Arbuscular mycorrhizal fungi (AMF) have the capability to improve crop yields by increasing plant nutrient and water supply. It is less known the contribution of indigenous mycorrhizae effects on carbon (C) and nitrogen (N) up take by sweet sorghum genotypes. Therefore, this study was undertaken in a greenhouse to investigate the effects of indigenous mycorrhizae inoculums which were collected at rhizosphere soil in two divers ecological zones. Sixteen sweet sorghum genotypes (collected from USA) and two Turkish soils (Haran (South Anatolia Region) and Arık (Mediterranean Region) soils series) were used in this investigation. Sweet sorghum genotypes growth response, root colonization, mycorrhizal dependency, C and N uptake as well as mitigation of carbon dioxide (CO_2) in plant tissue under sterile soil conditions were determined. Indigenous mycorrhizal inoculated sweet sorghum genotypes had more plant biomass than non-mycorrhizal plants. Likewise, Haran soil produce greater shoot and root dry matter than plant grown in Arık soil. In Haran soil, plant biomass fixed CO_2 on several sweet sorghum genotypes varies from 83.7 to 123.3 Mg/ha for mycorrhizae amended soil. Whereas, plant biomass CO_2 fixation varies from 49.6 to 78.1 Mg/ha for non-mycorrhizae amended soil. In Arık soil, plant biomass fixed CO_2 on several sweet sorghum genotypes varies 83.28 to 107.3 and 67.8 to 94.7 Mg/ha for mycorrhizae and non-mycorrhizae treatment, respectively. In Haran soil, total N uptake by several sweet sorghum genotypes varies 1.14 to 1.64 Mg/ha and 0.71 to 1.22 Mg/ha for mycorrhizae and non-mycorrhizae treatments, respectively. In Arık soil, total N uptake by several sweet sorghum genotypes varies 1.18 to 2.07 Mg/ha and 0.92 to 1.32 Mg/ha for mycorrhizae and non-mycorrhizae amendment, respectively. Root colonization of several sweet sorghum genotypes varies 33.3 to 63.3% and 33 to 73% in Arık and Haran soil, respectively due to indigenous mycorrhizae amendment. Similarly, mycorrhizal dependency varies 1.6 to 14.6% and 11 to 46% in Arkil and Haran soil, respectively. It has been concluded that indigenous mycorrhizae has the potentiality to increase diverse C and N uptake as well as mitigated CO_2 in between sweet sorghum genotypes which were grown under two ecological regions soil.

Keywords: Sorghum genotypes, carbon fixation, mitigation of CO_2, root colonization and mycorrhizal dependency.

(7716 - 1175) Influence of grazing intensities in integrated crop-livestock system on microbiological attributes in soil

Andrea S. Scaramal[1]; Gabriel E. Freitas[1]; Breynner G.P.Bertagnoli[1]; Maria F. Guimarães[2]; Arnaldo Colozzi Filho[1]

IAPAR[1]; UEL[2]

The Integrated crop-livestock system (ICLS) is an alternative for crop diversification and reduction of the environmental impact of the productive agricultural system, with potential to promote the recovery and conservation of soil quality. ICLS grazing intensity may interfere at soil quality, and depending on the amount of plant residues left in the system and the management of the animals. In order to verify the influence of the ICLS on microbiological attributes, were collected some samples of soils in the 0-10 cm layer in the treatments with different grazing intensities: 10; 20; 30; 40 cm pasture heights remaining (GI-10, GI-20, GI-30 and GI-40, respectively), and no grazing (NG). The microbiological attributes analyzed were carbon and nitrogen from microbial biomass (MBC e MBN), microbial respiration (MR), metabolic quotient (qCO_2), microbial quotient (qMIC) and β-glucosidase enzyme activity. After three years of ICLS, there was an increase in MBC, MR and qCO_2, and that pasture management with moderate intensities of animal grazing (GI-20) presented higher MBC contents than others management. About the relation to qCO_2 values, the GI-20 was significantly lower than the GI-10, being 2.5 times smaller than high grazing intensity (GI-10) and 1.91 times lower when compared to the GI- 30, GI-40 and NG. After grazing cycle, β-Glucosidase presented significant differences (p<0.05) between areas. The highest activity occurred in GI-40 and NG (211 and 217 µg PNH g^{-1} h^{-1}, respectively), which were significantly (p<0.05) higher than GI-10, GI-20 and GI-30. There were no significant differences in MR, MBN and qMIC values. Moderate grazing intensities (GI-20, GI30) resulted in a good vegetation cover, greater grazing renewal, which stimulates the microbial biomass as a result of the release of organic substances, besides having provided conditions of lower thermal variation and greater availability of water which favored the biomass and microbial activity of the soil.

(9085 - 1199) Inoculation of phosphate solubilizing bacteria enhance growth and nutrient accumulation of *Vigna unguiculata* (L.) Walp in an Oxisol

Leandro Marciano Marra[1]; Silvia Maria de Oliveira Longatti[1]; Cláudio Roberto Fonsêca Sousa Soares[2]; Fatima Maria de Souza Moreira[1]
Universidade Federal de Lavras[1]; Universidade Federal de Santa Catarina[2]

Lack of available phosphorous in tropical soils is one of the most limiting factors for plant yield. Therefore, high rates of phosphate fertilizers are needed to increase crop yield. Low availability is mainly due to immobilization of phosphorus with other soil components through precipitation, which forms insoluble phosphates. Microorganisms are capable of solubilizing phosphate precipitates, as well as phosphate from rocks, increasing nutrients in the soil solution for plant growth. The aim of this study was to evaluate the efficiency of bacteria isolated from cowpea bean [*Vigna unguiculata* (L.) Walp.] nodules in enhancing growth and phosphorus nutrition of this species grown in an Oxisol fertilized with Araxá rock phosphate (ARP). The strains studied were UFLA 03-08 (*Rhizobium tropici*), UFLA 03-09 (*Acinetobacter* sp.), UFLA 03-10 /UFLA 03-106 (*Paenibacillus kribbensis*), and UFLA 03-116 (*Paenibacillus* sp.). The treatments consisted of inoculation of the strains, separately, in pots in an Oxisol (2 dm^{-3}) containing 6.0 g of ARP (equivalent to 600.0 mg pot^{-1} of phosphorus), a control with ARP without inoculation, two controls containing 300.0 and 600.0 mg pot^{-1} of soluble phosphorus applied as triple superphosphate fertilizer without inoculation, and a control without the soluble phosphorus addition, ARP, and without inoculation. All the inoculated strains were capable of increasing the shoot dry matter, root dry matter and phosphorus and nitrogen content in the aerial part compared with the control ARP without inoculation. The UFLA 03-09 strain had the best performance among them; increases in shoot dry matter and phosphorous and nitrogen content were 600%rfh, 511.5%, and 747.4%, respectively. Thus, these strains clearly contribute to the growth of cowpea bean through rock phosphate solubilization, improving phosphorus and nitrogen nutrition. Use of these bacteria is recommended for future experiments under field conditions.

Keywords: cowpea bean; phosphorus, rock phosphate.

(5640 - 2295) Inoculations with efficient nitrogen fixing bacteria increase yields of common bean genotypes grown in separate areas

Maria Vitória Batista Duque Guttierrez Baptista[1]; Bruno Lima Soares[1]; Fábio Aurélio Dias Martins[2]; Damiany Pádua Oliveira[1]; Márcia Rufini[1]; Fatima Maria de Souza Moreira[1]; Messias José Bastos de Andrade[1]
Universidade Federal de Lavras - UFLA[1]; Empresa de Pesquisa Agropecuária de Minas Gerais-EPAMIG SUL[2]

The adoption of cultivars responsive to N_2 fixation that provide significant yields can lead to savings in production costs and result in greater financial return to farmers. However, their responses may be conditioned on the genotype of the nitrogen-fixing bacteria involved in the symbiosis. It is important to carefully select strains with affinity to the host genotype and that are highly efficient in the symbiotic process. Other factors, such as soil fertility and soil and climate conditions, cannot be ignored. The aim of this study was to evaluate the agronomic efficiency of common bean cultivars (IAC Alvorada, BRS Estilo, BRSMG Madrepérola, and BRS Notável) not inoculated (without mineral N or with 20 or 80 kg ha^{-1} of urea N) or inoculated with a recommended strain (CIAT 899 of *Rhizobium tropici*) or with a strain in the selection phase (UFLA 02-100 of *R. etli*). Four experiments were conducted in the field in the rainy crop season in Lavras, Patos de Minas, and two different areas of Lambari, MG, Brazil. A randomized block experimental design was used in a 4x5 factorial arrangement, with four replications. Fertilization with P_2O_5 and K_2O were defined by soil analysis. The rate of peat inoculant containing $\pm 10^9$ cells of *Rhizobium* per gram was 25 g per kg of seed. After individual and combined analysis of variance of the data, lower crop yield was found in Lambari. The effect of plant genotype on yield was conditioned on the source of N. The cv. IAC Alvorada, for example, produced more when fertilized with a high concentration of urea N or inoculated with the strain UFLA 02-100, whereas the yield of cv. BRSMG Madrepérola was greater with inoculation with CIAT 899. The good performance of the cv. BRS Estilo without inoculation and without mineral nitrogen fertilization indicates that it is ideal for adoption when there are no resources for inoculation. The cv. BRS Notável, in turn, appears to be less responsive to the different sources of N. However, its mean values when not inoculated and not fertilized with mineral N do not reach the high levels of the cv. BRS Estilo in the same situation. Although the effects of the sources of N on yield are dependent on the cultivars and growing location, the highest increases occur when there is inoculation or fertilization with 80 kg ha^{-1} of urea N. Therefore, the inoculation technique is viable and the strain UFLA 02-100 has potential for recommendation for the genotypes tested.

(5526 - 1465) Liming may affect *in vitro* AIA yields of *Digitaria eriantha* endophytic bacteria

Lira Junior, Mario Andrade[1]; Carvalho, Eric Xavier[2]; Barreto, Maria Carmo Silva[2]; Mendonça, Johny Jesus[1]; Alves, Michelle Justino Gomes[1]; Oliveira, José Paula[2]; Silva Junior, Josemir Ferreira[2]
UFRPE[1]; IPA[2]

There is an increasing tendency to use biological means to increase plant yield, and thus enhance sustainability. One of the most promising means is the inoculation with plant-growth promoting bacteria. Currently inoculants for corn and wheat, are second only to soybean inoculants in Brazil, indicating this technique immense potential. On the other hand, mechanisms of bacterial influence and major limitations are not as well understood for these systems. One of the major mechanisms is supposed to be increased nutrient absorption efficiency, due to a larger root system, through production of AIA by the endophytic bacteria. At the same time, the bacterial inoculant industry is based, among other aspects, on the continuous search for new genetical material, most frequently depending on the huge diversity of bacteria. There is currently a project under way evaluating the endophytic population of *Digitaria eriantha* which is a forage grass established in different areas of Pernambuco State, Northeast Brazil, mostly not receiving any fertilizers, and for which there are areas known to be under continuous coverage without major pasture degradation for over 30 years. As part of this project our team has isolated over 500 strains of endophytic bacteria from rhizospheric soil, colm, leaves and roots of these plants under dry and wet seasons, on areas limed or not, and using different nitrogen-free culture media. These were phenotypically characterized and grouped, and 80 representative strains were randomly selected for the evaluation of *in vitro* AIA yields using L-tryptophan enriched TSB

media and Salkowsky and light absorbance measured on a UV-VIS spectrophotometer at 520 nm, according to standard procedures. AIA yields were used to group the 80 strains into five groups at a 90% similarity level, based on Ward´s method, with the group means differing according to 95% confidence intervals. Grouping of the strains by isolation conditions (season of the year, plant part, soil liming, or N-free media used) indicate that groups formed by season, plant part or media did not differ, according to the respective 95 confidence intervals, while strains from limed soils presented significantly higher AIA yields. Groups of the strains by phenotypical characteristics (culture media pH changes and mucous production) indicated found that strains forming mucous in the Petri dishes had higher AIA yields, also according to the confidence intervals.

(9544 - 871) Mesofauna and soil quality in forest systems with leguminous tree

Maurício Rumenos Guidetti Zagatto[1]; Arthur Prudêncio de Araújo Pereira[1]; Rafael Fabri Pereira[1]; Renan Viccino Lopes[1]; Luis Fernando Baldesin[1]; Elke Jurandy Bran Nogueira Cardoso[1]
ESALQ/USP[1]

The cultivation of leguminous nitrogen-fixing tree species improves soil chemical properties, especially with regard to N, and has been identified to be ecologically and economically interesting in intercropped systems with Eucalyptus spp. However, the effect of this management system on soil invertebrates is still unknown, and this is our main reason for evaluating soil mesofauna parameters, trying to establish correlations between the soil invertebrates and soil chemical and microbiological attributes, as well as to create a general indicator of soil quality for pure plantations of *Acacia mangium* (AC), *Eucalyptus grandis* (EU) and for mixed plantations of those tree species (M). Therefore, we evaluated abundance, diversity and richness of soil mesofauna, microbial carbon, soil moisture, dehydrogenase activity, soil respiration qCO_2 and Cmic / Ct in two seasons: October 2015 (dry weather) and March 2016 (rainfall), while soil chemical analyses were performed only in October. The mean values of each attribute in each of the three forest systems were compared, and regression and multivariate analyses were performed to derivate a general indicator of soil quality. Therefore, we established the main interactions occurring between mesofauna and chemical or microbiological attributes. Few differences were observed between the forest treatments, but we found higher microbial activity and soil quality in the rainy season. In the dry season, there were some positive correlations between mesofauna and soil microbiological parameters, evidencing prevailence of mutualistic interactions between mesofauna and microorganisms.
Keywords: soil fauna, microbial activity, seasonality, mutualistic interactions, intercropped plantation.

(6626 - 878) Metabolic quantity of edaphic microbiote in different soil uses in the region of the central cerrado of brazil

Lídia Justen[1]; Talita Maia Freire[1]; Nayara Monteiro Rodrigues[1]; Danilo Marcelo Aires dos Santos[1]; Alexandre Uhlmann[2]; Michele Ribeiro Ramos[1]
Universidade Estadual do Tocantins[1]; Embrapa Florestas[2]

Intensive and inadequate soil use can lead to degradation, which is often irreversible. In this way, it is necessary to monitor them in order to preserve their quality so that it can provide good productivities. Biological attributes are used with this function. The objective was to evaluate the metabolic quotient obtained through biomass and microbial respiration in different soil uses in the cerrado region, a biodiversity hotspot on the planet. The evaluated treatments were: pasture, forest planting of Eucalyptus spp., Organic banana and plowed soil. Soil samples were collected from horizon A. The metabolic quotient was calculated by the ratio between basal respiration and the carbon of the microbial biomass. Microbial respiration (RMS) was determined by the NaOH solution capture method of CO_2 evolved from the soil using incubation chambers. Soil microbial biomass (BMS) was determined by the Substrate Induced Breathing (RIS) method. The mean values found for RMS were: 0.28 C-CO_2 mg Kg^{-1} h^{-1}, 0.84 C-CO_2 mg Kg^{-1} h^{-1}, 1.08 C-CO_2 mg Kg^{-1} h^{-1}, 54 C-CO_2 mg kg^{-1} h^{-1}, respectively, plowing, pasture, forest planting and organic banana cultivation. The higher release of CO_2 in the latter is due to greater biological activity, caused by the greater availability of organic material. For BMS, the average result was 65.21 µg C g^{-1}, 181.2 µg C g^{-1}, 237.3 µg C g^{-1} and 237.3 µg C g^{-1}, respectively eucalyptus, grassland, and organic banana. Similar result in the last two treatments, justified by the higher amount of organic matter, due to the organic fertilization and manure of the animals in the pasture. The low values in the eucalypt forest are justified by the presence of antimicrobial substances in litter that hinder the survival and growth of some microorganisms. Plowed soil showed the lowest value due to soil exposure, no vegetation cover, greater application of agrochemicals and greater soil rotation. Absence of vegetation on the soil surface, maintains absence of microbial activity and therefore the lowest metabolic quotient. In the cultivation of banana and forest the quotient were the largest, due to the greater presence of organic material and soil cover. Incorporation of crop residues increases the metabolic quotient. Plowed soil had the lowest metabolic activity. And the eucalyptus forest and organic banana cultivation are releasing more carbon, lowering the carbon content in the soil.

(2235 - 344) Microbial Biomass Carbon and Edaphic Fauna under the influence of Coverage Plants with the use of Calder Ash.

Rodrigo Roani[1]; Jonas Guerra[1]; Wilson Galli[1]; Luís Carlos Iuñes de Oliveira Filho[2]; Cristiano Nunes Nesi[1]; Mauricio Vicente Alves[1]
(UNOESC) University of West of Santa Catarina[1]; Santa Catarina State University[2]

Adequate soil management that contributes to the increase or conservation of quality is important in current agricultural practices, seeking alternatives such as the use of cover crops together with ash being an ally to the soil as a good secondary material. The study was implemented at the experimental unit of Unoesc - Xanxerê, from July 2016 to March 2017. The soil of the region is classified as a dystrophic Red Latosoil (Oxisoil). Four treatments were implanted: 1) Fallow (without cover plants and without application of ash); 2) Fallow + ash; 3) Cover crops without ash application (CC); and 4) CC within ash application. In the CC plots, a consortium was used between vetch (40 kg ha^{-1}) and oat (50 kg ha^{-1}), grown under no-tillage system. In the treatments with ash application, the dosis applied was 10500 kg ha^{-1}, being calculated according to the content of K present in the ash along with the need for the crop. The ash used was provided by the boiler of a pulp mill. The edaphic fauna was evaluated in two seasons; the first in the cover plants flowering, and a second sampling in the corn crop, using *pitfall traps traps*, in each plot with 8x10 mts measures, a trap was installed. At the same time the Carbon of the Microbial Biomass (CMB) was evaluated. Samples 0-20 cm of soil depth were taken in the same treatments of the fauna, and the samples composed of 7 points per plot were collected on the same day of the allocation of the fauna traps during the winter season. After sampling and screening, the indexes of Richness and abundance, Dominance,

Simpson, Shannon, Evenness, Margalef, Equitability were evaluated. The use of ash and cover crops did not influence the abundance and richness of the edaphic fauna in the winter. However in the summer the vegetal remains of the previous cultures served as food for the fauna and influenced in these indices: Richness; Abundance; Evenness. The CC + ash treatment is more abundant with greater richness than the others and with greater diversity of species. For the Evenness and Equitability index showed that there was no pattern of distribution of the species. Regarding CMB, the use of CC + ash, and ash favored the development of soil microbial biomass in relation to other treatments. It can be observed that ash favored microbial activities along with cover crops. For the fauna of the soil the positive effect of the CC + ash happened in the summer season.

(2720 - 1618) Native rhizobia effectiveness from legume-based silvopastoral systems

Adriana Bezerra dos Santos[1]; Mario de Andrade Lira Junior[1]; Giselle Gomes Monteiro Fracetto[1]; Felipe José Cury Fracetto[1]; Carina Vasconcelos Moreira Tavares[1]; Leandro Reis Costa Santos[1]; Aleksandro Ferreira da Silva[1]
Universidade Federal Rural de Pernambuco[1]

Forage tree legumes on silvopastoral may contribute to the systems by biological nitrogen fixation, since most form rhizobial symbiosis. This study aimed to evaluate the relative efficiency of 69 rhizobial strains isolated from such systems. These were captured from soil samples from silvipastoral systems formed by *Gliricidia sepium* ((Jacq.) Steud) or *Mimosa caesalpiniifolia* (Benth.) with signal grass (*Brachiaria decumbens* (Stapf.)) or by sole signal grass, under greenhouse conditions, and including a nitrogen fertilized treatment with the equivalent to 50 $kg.ha^{-1}$, and two strains recommended for commercial inoculant production (BR3267 and BR3262) on cowpea (*Vigna unguiculata* ((L.) Walp)). Harvest was 35 days after inoculation, and measured Shoot (SDM), Root (RDM) and Nodule (NDM) dry masses, nodule number, relative efficiency to nitrogen control (RENC), to uninoculated control (REUC) and to recommended strains (RERS). When strains were grouped based on the silvipastoral system, those isolated from the sole signal grass presented higher SDM, NN, RDM, RENC and RERS than those from the silvipastoral systems. These may be due to the highly promiscuous nature usually attributed to cowpea rhizobia, coupled with the presence of several native forage legumes as infestants in the sole signal grass pasture, and natural selection by these legumes for more efficient strains due to the competition with the grass for available nitrogen. On the other hand, it is now recognised that Brazilian *Mimosa* species tend to form most of the symbiotic associations with β-rhizobia, which are not usually as infective on cowpea, but this is not well understood for *G. sepium*.

(1307 - 867) Phosphatase activity in sugarcane fields after application of organic compost and inoculation of P solubilizing bacteria

Antonio Marcos Miranda Silva[1]; German Andres Estrada Bonilla[1]; Elke Jurandy Bran Nogueira Cardoso[1]
ESALQ/USP[1]

Phosphorus (P) is an essential element for microbial metabolism and plant growth. However, in tropical soils, most of the P is unavailable, present in a form adsorbed to soil colloids. Inoculation of P solubilizing bacteria (PSB) into a mixture of composting wastes of the sucro-energetic industry (filter cake and ashes) was shown to produce an organic compost enriched in P, which can substitute for synthetic fertilizers, constituting a biotechnological alternative for the synthetic fertilizers used in traditional sugarcane cultivation. The P enriched compost was applied in a field experiment with sugarcane, in a randomized block design with a (3 x 2 + 1) factorial scheme. The first experimental factor was the P source, either compost produced without additional P (C), or compost prepared with Araxá rock phosphate (C+RA). The second factor was with or without field inoculation of PSB. The additional treatment consisted of the traditional formulation of synthetic fertilizers. We monitored the activity of acid and alkaline phosphatases in the soil at 6 and 12 months after sugarcane planting. There was no difference between the traditional and the biotechnological treatments for enzyme activity, but we found a significant interaction (Tukey's test $p \leq 0.05$) between P source and bacterial inoculation, only in the activity of the alkaline phosphatase, at both harvesting periods. At 12 months after planting, the treatments C and C+RA, with bacterial inoculation, did not differ in alkaline phosphate activity. Without bacterial inoculation, however these two treatments differed, C+RA showing higher values than C. Inoculation together with C+RA showed a 1.6 times higher phosphatase activity, varying from 30.75 to 49.41 µg PNF. g^{-1} soil . h^{-1}, while in the treatment C, inoculation increased phosphatase activity by 2.4 times, varying from 17.98 to 43.17 µg PNF. g^{-1} soil . h^{-1}. This increase in the activity of alkaline phosphatase may be the result of an increased demand of P to sustain the metabolism of the inoculated bacteria or even of other interacting microorganisms. Since this effect was found only for the alkaline phosphatase, these data highlight the supposition of many alkaline microsites present during the composting process.

(7590 - 830) Potential of Plant Growth Promoting Rhizobacteria biofertilizer to increase plants production efficiency

Kunlayakorn Prongjunthuek[1]; Suphakarn Luanmanee[1]; Phatchayaphon Meaunchang[1]
Department of Agriculture[1]

Department of Agriculture (DOA), Thailand has developed Plant Growth Promoting Rhizobacteria (PGPR) biofertilizer which is categorized into 3 products i.e. PGPR-I for corn and sorghum, PGPR-II for rice, and PGPR-III for sugarcane and cassava. Since each product contains different species of rhizobacteria, the product efficiency to each crop was investigated. First, an investigation of PGPR-I efficiency on growth and yield of maize and sweet corn grown on sandy loam and clay loam was carried out during 2011 to 2013. The results showed that maize and sweet corn differently responded to the PGPR-I. Application of the PGPR-I in sandy loam showed highly response of maize and sweet corn to PGPR-I than in clay loam. This could reduce N, P and K fertilizer application by 50% of the recommendation rate. Second, a study of PGPR-II efficiency on rice growth and yield was conducted in dry and rainy seasons during 2015 in comparison to none application of the PGPR-II. The results showed that there were not significant different in percentage of filled grain but the application of PGPR-II significantly increased straw dry weight and grain yield. This could reduce production cost about 22.5%. Third, a determination of the PGPR-III efficiency on growth and yield of sugarcane grown on sandy loam soil was carried out during 2010 to 2011. The result showed that the PGPR-III inoculated did not significantly promote height, stalk diameter and aboveground fresh weight. However, it was found that the PGPR-III application significantly increased stalk number per tiller, cane yield and sugar yield about 36%, 11.2% and 13.8%, respectively. In addition, the use of PGPR-III can decrease N and NPK fertilizers application about 50% and 25% of recommendation rate, respectively. Forth, efficiency of PGPR-III application on growth and yield of cassava grown on sandy soil was

investigated. The result showed that the application of PGPR-III significantly increased plant height, fresh root yield as well as starch yield about 5.1%, 5.8% and 4.2%, respectively as compared to non PGPR-III application. Moreover, the application of the PGPR-III in combination with chemical fertilizer at 100% of recommendation rate showed increasing of fresh root yield about 8.98% as compared to application of only chemical fertilizer. This could reduce N fertilizer application for cassava production in sandy soil by 20% of the recommendation rate and subsequently reduced production cost.

(7192 - 1865) Response of N cycling microbes to a urease inhibitor and a nitrification inhibitor in 3 land uses

Aineah Obed Luchibia[1]; Suter Helen[1]; Shu Kee Lam[2]; Jizheng He[2]

The University of Melbourne[1]; [2]

The application of N-(n-butyl) thiophosphoric triamide (NBPT) and 3,4-Dimethylpyrazole phosphate (DMPP) has been shown to be effective in mitigating nitrogen (N) loss from agricultural systems. However, there is still need for more information on how these chemicals affect N-cycling processes and dynamics of associated microbes in the soil. To assess the effect of the application of urea fertilizer amended with NBPT or DMPP on N transformations in soil and dynamics of associated microbial communities, a 28-day microcosm incubation experiment was established at 25^{O}C and 60 % water-filled pore space (WFPS), using 5 soil types with different physiochemical properties from three land uses. The treatments included Control, urea, Urea + NBPT, Urea+ DMPP and Urea + NBPT + DMPP. Data was collected by destructive sampling of soil to study mineral N dynamics on days 0 (4 hours), 1, 2, 4, 7, 14, and 28, after treatment application, and DNA extraction for microbial studies on days 0, 7, and 28, after treatment application. Urea addition significantly increased ammonium and nitrate concentration in soil compared to control. However, addition of urea amended with NBPT significantly reduced soil ammonium concentration but had little or no effect on nitrate concentration, size of ammonifying and nitrifying microbes. Addition of urea amended with DMPP significantly reduced nitrate concentration and size of nitrifying microbes, but significantly increased ammonium concentration compared to urea alone. The effect of the inhibitor chemicals on mineral N dynamics did not last long in the soils with higher organic carbon and low pH compared to those with neutral to alkaline pH and low organic carbon and this was linked to the varied microbial activities in the soils and the sorption of these chemicals to soil particles, influencing the activity and degradation rates of NBPT and DMPP.

(8223 - 662) Rice rhizosphere and nitrogen input influence microbially mediated nitrogen loss and retention in Australian rice paddies

Arjun Pandey[1]; Helen Suter[1]; JiZheng He[1]; Hang-Wei Hu[1]; Deli Chen[1]

The University of Melbourne[1]

Microbial nitrogen (N) transformation such as denitrification, anaerobic ammonium (NH_4^+) oxidation (anammox), biological N_2 fixation (BNF), and dissimilatory nitrate (NO_3^-) reduction to ammonium (DNRA) can influence the N use efficiency of rice paddies. These processes are often studied separately which makes it difficult to understand their relative importance in N cycling. In addition, the rhizosphere and non-rhizosphere of rice and the N input affect denitrification and BNF but limited information is available about how these factor affect DNRA and anammox. Therefore, we investigated the processes rates and the related microbial gene abundance using paddy soils from the Finley, Jerilderie and Coree in Australia. Rice was grown in pots in glasshouse with (+N) and without (-N) for 75 days and the soils from the rhizosphere and non-rhizosphere were collected separately and used for $^{15}NO_3^-$ tracer, acetylene reduction assay (ARA) and qPCR assay in laboratory. The results showed that the denitrification dominated the N_2 production, consuming 14-30% of the NO_3^- available in the soils. Anammox was only detected in the Finley soil and used only 1.5% of the soil available NO_3^-. Denitrificaion was significantly lower ($p < 0.05$) in the rhizosphere than in the non-rhizosphere in all the soils. Denitrification was also significantly lower in the +N treatment than in the –N treatment. The abundance of the *nosZ* gene in denitrifiers followed the similar trend as denitrification. Anammox activity and the associated gene, *hzsB*, abundance did not show any effect of the N input or the rhizosphere and non-rhizosphere. There was no significant difference in DNRA between the rhizosphere and non-rhizosphere but the N input reduced DNRA in all the soils. DNRA consumed 12-20% of NO_3^- available in the paddy soils. The *nrfA* gene abundance responsible for DNRA activity was similar between the rhizosphere and the non-rhizosphere except in the Jerilderie and the gene abundance mostly remained unaffected by the N input. The ARA showed that the BNF added 0.02-0.25 µg N g^{-1} soil day^{-1}. The rhizosphere and non-rhizosphere did not have any effect on the BNF and the associated, *nifH*, gene abundance. Similarly, the N input had no effect on the BNF and the *nifH* gene abundance except in the Coree soil. This study demonstrates that the localized conditions in the rice paddies affect N loss but not the N retention, and the N input enhances the N loss and reduces the N retention in rice paddies.

(5226 - 2939) Soil Enzyme Activities as a Soil Quality indicator under Tillage and No-Tillage Management

Nicola Lorenz[1]; Linda K Dick[1]; Nathan R Lee[2]; Cliff Ramsier[3]; Richard P Dick[2]

The Ohio State University[1]; The Ohio Stae University[2]; Ag Spectrum[3]

The condition of soils is fundamental for delivering ecosystem services, particularly for agriculture. Standards for soil quality indicators have been difficult to establish because of the complexities of the interrelated physical, chemical, and biological properties of soils. To be useful and guide land management, measures are needed that detect changes rapidly (a few years); can be calibrated and interpreted independent of soil type (a major obstacle for soil measures as soil quality indicators); have high throughput capability, being cost-effective, and have seasonal stability. We evaluated different farmer's fields in the US (Ohio, Illinois, and Iowa) under *Zea mays* (corn) and *Glycine max* (soybean) to compare their tillage systems (no tillage and tillage). A total of 298 soil and crop yield samples were collected in 2015, 2016 and 2017 at four different spots on a single field by considering a functional soil classification by using the Agsoil Analytics functional map technology. To further broaden the study, we collected 368 complementary soil samples from long-term crop management research sites across the US (19 states). Selected enzyme assays were run and enzyme activity ratios were calculated and will be presented (activity per unit soil organic C or clay) and will be assessed for their calibration potential to detect land management practices, independent of soil type. Furthermore,

mechanistic understandings of enzyme activity as a soil indicator will be determined by profiling microbial communities and comparing and correlating enzyme data with soil chemical and soil physical properties. Finally, soil properties will be correlated with yield and soil quality indicators will be presented.

A dairy cattle of great importance for the Northwest Region of Rio Grande do Sul (RS), where predominantly family farmers have increasingly sought to optimize an activity, reducing costs and improving pastures. Soil fauna plays important roles in soil, essential for forage productivity and quality. However, is little understood the influences of the pasture species under different fertilization systems on a soil fauna. The objective of this work was to study a composition of the edaphic fauna in areas with forages submitted to different fertilization systems, in the Northwest Region of RS. The State University of RS (Uergs), Unit Três Passos, carried out the research. The experiment was carried out in a randomized complete block design with 4 replicates, with treatments as follows: T1: Jiggs (J) + PS (pig slurry); T2: J +CM (cattle manure); T3: J + NPK; T4: J + Without Fertilizer (WF); T5: Forage Peanut (FP) + PS; T6: FP + CM; T7: FP + NPK; T8: FP + WF; T9: Consortium (J + FP) + PS; T10: Consortium + CM; T11: Consortium + NPK; T12: Consórcio + WF, with T13: fallow (F) and T14: native forest (NF), as a parameter. In order to survey the edaphic fauna, catch traps are installed following the PROVID method (ANTONIOLLI, 2006), in two seasons (winter and spring). To abundance, diversity and wealth of edaphic fauna were determined, in addition to the Shannon (H) and Simpson (Is) Diversity indices. The data were submitted to analysis of variance (ANOVA) and as averages compared by the Tukey test ($p < 0.05$). In relation to abundance there was no statistical difference between treatments, however, with the exception of T3, T5, T9, F and NF, in the winter, the youngest presented the highest abundance in the spring collection, with emphasis on T1, with 579 organisms. For a richness it is not a differential between the treatments, however, T8, T7 and T2 presented superior richness in the spring collection, in relation to winter. The H was numerically higher in the T11, T9, T3 and NF, respectively, in the winter collection, considering the other treatments and both collection season. The Is was numerically higher in the T1, T11, NF, and T7, respectively, in the spring collection, considering the other treatments and both collection season. There was no influence of pasture species or fertilization systems on an edaphic fauna, which varied according to a collection season.

(5737 - 1825) Soil microbial activities are affects by straw of cover plants cultivated in the savannahSoil microbial activities are affects by straw of cover plants cultivated in the savannah

Lizandra de Sousa Luz Duarte[1]; Sarah Priscilla do Nascimento Amorim[1]; Daniela Fernandes de Oliveira[1]; Cíntia Bezerra Rocha[1]; João Carlos Medeiros[2]; Adriana Miranda de Santana Arauco[1]; Cácio Luiz Boechat[1]
Cinobelina Elvas Campus, Federal University of Piauí[1]; Federal University of Sul da Bahia[2]

Cover crop straw is important because it influences the microbiological attributes of soil, provides the highest carbon levels in humic fractions, increases water infiltration, reduces surface runoff and erosion, and serves as a primary form of organic matter input that enhances soil biological activity. The objective of this study is to evaluate the effect of straw of different plant covers on the microbial activity in Cerrado Biome soil. The experiment was conducted using a BOD incubator at a controlled temperature of 28 ± 2 ^{o}C. The amount of straw incorporated into each treatment was 10 Mg ha^{-1} providing an amount of 16 to 24 kg N ha^{-1} and 51 to 54 kg C ha^{-1}. Treatments were distributed in a completely randomized experimental design in a factorial scheme 8 x 7 + 4, with seven types of straw from cover plants (MI) millet (*Pennisetum glaucum*); (BR) *Brachiaria brizanta*; (CS) *Crotataria spectabilis*; (CO) *Crotalaria ochroleuca*; (GA) Guandu anão (*Cajanus cajan*); (GF) guandu Fava (*Cajanus cajan*) and (MP) *Mucuna aterrima* incorporated into the soil and soil without incorporation of straw (control), evaluated at 7; 14; 21; 28; 42; 63 and 105 days after incubation, with three replicates plus four blank controls (without soil and straw). Soil basal respiration (SBR) at 7, 14 and 105 days after incubation was lower in the control treatment (soil without plant cover straw) and higher values were found in the other treatments with values ranging between 66.45 (CO) to 86.29 (CS) at 7 days; between 107.71 (BR) to 133.17 (GA) at 14 days and, between 46.04 (MP and GA) to 75.18 mg CO_2 100 g^{-1} h^{-1} (MI) at 105 days. At 21 days of incubation the SBR were higher in the BR, CS, CO and GA treatments, followed by MI, MP and GS and lower SBR were observed in the control treatment. At 28 days no significant differences were found between studied treatments, except in the MP, followed by the control with worse results for this variable. The same results were found for MP and MI at 42 days, followed by the control. At 63 days of incubation the higher values were observed in the MI, CS, CO and GF treatments and the lowest value in the control. In the tropical climate the soil microbial stimulation was highly sensitive to the quality of the organic residues, for the C/N ratio. Organic material applied to soil by cover plant straw increases soil microbial activity, measured by the release of carbon in the form of carbon dioxide (C-CO_2), both with legumes and grass straw.

(1778 - 406) Soil microbial biomass and activity in an integrated crop-livestock system after 15 years under different grazing intensities

Ângela Denise Hubert Neufeld[1]; Hazael Soranzo de Almeida[1]; Daiane Dalla Nora[1]; Ibanor Anghinoni[2]; Rodrigo Josemar Seminoti Jacques[1]
Department of Soil Science, Federal University of Santa Maria, Roraima Avenue, 1000, Santa Maria, RS, 97119-900, Brazil[1]; Department of Soil Science, Federal University of Rio Grande do Sul, Bento Gonçalves Avenue, 7712, 91501-970, Porto Alegre, RS, Brazil[2]

Integrated crop-livestock systems (ICLS) can improve soil chemical, physical and biological characteristics. However, intensive grazing may outweigh these benefits and cause serious damage to ICLS. Microorganisms are sensitive bioindicators and may indicate changes to soil quality. The aim of the present study was to investigate the

effects of 15 years of intensive grazing in an integrated soybean-beef cattle system on soil microbial biomass and respiration, identifying which edaphic factors most affect these parameters. The experiment was conducted over a 15-year period in a 23-ha area, characterized by the crop succession *Glycine max* (summer grain production) and *Avena strigosa + Lolium multiflorum* (winter pasture). The treatments consisted of four grazing intensities: intense (10-cm grazing height), moderate (20- and 30-cm grazing heights), light (40-cm grazing height) and no grazing (control plots). A randomized block experimental design was used, with three replicates per treatment. The size of the plots with grazing varied from 0.9 to 3.6 ha. All plots had continuous grazing in winter and three tester animals, resulting in the different grazing heights tested. Four samplings were performed between 2014 and 2016, two following the grazing season and two following the soybean harvest. The soil basal respiration and microbial biomass carbon content were evaluated. The soil chemical and physical parameters and plant cover parameters were measured for correlation. Soil respiration and microbial biomass carbon content were highest for the treatments without grazing and with higher grazing heights. Negative effects on physical soil characteristics were observed for the treatment with the lowest grazing height, resulting in decreased soil moisture and microbial biomass and activity.

Keywords: microorganism, metabolic quotient, bioindicators, soybean-beef cattle system, sustainability.

(5154 - 2538) Soil microbial biomass carbon under alternative forage crops over weather seasons

Igor Alexandre de Souza[1]; Nicholas D. Warren[2]; Jörg Schnecker[2]; Adalfredo Rocha Lobo-Jr[1]; Richard G. Smith[2]; A. Stuart Grandy[2]; Andre F. Brito[2]

Federal University of the Jequitinhonha and Mucuri Valleys - UFVJM[1]; University of New Hampshire - UNH[2]

Even in small amounts, microbial biomass plays a fundamental role in soil organic matter dynamics. Microbial biomass is positively related to the return of carbon to the soil. This research investigated how alternative forage crops and weather seasons influence the soil microbial biomass carbon. The study was conducted at the University of New Hampshire Kingman Research Farm in Madbury, NH (43°11'N 70°56'W), during spring, summer and autumn of 2015. The dominant soil type is a sandy loam, with an average annual temperature of 8.1°C and annual precipitation of 1108 mm. Based on previous studies 14 alternative forage crop species were selected according to seasonal specificities. Spring were selected wheat, triticale, barley, cereal rye and hairy vetch. Summer were, BMR Sorghum, buckwheat, teff, millet, oats and chickling vetch. For fall were, forage radish, oats, canola, wheat, triticale, and crotalaria. The experimental design and arrangement of blocks and treatments were randomly allocated. Seeds were purchased and the seeding rate defined according to the recommendations. Samples for spring were collected on the same day when the plants were harvested. Soils collected in summer and autumn were collected at the seeding day, in the middle and at the end of the cycle of the plants. We collected three soil cores, 15 cm deep by 9 cm diameter, at each time point. Soil microbial biomass carbon (MBC) were determined using the chloroform fumigation and extraction method. The extracts were analyzed on a TOC analyzer and the extraction efficiency factors 0.45 was used. ANOVA were performed, according to a randomized complete block design ($p < 0.05$). For the spring the MBC averages ranged from 304.8 to 387.3 µg C g soil^{-1}. The summer cultivated plants did not have conditions to influence the communities or the activity of the decomposing microorganisms, the contents ranged from 662.1 to 847.6 µg C g soil^{-1}. The MBC content found at 10 days after seeding was 909.5 µg C g soil^{-1}, and was higher than the other times. For the fall MBC, the variation was particularly interesting, because during the time of collections reduced and increased ($p<0.05$). At 7 days after seeding the MBC was 600.4 µg C g soil^{-1}, at 36 days decreased ($p <0.05$) to 236.0 µg C g soil^{-1}, and increased again ($p <0, 05$) to 808.3 µg C g soil^{-1} at 66 days. The microbial biomass does not change considerably when the soil is cultivated by the forage species studied and the seasons can change de MBC levels.

Keywords: Alternative forages crops; microbial biomass carbon; weather seasons.

(5352 - 1155) Soil Microbial Community Assessment of Highland Vegetable Production Systems in La Trinidad, Benguet, Philippines

Karen S. Bautista[1]; Jacqueline S. Rojales[1]; Vicky T. Dimaano[1]; Digna R. Allag[1]; Luis Angelo A. Cortez[1]; Jerry Paul P. Arciaga[1]; Melody M. Orogo[1]

Bureau of Soils and Water Management[1]

Soil microorganisms are considered as sensitive indicators of soil health. Community-Level Physiological Profile (CLPP) analysis is an innovative, sensitive, and rapid method to assess functional diversity and rate of activity of soil microbial community. During the April 2016 and 2017 dry seasons, soil samples were collected from vegetable farms practicing organic (ORG), low-external input (LEI), and conventional (CON) production systems in La Trinidad, Benguet, Philippines. The samples were properly labeled, stored, and brought to the laboratory for soil microbial CLPP analysis using the Biolog^{TM} Microstation System. Shannon Index of Diversity (H) and Average Well Color Development (AWCD) were determined. H quantifies the functional microbial diversity, while AWCD quantifies the overall rate of activity (in terms of density and carbon use capability) of the microbes inhabiting the soil. Using a two-way ANOVA, results showed that while there were significant differences found for H values per year ($p < 0.001$), there were no significant differences seen for the value in terms of production system ($p = 0.0552$), which is coupled with it not having any significant interaction with the year ($p = 0.5610$). However, in terms of AWCD, a significant interaction was noted ($p = 0.0288$), which prompted an additional analysis of simple main effects for the metric. Results of the aforementioned analysis yielded the following: firstly, AWCD values were generally higher from farms collected during the 2017 dry season with the exception of ORG farms, which remained statistically similar to the value it had the year before; secondly, during the 2016 dry season, ORG farms exhibited a significantly higher AWCD compared to the other two systems; and lastly, no significant differences for AWCD was seen per production system during the dry season of 2017. These results suggest that environmental factors exert a greater influence on soil microbial diversity regardless of production system. The production system affects the rate of density, activity, and carbon use capability of inhabiting soil microbes. As seen during the 2016 dry season, a lesser rate of microbial activity was found in LEI and CON farms as compared to ORG farms. Since environmental factors are also dynamic, their contribution to microbial activity is not constant on a yearly basis, which explains the lack of significant differences in AWCD per production system during the 2017 dry season.

(5723 - 1862) Soil microbial ecology of Laurel-Leaved and Cryptomeria japonica Forests

Ayuko Itsuki[1]; Sachiyo Aburatani[2]
NITNC[1]; NIAIST[2]

In forest ecology, microorganisms decompose organic soil matter from plant residue as a source of nourishment, which they then absorb. During this process, microorganisms produce enzymes that convert organic matter to carbon dioxide, water, and other compounds. The biochemical metabolism of microorganisms can therefore be indirectly investigated by measuring the activities of these enzymes. We assessed the soil microbial ecology (microbial numbers, enzyme activities, and soil respiration rate) of the organic and mineral soil layers of laurel-leaved and Cryptomeria japonica forests in the Kasugayama Hill Primeval Forest (Nara, Japan). The numbers of bacteria and fungi, and soil respiration rate were higher in the deeper horizons (F and H) of the organic layer than in the mineral soil layer. This suggests that active microbial metabolism preferentially occurs in organic soil layers. The uppermost L horizon consists of high levels of fresh plant residue and high C/N ratio, but low levels of moisture content and microorganisms. In the F horizon, the proportion of microorganisms that absorbed plant nutrients increased as decomposition progressed. In the H horizon, which contains decayed organic matter, the proportion of these microorganisms in the soil decreased. The laurel-leaved organic layers exhibited more soil microorganism activity than C. japonica organic layers, possibly due to differences in forest vegetation, which appear to influence several salient soil properties—particularly the pH and C and N content in the F and H horizons. This result is consistent with the fact that laurel-leaved forest soil generally contains more easily decomposable organic matter, such as water-soluble polysaccharides, hemicellulose, cellulose, and protein, and less decomposable organic matter, such as lipid and resin.

(5312 - 998) Soil quality in Integrated Crop-Livestok-Forest systems can be evaluated by biochemical indicators

Leciana de Menezes Sousa Zago[1]; Samantha Salomão Caramori[1]
Universidade Estadual de Goiás, Câmpus CET, Laboratório de Biotecnologia, Anápolis, CEP: 75132-903, Brazil.[1]

Land use changes alter the diversity of microorganisms in the soil, microbial processes, nutrient cycling and consequently the soil quality. The replacement of some conventional crop systems by integrated crop-livestock-forest systems (ICLFS) can input nutrients in the soil and provide better conditions to both agricultural and native ecosystems. Here we evaluated the enzymatic and microbial activities associated with carbon cycling, phosphorus, nitrogen and sulfur in soils in ICLFS areas, in comparison to conventional livestock and native Cerrado. Three soil composite samples were collected from five areas (ICLFS after three years (ICLFS3), five years (ICLFS5) and eight years (ICLFS8), livestock and native Cerrado), at the 0-10 cm, in Cachoeira Dourada, Goiás, totaling fifteen composite samples. The enzyme activity was monitored spectrophotometrically at 400nm (β-glucosidase, acid phosphatase, arylsulfatase), at 405nm for glycine aminopeptidase and at 460nm for phenoloxidase using specific substrates. In addition, the variations on microbial biomass carbon (MBC) were evaluated. Data were analyzed using ANOVA and Tukey test ($p < 0.05$). The behaviour of the five enzymes showed variations ($p<0.05$) in the different sampling areas. The activity of β-glucosidase and acid phosphatase were higher in soils of native Cerrado and ICLFS3, respectively. Both enzymes presented the minor values for ICLFS8, which can be explained by the absence of fertilization since four years ago. For arylsulfatase and glycine aminopeptidase, the major values were in native Cerrado soils, followed by ICLFS systems. Phenol oxidase was the only enzyme to respond better in ICLFS8, probably due to the prevalence of lignin in comparison to the other nutrients in soil. The MBC was higher in native Cerrado soils, but presented significant values in fertilized ICLFS areas. In general, pasture soils presented the minor enzyme activity values and the minor MBC values. The soil biochemical analyzes showed that hydrolase activities (β-glucosidase, acid phosphatase, aminopeptidase), oxidorreductase (phenol oxidase), sulfatase (arylsultase), and MBC are under land use and tillage conditions and can be altered as long as ICLFS is established. Moreover, those results demonstrate the potencial of use soil enzymes in order to evaluate the quality of agricultural production integrated systems.

(7848 - 778) Spider community response to grazing in an integrated crop-livestock system

Joice Aline Freiberg[1]; Cristian de Sales Dambros[1]; Everton Nei Lopes Rodrigues[2]; Paulo César de Faccio Carvalho[3]; Rodrigo Josemar Seminoti Jacques[1]
Federal University of Santa Maria[1]; University of Vale do Rio dos Sinos[2]; Federal University of Rio Grande do Sul[3]

Soil tillage, sowing, harvesting, pesticide application, and the removal of plant cover can reduce the abundance and richness of soil invertebrates that are essential to soil health. Spiders are among the most important top predators in crop systems and, as predators, have the potential to regulate the dynamics of entire food webs. In spite of their importance, no study has investigated the dynamics of these predators in integrated systems that have a potentially lower impact on species diversity than traditional cultures. We investigated the effect of grazing intensification on the abundance and species richness of soil spiders in an integrated crop-livestock system (ICLS). The study was conducted in an ICLS in São Miguel das Missões county, Rio Grande do Sul (RS) State, Southern Brazil (28°56'14.00 ''S, 54 °20'45.61''W, 417m). Since its installation in 2001, the experiment is cultivated with the rotation of mixed oat (*Avena strigosa* Schreb.) and annual ryegrass (*Lolium multiflorum* Lam.) for continuous cattle grazing in winter and soybean (*Glycine max* L.) for grain production in summer. The treatments were based on five grazing intensities: 10, 20, 30 and 40 cm of grazing height and control plot (no grazing), distributed in a randomized complete block design with three replications. Spiders were sampled with pitfall traps immediately after cattle removal from pasture in November 2014 and November 2015. Nine pitfall traps were sampled in grazing plots and three to seven pitfalls were sampled in non-grazing plots. The effect of grazing height on the average abundance of spider species was tested using a generalized linear mixed effect model (GLMM), with a Poisson error distribution. We collected 1,385 individuals and 34 species. Most species were rare and showed a weak association with grazing intensity. Nevertheless, the lower pasture heights favored species such as *Laminacauda montevidensis* Millidge, 1991 and *Mermessus* sp., whereas *Glenognatha lacteovittata* (Mello-Leitão, 1944), *Ostearius melanopygius* (O. Pickard-Cambridge, 1880) and *Styposis selis* Levi, 1964, responded positively to increased pasture height. These five spider species can be used as bioindicators of grazing intensification in ICLS.

(8524 - 287) Straw biochar amendment suppressed Phytophthora blight of pepper by changing soil microbial community with proper application technology

Yan Ma[1]; Guangfei Wang[1]; Roshini Govinden[2]; Hafizah Yousuf

Chenia[2]
Institue of Agricultural Resources and Environment, Jiangsu Academy of Agricultural Sciences[1]; School of Life Sciences, University of KwaZulu-Natal[2]

Biochar functions potentially to improve soil performance. Phytophthora blight is one of the most widespread and severe soil-borne diseases for pepper production around the world. To ascertain the control effect of biochar against Phytophthora blight of pepper and its underlying microbial mechanisms, we carried out the pot experiment using straw biochar with different properties and application technologies and proposed the microbial mechanisms for disease control. Straw biochar with high nutrient-related indices such as electric conductivity (EC), ash content, and available P and K content had a high control efficacy. The application rate and application time of biochar had significant influence on disease control of Phytophthora blight of pepper . An optimal application technology were obtained based on pot experiment. Biochar had different impact on various microorganisms of soil. A significant change of the soil fungal community structure was observed, and the relative abundances of beneficial fungi and pathogenic fungi were impacted with opposite change trend. However, biochar had an insignificant influence on the soil bacterial community structure. Biochar application increased not only the populations of *Trichoderma spp.*, *Penicillium spp.*, *Aspergillus spp.*, *Chaetomium globosum*, *Bacillus spp.*, and *Pseudomonas spp.*in soil according to both plate cultivation and RT-PCR determination but also the proportion of antagonistic fungi and bacteria . All the potential biocontrol microorganisms were screened out from biochar- amended soil and their ability for suppression of Phytophthora blight of pepper was confirmed by subsequent pot experiments. Our results showed that biochar-mediated pepper blight control is a comprehensive effect of the improvement of soil properties. However, the improvement of soil microbial property is the main mechanism. This study provides approaches for biochar selection and application to facilitate the control of Phytophthora blight of pepper and other soil-borne diseases, and offers a theoretical data to strengthen biochar-mediated disease control effect .

(3214 - 3122) Sugarcane straw removal does not change C and N dynamics from sugarcane trash mulch

Guilherme Dietrich[1]; Adriane Luiza Schu[1]; Patrick Leal Pinheiro[1]; Sylvie Recous[2]; Douglas Adams Weiler[1]; Mathias Roberto Leite Rambo[1]; Sandro José Giacomini[1]
Federal University of Santa Maria[1]; Université Reims-Champagne Ardenne[2]

The partial straw removal (SR) from field after sugarcane harvesting in the green cane trash blanketing system should affect the mulch decomposition and C and N dynamics, because it increase the proportion of straw in contact with soil. However, recent studies indicate that the decomposition is not altered with SR and in conditions of high amount of straw the decomposition may be greater without than with SR. The causes of these results are uncertain. Here, we studied the dynamics of decomposition and C and N loss over a year from three trash quantities (4, 8 and 12 Mg ha^{-1}) left on soil surface, in Santa Maria, Rio Grande do Sul state, Brazil. We specifically investigated how trash quantities creates a spatial heterogeneity on C and N loss within of the mulch. Thus, after sugarcane cane plant harvest, we placed the trash into open-wooden frames with a 2-mm aperture mesh at the bottom and we stacked either a single layer of 4 Mg DM trash ha^{-1} (L/T), or 2 layers (L+T) or 3 layers (L+M+T) on soil surface. L (low), M (medium) and T (top) layers were separated by a malleable 10-mm synthetic mesh with wide aperture to allow each layer to be sampled independently. Plots were fertilized with 100 kg N ha^{-1}, 53 days after trash addition on soil surface. We quantified C and N contents and humidity of the remaining mulch in each layer. Soil volumetric water content was measured continuously using sensors. The decomposition and C and N loss was not affected by SR and by N fertilization. C and N loss of 4 Mg ha^{-1} was similar to T layers of 8 and 12 Mg ha^{-1} after a year (71% for C and 49% for N); although the trash of the T layer was not in contact with the soil in latter treatments; in contrast C loss from L layers of 8 and 12 Mg ha^{-1} trash quantities was around 78 e 85%, respectively, and N loss was 57 and 68%. These differences were explained by the higher humidity in the straw of L layers and higher soil water content in 8 and 12 Mg ha^{-1} trash quantities than 4 Mg ha^{-1}. Our results suggest that higher soil-trash contact of 4 Mg ha^{-1} treatment (mulch with lower thickness) could be offset by higher loss of straw and soil water content, supporting microbial activity for shorter periods compared to 8 and 12 Mg ha^{-1} treatments. These results suggest that the dynamics of the mulch is primarily driven by the dynamics of water in the soil and mulch. Therefore, the partial SR after sugarcane harvesting does not change the decomposition and C and N loss from the trash mulch.

(6574 - 1446) Technological viability of rhizobia inoculation in the planting furrow in common bean

Damiany Pádua Oliveira[1]; Márcia Rufini[1]; Fábio Aurélio Dias Martins[2]; Jacqueline Savana da Silva[1]; Thiago de Assis Pereira[1]; Maria Vitória Batista Duque Batista Guttierrez Baptista[1]; Celso Leandro da Silva Junior[1]; Lourdes Cláudia da Silva[1]; Messias José Bastos de Andrade[1]; Fatima Maria de Souza Moreira[1]
Universidade Federal de Lavras[1]; Empresa de Pesquisa Agropecuária de Minas Gerais-EPAMIG SUL[2]

Common bean producers that adopt a high level of technology have shown interest in liquid inoculation through the planting furrow, above all through the practically of the operation in large-scale production. However, publications on this matter are not found for common bean, which requires investigation to assist the producer in choosing the inoculation method to be adopted and in determining the suitable application rates for good performance of biological nitrogen fixation. For this purpose, two field experiments were conducted in the winter crop season 2017 (one in a *Latossolo Vermelho eutrófico* in the municipality of Lavras, and the other in a *Latossolo Vermelho distroférrico* in Patos de Minas, Minas Gerais, Brazil. Both crops were planted over maize crop residue in irrigated areas without a previous record of inoculation for common bean. A randomized block experimental design was used with four replications and seven treatments: liquid inoculation in the furrow (rates of 0.875, 1.75, and 3.50 L ha^{-1}), peat (10 g kg^{-1}) or liquid (4.0 mL kg^{-1}) inoculation on the seed, and two controls without inoculation (without and with 80 kg N-urea ha^{-1}). All the plots were fertilized with P_2O_5 and K_2O, defined by soil analysis. The cultivar used was BRSMG Madrepérola at a density of 15 seeds per linear meter, and the strain used was CIAT 899 of *Rhizobium tropici*, approved as an inoculant for the crop by the Brazilian Ministry of Agriculture. The inoculants contained ±10^9 cells of *Rhizobium* per mL or gram. Inoculation on the seed was performed a short time before sowing. Distribution in the

planting furrow was made with a manual backpack sprayer with a conical nozzle, and the spray application rate was 350 L ha^{-1}. Data were subjected to analysis of variance. In the cases of significant effect of the treatments, the means were clustered by the Scott-Knott test. The levels of the locations were compared through the F test since this factor has only two levels. In spite of the large number of nodules registered in Lavras, there was a higher yield in Patos de Minas. Inoculation in the planting furrow at the rate of 3.5 L ha^{-1} provided higher yields than inoculations on the seed, and also ensured yield of around 1,900 kg ha^{-1}, equivalent to the treatment with mineral N. Due to operational practicality, therefore, inoculation in the planting furrow is the most advantageous of the inoculations tested, regardless of the soil and climate conditions of the crop.

(6660 - 362) The impact of post-fire salvage logging on microbial nitrogen cyclers in Mediterranean forest soil

Lily Pereg[1]; Jorge Mataix-Solera[2]; Mary McMillan[1]; Fuensanta García-Orenes[2]

School of Science and Technology, University of New England, Armidale, NSW 2351, Australia[1]; GEA – Environmental Soil Science Group, Department of Agrochemistry and Environment, University Miguel Hernández. Elche, Alicante, Spain[2]

Forest fires are a regular occurrence in the Mediterranean basin. High severity fires and post-fire management can affect biological, chemical and physical properties of soil, including the composition and abundance of soil microbial communities. Salvage logging is a post-fire management strategy, which involves the removal of burnt wood from land after a fire. The main objective of this work was to evaluate the impact of post-fire salvage logging and microaggregation on soil microbial communities, specifically on the abundance of nitrogen cyclers and, thus, the potential of the soil for microbial nitrogen cycling. The abundance of nitrogen cyclers was assessed by quantification of microbial nitrogen cycling genes in soil DNA, including *nifH* (involved in nitrogen fixation), *nirS/K* and *nosZ* (involved in denitrification), *amoA*-B and *amoA*-Arch (involved in bacterial and archaeal nitrification, respectively). It was demonstrated that salvage logging reduced bacterial load post-fire when compared to tree retention control and resulted in significant changes to the abundance of functional bacteria involved in nitrogen cycling. Microbial gene pools involved in various stages of the nitrogen cycle were larger in control soil than in soil subjected to post-fire salvage logging and were significantly correlated with organic matter, available phosphorous, nitrogen and aggregate stability. The microaggregate fraction of the soil, which has been associated with greater organic carbon, was shown to be a hotspot for nitrogen cyclers particularly under salvage logging. The impact of post-fire management strategies on soil microbial communities needs to be considered in relation to maintaining ecosystem productivity, resilience and potential impact on climate change. This work has been recently published (2018) in the journal: Science of the Total Environment 619-620: 1079-1087

C2.3.2 - Molecular techniques as a useful tool to reveal soil biodiversity and biotechnological potential of microbial genomes

(3822 - 2695) 16s rRNA gene sequencing reveal microbiome variations during different fertilisation practices

Loredana Canfora[1]; Elisa Vendramin[2]; Barbara Felici[2]; Luigi Tarricone[2]; Alessandro Florio[3]; Anna Benedetti[2]

[1]; CREA[2]; LEM INRA[3]

Fertilisation practices are increasingly recognised as factors influencing the soil microbial communities, and they have a pivotal role in maintaining soil fertility and regulating ecosystem functions. Soil microbial communities react to different fertilisation practices and environmental conditions. It is known that vineyards harbour a specific set of microorganisms. The vineyard microbiome has been extensively investigated to decipher the associated microbial populations in soil, as well as the dynamics of microorganisms in grapes and the phyllosphere. Wine harbours a wide range of microorganisms originating from the belowground environment, many of which are recognised for their role in driving the grapevine quality. This study evaluates the long term-effect of two fertilisation practices (mineral, MD and organo-mineral, OMD) on the soil bacterial community in a nine-year-old vineyard. Sequencing was done on environmental DNA soil samples to amplify the hypervariable region V3-V4 of the 16S rRNA gene using an Illumina platform. The results provide information on the distribution of different bacterial groups in relation to fertilisation practices and temporal variability. Our work reveals that the assortment and distribution of microorganisms in agricultural systems depend on several factors, underlining the importance of fertilisation strategy in the overall management of soil quality and fertility.

(1385 - 2418) Bacterial communities monitoring from different uses of Amazon soils focusing on the metanotrophs group.

Bresciani, L.[1]; Santos, D. G.[1]; Pylro, V. S.[1]; Tsai, Siu Mui[2]; Andreote, F. D.[1]

ESALQ/USP[1]; CENA/USP[2]

The Amazon forest is the biggest tropical forest and hosts the largest biodiversity in the world, representing fundamental importance in biogeochemical cycles. Nevertheless, the increasing anthropic interference in the Amazon Forest in the last decades has been causing major damages in the resident biological diversity. Beyond the ecological dynamics changes, another change involves the gases related to the greenhouse effect, such as methane. Here we aim to measure the total bacterial communities and which are able to consume methane, named methanotrophic, in the Forest and grassland soil. The draft was conducted comparing the bacterial communities of soils of primary, secondary forest and grassland sampled in the region of Tapajós National Forest (Brazil). The total DNA was extracted from the soil samples, the communities were quantified by real-time quantitative PCR using 16S rRNA gene, followed by the 16S rRNA gene sequencing. The results show that the total quantification of communities was similar between the treatments, however, the 16S rRNA gene sequencing shown differences between the composition of the sample of primary forest, secondary forest, and grassland. Alphaproteobacteria and Verrucomicrobia were more abundant in forest samples than in grassland samples, whereas Actinobacteria, Chloroflexi, and Firmicutes were more abundant in the last one. On methanotrophic communities, we notice that the relative abundance in the forest soils was similar than in grassland. Although, the 16S rRNA gene sequencing suggests that methanotrophic community present differences in their composition between the treatments. Therefore, these results imply that grassland soil lodge a different community than forest, including the methanotrophic group, which is relevant to improve our knowledge about Amazon soil diversity and methane emission in the Amazonia. Moreover, these results show the effect of

different land uses in Amazonia on bacteria biological activity and methane oxidation.

(7625 - 358) *Bradyrhizobium brasilense* sp. nov., a symbiotic nitrogen-fixing bacterium isolated from Brazilian tropical soils

Elaine Martins da Costa[1]; Amanda Azarias Guimarães[2]; Rayssa Pereira Vicentin[2]; Paula Rose de Almeida Ribeiro[2]; Aniele Carolina Ribas Leão[3]; Eduardo Balsanelli[3]; Liesbeth Lebbe[4]; Maarten Aerts[4]; Anne Willems[4]; Fatima Maria de Souza Moreira[2]
Universidade Federal de Mato Grosso do Sul[1]; Universidade Federal de Lavras[2]; Universidade Federal do Paraná[3]; Ghent University[4]

Four strains of rhizobia isolated from nodules of *Vigna unguiculata* (UFLA 03-321^T, UFLA 03-320 and UFLA 03-290) and *Macroptilium atropurpureum* (UFLA 04-0212) in Brazilian soils were previously reported as a new group within the genus *Bradyrhizobium*. To determine their taxonomic position, these strains were characterized in this study using a polyphasic approach. The analysis of the 16S rRNA gene grouped the strains with *Bradyrhizobium elkanii* USDA 76^T and *Bradyrhizobium pachyrhizi* PAC 48^T. However, the concatenated sequence analysis of the two (*recA* and *glnII*) or three (*atpD*, *gyrB* and *recA*) housekeeping genes indicated that these four strains represent a novel species of *Bradyrhizobium,* which is very closely related to *B. elkanii* USDA 76^T and *B. pachyrhizi* PAC 48^T. Genomic relatedness analyses between strain UFLA 03-321^T and *B. elkanii* USDA 76^T and *B. pachyrhizi* PAC 48^T reveled an average nucleotide identity below 96% and values of estimated DNA–DNA hybridization (using the genome-to-genome distance calculator) below 70%, confirming that they represent genomically distinct species. Analysis of MALDI-TOF MS (Matrix-assisted laser desorption ionization-time-of-flight mass spectrometry) profiles and phenotypic characteristics allowed also the differentiation of the novel species from its two neighboring species. In phylogenetic analysis of *nodC* and *nifH* genes, UFLA03-321^T presented maximum similarity with *B. tropiciagri* CNPSo 1112^T. Based on the data presented, it is suggested that these strains represent a novel species, for which the name *Bradyrhizobium brasilense* sp. nov. is proposed, with UFLA03-321^T (= LMG 29353 =CBAS645) as type strain. G+C content in the DNA of UFLA03-321^T is 63.9 mol%.

(1913 - 2765) Denitrification potentials and riverbank soil bacterial structures along Shibetsu river, Japan

Yoshitaka Uchida[1]; Hirosato Mogi[1]; Toru Hamamoto[1]; Miwako Nagane[1]; Misato Toda[1]
Hokkaido University, JAPAN[1]

Riverbank soil ecosystems are important zone in terms of transforming inorganic nitrogen (N), particularly nitrate (NO_3^--N), in soils to gases. Better understanding of the factors controlling the variability of the denitrification potentials may result in the more accurate evaluation of ecosystem services provided by riverbank soil ecosystems. Thus, we investigated the denitrification potentials along Shibetsu river, Hokkaido, Japan. We sampled riverbank soils from eight sites and their denitrification potentials with added glucose-carbon (C) and NO_3^--N varied from 4.73–181 μg N kg^{-1} h^{-1}. Some soil samples responded positively to C and N addition, regarding the denitrification potentials, but others did not. The increase of the denitrification after the addition of C and N was negatively controlled by soil pH and positively controlled by soil NH_4^+-N levels. Then, we investigated the changes in 16S rRNA bacterial community structures before and after an anaerobic incubation with added C and N. We found that the genus *Gammaproteobacteria Aeromonadaceae Tolumonas* was markedly increased, from 0.0 ± 0.0% to 16 ± 17%, before and after the anaerobic incubation with the excess substrates. Although we could not find a significant interaction between the denitrification potential and the increase rate of *G. Aeromonadaceae Tolumonas*, our study suggested that along the Shibetsu river, bacterial response to added excess substrates was similar at the genus level. Further studies are needed to investigate whether this is a universal phenomenon even in other rivers.

(8613 - 2596) Diversity of fungi associated with the rhizosphere of *Canavalia ensiformis* and *Crotalaria juncea* in soils treated with herbicide sulfentrazone

Karen Caroline Ferreira Santaren[1]; Isis Capella Soares[1]; Ana Luiza da Rocha Fortes Saraiva[1]; Ana Carolina Roos Pinheiro[2]; Esequiel Santos[2]; Fábio Ribeiro Pires[2]; Irene da Silva Coelho[1]
Universidade Federal Rural do Rio de Janeiro[1]; Centro Universitário Norte do Espírito Santo[2]

The indiscriminate utilization of herbicides is a potential source of environmental contamination. Sulfentrazone is an herbicide used for selective weed control in different crops, such as soybean and sugarcane, being considered persistent in soils, besides having high leaching potential. Phytoremediation stands out as an alternative to minimize this problem. This technique involves plants and their associated microbiota, which, combined with certain agronomic practices, are able to remove, immobilize or reduce the toxicity and harmfulness of these contaminants in the environment. From this perspective, the present work aims to evaluate the impact of the herbicide sulfentrazone on fungal diversity in rhizospheric and non-rhizospheric soils from the plants *Canavalia ensiformis* and *Crotalaria juncea*. These two species were cultivated for 75 and 110 days, respectively, in substrate containing three concentration levels of herbicide sulfentrazone (0, 200 and 800 g ha^{-1}). After this period, samples of rhizospheric and non-rhizospheric soils of each treatment were collected. Total DNA was extracted from the soil samples and the amplification of the fungal 18S rRNA gene by Polymerase Chain Reaction (PCR) was performed. The products of the PCR reactions were separated on a polyacrylamide gel with concentration gradient between 30 and 40%, by the DGGE (Denaturing Gradient Gel Electrophoresis) technique. According to the average of the bands number observed in the gels, rhizosphere soils of *C. juncea* presented higher richness of fungal populations in the three herbicide doses, when compared to the non-rhizospheric soils submitted to the same treatments. A similar result was observed for *C. ensiformis*, except for the herbicide dose of 0 g ha^{-1}, where the diversity was higher in the non-rhizosphere plant. In addition, the fungi population remained stable despite the dose of the herbicide, varying mainly according to the cultivated plant and with a rhizospheric or non-rhizospheric condition. The maintenance of fungi profiles, even at high concentrations of sulfentrazone, emphasizes their role, with the plant, in herbicide degradation, presenting high bioremediation potential of soils contaminated with sulfentrazone.

(6999 - 2888) DNA concentration of the soil may be affected by herbicide applications in high weathered soils

Marco Aurélio Pessoa-de-Souza[1]; Hugo Delleon da Silva[2]; Elisângela de Paula Silveira-Lacerda[2]; Evandro Novaes[2]; Virgínia Damin[2]
Pontifícia Universidade Católica de Goiás; Universidade Federal de Goiás[1]; Universidade Federal de Goiás[2]

Savanna Tropical soil has a tendency to be weathered due intensive climatic characteristic. These condition may offer a specifically condition of charges exposure contained in the external sites of the clay minerals. Herbicide, frequently used in Brazilian crop production, may interact with soil charges and microorganisms of the soil, and this relationship is dependent of molecular and soil physic-chemical profile. Microbiote is sensitive parameter and biological indicator to prognosticate soil management especially when assessments are at the molecular level. In this way, our aim was evaluate soil capacity to extraction Soil DNA when submitted to herbicide application. The experiment were established in factorial design 4 X 4 (three herbicides – Oxyfluorfen, Sulfentrazone e Diclosulam – and control, and four soil classes - LATOSSOLO VERMELHO Ácrico (LVw), LATOSSOLO VERMELHO Distrófico (LVd), GLEISSOLO MELÂNICO (GM) and NEOSSOLO QUARTZARENICO (RQ)). Soils were collected in 30 cm of profundity, sieved 2 mm and disposed in black vases with near of 1000 ± 20 g, considering soil density. Before DNA extraction procedure, samples were prepared by 8 months in semi controlled site, with application time intervals of the 2 months, with humidity control (60%) e temperature (30 ± 5°C). Extraction was procedure using Fast DNA^{TM} SPIN KIT for Soil$^{®}$ (MPBio), and DNA concentration was mesure by Digital Fluorimeter FD-570, 0.02 mg·L^{-1} precision. The main results point to two ways: soil and herbicide effects. Among the soils, the organic character (GM) was the most affect reached the highest levels of DNA concentration and with herbicide application low DNA levels. RQ had low DNA concentration. All herbicides decreased the DNA concentration for all studies soils, following the order GM > LVw > LVd > RQ. Finally, we conclude the herbicide may impact negatively DNA concentration and microbiota persistence.

(5664 - 1181) Fish processing effluent discharges influenced chemical properties and microbial diversity in arid soils from Patagonia

María Belén Vallejos[1]; Magalí Marcos[1]; Cristian Barrionuevo[1]; Nelda Lila Olivera[1]
Instituto Patagónico para el Estudio de los Ecosistemas Continentales (IPEEC-CONICET)[1]

Even though fish processing industry uses large amounts of water, there is scarce knowledge about the possibility of its reuse for irrigation. In the arid Patagonian Monte, there are sites where fish processing effluents are discharged, resulting in a visible stimulation of native vegetation. We analyzed soil chemical properties and microbial diversity in a site where fish processing effluents are discharged (ES) and in a control site not disturbed (CS). At each site, 5 surface soil samples were randomly taken under plant-covered patches. We determined soil moisture, pH, electric conductivity (EC), sodium adsorption ratio (SAR), total C, inorganic C, total N, and concentrations of ammonium and nitrates+nitrites. Bacterial 16S V4 rDNA region was amplified and sequenced using MiSeq® Illumina platform. Operational taxonomic unit (OTU) clustering was performed with mothur using the Silva database. ES showed significantly higher values ($p<0.05$) of soil moisture (ES 12.9±0.7, CS 9.4±0.3%), EC (ES1.2±0.5, CS 0.6±0.2 mmhos/cm), total C (ES 0.86±0.10, CS 0.42±0.03%), inorganic C (ES 0.46±0.12, CS 0.10±0.02%), and nitrates+nitrites (ES 74.1±48.2, CS 4.26±0.13 µg/g) than CS. No significant differences were detected for pH, SAR, ammonium, and total N between sites. A total of 874,827 high quality reads were obtained for 10 samples (GOOD´s coverage > 94%). Effluent discharges induced a diminution of bacterial richness (OTUs) and diversity (Inverse Simpson). Dendrogram (Bray-Curtis distance) as well as principal co-ordinate analysis show that control samples clustered together, while some samples from ES clustered with control samples and others with themselves. LEfSE analysis showed 580 biomarker OTUs with significantly differential abundances between sites, which were classified into 16 phyla. This analysis showed that Archaea, mainly represented by *Nitrososphaeraceae*, were more abundant in CS. Besides, bacterial lineages enriched in CS included *Acidobacteria*, *Actinobacteria*, *Chloroflexi*, *Gemmatimonadetes*, *Nitrospirae*, *Planctomycetes*, *Alphaproteobacteria*, *Deltaproteobacteria*, and *Verrucomicrobia*. Biomarker OTUs from *Gammaproteobacteria* were more numerous in ES. Fish processing effluent discharges increased heterogeneity of soil chemical properties, reducing bacterial diversity and inducing shifts in the structure of the microbial community. This would be considered, and hence monitored, to preserve soil fertility when proposing fish effluent reuse for irrigation.

(7721 - 1593) In situ cultivation and 16S rRNA-based identification of rhizobacteria associated with wheat seedlings grown in a Chilean Andisol

Jacquelinne Acuña[1]; Luis Marileo[1]; Anchi Punolef[1]; Slava Epstein[2]; Milk Jorquera[3]
Applied microbial ecology laboratory, Scientific and Technological Bioresource Nucleus, Universidad de La Frontera, Temuco, Chile[1];

College of Science, Northeastern University, Boston, USA[2]; Applied microbial ecology laboratory, Departamento de Ciencias Química en Recursos Naturales, Universidad de La Frontera, Temuco, Chile[3]

The use of next-generation sequencing technologies have revealed that rhizosphere harbours thousands of different bacterial taxa, which living in a constant interaction with the roots of their host plant. However, it is widely accepted that only a minor portion (≤1%) of rhizobacterial populations can be cultured under laboratory conditions. This limitation underestimates the total diversity of rhizobacteria, particularly of bacterial groups defined as 'rare taxa' or 'unculturable', and commonly present in low abundance. Novel culture techniques have recently been focused on mimicking of the natural environment to unravel the diversity, activity and biotechnological potential of rare or unculturable bacterial portion. In this sense, diffusion chambers for in situ cultivation is one of the most promissory advance for the cultivation and isolation of previously unculturable environmental bacteria. In this study, we used the in situ cultivation using micro-well chambers to isolate rhizobacteria associated with wheat seedlings grown in a Chilean Andisols. Samples of 1 g of rhizosphere soils were serially diluted in sterile distilled water. Distilled water supplemented with agar (1.5% and 60ºC) was used for 10^{-3} dilution, which was then inoculated into a micro-well chambers. The micro-well chambers were incubated in the rhizosphere of wheat seedlings (previously grown for 1 month) and maintained for 2 months under greenhouse conditions (2 months at 20ºC). A total of 236 isolates were obtained by in situ cultivation and 206 isolates were able to identified based on partial sequencing of 16S rRNA genes. Taxonomic analysis revealed that 70% of isolates were identificated as belonging to Proteobacteria, following by Firmicutes (24%), Actinobacteria (4.4%), and Bacteroidetes (1.5%). At the order level, higher abundance were predominated by isolates belonging primarily to Bacillales (24%), Pseudomonadales (22%), Burkholderiales (21%) and Xantomonadales (17%). Isolates with lower abundance (<10

isolates) were dominated by Rhodospirillales (4%), Rhizobiales (3%), Corynebacteriales (2%), Actinobacteriales (2%), whereas only the 1% of isolates were classified as Enterobacteriales, Flavobacteriales and Sphinogomonadales. The use of micro-well chambers showed to be an attractive strategy to traditional culture techniques for explore and characterize novel isolates from rhizospheres of cereal crops in southern Chile.

(4085 - 3223) Increased enzymatic activity and decreased microbial diversity of rice paddy under a long-term no-tillage soil management system

Filipe Selau Carlos[1]; Naihana Schaffer[1]; Roberta Mariot[1]; Luis Riesch[2]; Flavio Anastácio de Oliveira Camargo[1]
Universidade Federal do Rio Grande do Sul (UFRGS)[1]; Universidade Federal do Pampa (Unipampa)[2]

Soil management systems cause many changes in the soil microenvironment that directly affect soil microorganism activity and diversity. This study evaluated the microbial enzymatic activity and diversity in an Entisol cultivated with rice under different managements for more than 20 years. The experiment started in the 1994/95 growing season. Treatments included no-tillage, conventional, and pre-germinated management systems. Soil samples were collected before and after harvest for enzymatic analysis in 2014/15 and 2015/16 and for carbon and nitrogen content determination in September 2015. Microbial C and N, basal respiration, fluorescein diacetate (FDA) hydrolysis, acid phosphatase, urease, and β-glucosidase were also measured. To quantify microbial diversity, total microbial DNA was extracted from soil samples, amplified by polymerase chain reaction (PCR), and sequenced using the V4 region of 16S rRNA gene as target. After 20 years, the data obtained on most of the evaluation dates indicated that no-till increased microbial carbon, nitrogen, and enzyme activity. The enzyme activity was correlated with the soil organic carbon content and particulate fraction. Despite the relatively high enzyme activity with no-tillage, microbial diversity was reduced in this soil management system. The results suggest that no-tillage is an important management tool in the recovery of irrigated rice areas whose soil has undergone microbiological degradation. No-tillage increases soil carbon and extracellular enzyme (EE) activity, which are essential for soil quality maintenance and sustainable medium- and long-term food production.

Keywords: microbial activity, carbon, microbial diversity, no-tillage, Oryza sativa L.

(4249 - 1929) Isolation and genetic identification of diazotrophic bacteria in *Eucalyptus* sp.

Kamila Cabral Mielke[1]; Dany Roberta Marques Caldeira[2]; Roberlan Ferreira da Silva[3]; Kerwin Araujo Costa[1]; Rafaela Ramos Bertuani[1]; Andréia Lopes de Morais[1]; Jéssica Rodrigues Dalazen[1]
Universidade Federal do Espirito Santo[1]; Instituto Federal de Rondônia[2]; Universidade Estadual do Sudoeste da Bahia[3]

The studies to optimize forest production have been increasing, and the use of beneficial microorganisms in this sector has become an option to improve this production. Despite the commercial and economic importance of *Eucalyptus*, there are few studies on microbial communities in their ecosystems, and little is known about how soil microorganisms interact and benefit *Eucalyptus* plants. The beneficial effect of the application of rhizobacteria on rooting, growth and biocontrol of diseases in *Eucalyptus* was demonstrated. The aimed in this work was isolate diazothrophic bacteria of roots of the spontaneous hybrid of *Eucalyptus urophylla,* clone I144 and to realize the genetic identification of the isolates found. The isolation process was carried out at the Federal Institute of Education, Science and Technology of Rondônia, Campus Colorado do Oeste as described by Döbereiner (1995). The molecular and functional characterization of the bacterial strains was performed at the Laboratories of Genetics and Biochemistry, Grasses and Molecular Biology in the National Center for Agrobiology Research (EMBRAPA Agrobiologia), Seropédica - RJ. It were isolate twelve bacterial strains, seven in LGI medium and five in the JMV medium. No isolates were obtained in the NFb and JNFb media. Among the isolates *Azospirillum amazonenese, Stenotrophomonas maltophilia, Pantoea agglomerans, Herbaspirillum frisingensee* and *Ideonella dechloratans* were identified. All the isolates presented amplification of the nifH gene, showing ability in nitrogen fixation. The isolates studied were able to synthesize indole compounds (Indole Acetic acid IAA). There was a significant difference between the isolates, showing a greater synthesis capacity for the IFROJV5E-*Pantoea agglomerans* strain (70.1 ug of indolic compounds mg of protein-1 in 24 h time). It were obtained increased auxin synthesis after 48 h (45.6 ug of indolic compounds mg of protein -1) by the IFROJV4E - *Pantoea agglomerans*, IFROJV3E -*Ideonella dechloratans* and IFROL4E - *Azospirillum amazonense* strains. The lowest auxin production was approximately 4,0 ug of indolic compounds mg protein-1, synthesized by the *Azospirillum amazonense* strains. The presence of auxins production in the studied strains is positive; showing that the strains have the capacity to stimulate cell division, increase of roots, stimulate plant growth, showing positive effect on the development of quality seedlings to initial establishment.

(5308 - 2989) Land use change and soil moisture alter the methanogenesis process in the Amazon Rainforest

Alexandre Pedrinho[1]; Fabiana de S. Cannavan[1]; Lucas W. Mendes[1]; Fernando D. Andreote[2]; Jorge L.M. Rodrigues[3]; Tsai Siu Mui[1]
Center of Nuclear Energy for Agriculture, University of Sao Paulo, Piracicaba, SP, Brazil[1]; College of Agriculture "Luiz de Queiroz", University of Sao Paulo, Piracicaba, SP, Brazil[2]; Department of Land, Air and Water Resources, University of California, Davis, CA, USA[3]

Methanogenesis, a microbial process known to reduce carbon compound to methane (CH_4), is highly influenced by soil moisture. It is considered a major biological loss of soil organic carbon and a source of CH_4, a potent greenhouse gas, to the atmosphere. Tropical forest soils are the largest natural source of CH_4, and it is estimated that the Amazon River Basin contributes 7 % of the annual flux to the atmosphere. This tropical forest ecosystem has experienced extensive deforestation and land use change during the past 30 years and previous research has shown that forest-to-pasture conversion results in a series of environmental alterations that include change in the microbial community structure and functional processes associated with the C cycle that lead to increases in CH_4 emissions. Thus, to illuminate the effects of soil moisture in methane production/consumption (and the microbes that mediate them) across land use gradients in the Amazon, we performed a controlled laboratory incubation experiment by varying moisture content of soils collected from primary forest, pasture, and secondary forest, at Belterra, State of Para, Brazil. Soils were incubated under two different water contents, 60% water holding capacity (WHC), close to the original value and 90% WHC for 42 days. CH_4 fluxes were measured throughout the experiment and DNA extractions were

performed in the beginning, middle and the end of the incubation. Quantitative PCR (qPCR) targeting the *mcr*A and *pmo*A genes were used to follow changes in the methanogenic and methanothrophic population, and metagenomic sequencing to assess the diversity and composition is currently in progress. Our results show that CH_4 fluxes and the number of copies of *mcr*A and *pmo*A genes are differently affected according to the land use and water content. Throughout the incubation period, pasture, primary forest, and secondary forest soils under 60% WHC acted as methane sink. Conversely, pasture, primary forest, and secondary soils under 90% WHC acted as methane source. A positive correlation between CH_4 fluxes and water content, *mcr*A and *pmo*A genes were observed across all areas. A combination of metagenomics analysis, CH_4 gas fluxes and qPCR data will aid in the understanding of microbial CH_4 production in Amazonian soils and help to identify the soil microbiome associated with response to land use change and biogeochemical processes.

(1337 - 2405) Metagenomic and metaproteomic analysis to unravel microbe associated processes in ferruginous Canga soils.

Rafael Borges Da Silva Valadares[1]; Gisele Lopes Nunes[1]; Aline Madeira Marques[1]; Isa Rebecca Chagas da Costa[1]; Eder Soares Pires[1]; Ronnie Alves[1]; Jose Oswaldo Siqueira[1]; Guilherme Oliveira[1]

Instituto Tecnológico Vale[1]

In Brazil, Canga refers to an ecosystem generally associated with superficial iron crust, occurring mainly in Minas Gerais and Pará states. It can be classified according to their phytophysiognomies: Rocky outcrops; Shrub-Canga, Vellozia-Canga and Forests. Canga has suffered from intense disturbance caused by iron ore extractions. After mining these land has to be reclaimed in order to bring back vegetation and ecological functions, such as nutrient and energy cycling. In this sense, microbes play key roles in processes that guarantee ecosystem functioning and maintenance. We sampled soil from 12 different locations, at Canga plateau in the mining complex of Carajás, in order to unravel microbial diversity and functions associated to each environment. Samples were kept at 4Cº and brought to the laboratory for metagenomics and metaproteomic analysis. DNA sequencing was performed in Illumina Hiseq sequencer and proteins were analyzed by liquid chromatography and mass spectrometry. A total of 409.917.823 reads, with average length of 75 bp, were obtained in the metagenome analysis and an average of 120 unique proteins were identified per sample. Among detected phyla Proteobacteria, Actinobacteria, Acidobacteria and Firmicutes were the most abundant in all phytophysiognomies. Proteobacteria was predominant group in Forest, Herbaceous-Canga and Shrub-Canga while Actinobacteria was the most present in Velozzia-Canga. Noteworthy, bacterial groups related to N fixation such as *Bradyrhizobium*, *Rhizobium, Mesorhizobium* and *Frankia* were expressively detected in all studied locations. Clustering analyses at genus level revealed that bacterial community structure is very similar within each Canga phytophysiognomies, even when samples were collected at distant plateau. A 60 KDa chaperone was found in all environments whilst an Allophycocianin was specific to Canga Rocky Outcrops. Protein functional characterization showed that the number of active biological processes and molecular functions increases accordingly to environmental complexity, being the soil from Forest the most functional diverse and soil from Rocky Outcrops the less diverse. Our results pointed to key microorganisms mediating essential functions for ecosystem maintenance in Canga environments. Metagenomic and metaproteomic platforms proved to be powerful tolls to unravel soil microbe-associated processes and its importance to knowledge-driven land rehabilitation.

(8969 - 1388) Microbial soil diversity: real-time quantitative polymerase chain reaction (qPCR) and phospholipid fatty acid profiles (PLFA) from communities in response to sustainable agricultural intensification.

Dannae Lilia Serri[1]; Carolina Pérez-Brandan[2]; Diego Chavarría[3]; Fernando Salvagiotti[4]; Silvina Bacigaluppo[4]; José Meriles[5]; Silvina Vargas-Gil[6]

Institute of Plant Pathology (IPAVE) - CIAP - INTA[1]; INTA EEA Salta[2]; CONICET[3]; INTA EEA Oliveros[4]; Multidisciplinary Institute of Plant Biology (IMBIV) - FCEFyN - UNC[5]; Institute of Plant Pathology (IPAVE) - CIAP - INTA, CONICET[6]

In agricultural ecosystems, the replacement of natural vegetation by the introduction of high-productivity crop species implies significant changes in the structure of the soil microbial community. The hypothesis of this work was that the reduction in the diversity of plants would simultaneously diminish soil microbial diversity, affecting important ecological functions. To counteract these effects, the sustainable intensification of agricultural systems, through the combination of different plant species and/or the use of winter service crops. This could contribute to the diversification of the system increasing soil microbial diversity. The objective of this work was to evaluate the response of soil microbial diversity to the sustainable intensification of agricultural systems. This study was conducted at the Oliveros Agricultural Experimental Station, Instituto Nacional de Tecnología Agropecuaria (INTA), Santa Fe province, Argentina. The field trial was performed under no-tillage and started in 2006, and soil sampling was carried out in 2015 and 2016. The treatments were different agricultural sequences combining soybean (S), maize (M) and wheat (T) crops, including the alternative of T as a winter service crop (C). In this way, the treatments tending to the sustainable intensification of the agricultural system were: S-S; C-S; M-T / S and M-T / S-C. The structure of soil microbial communities were studied by qPCR and PLFA. Total bacteria (16S rDNA) and total fungi (18S rDNA) were determined by qPCR; and Gram-positive bacteria (GP), Gram-negative bacteria (GN), total bacteria and total fungi, arbuscular mycorrhizal fungi, Actinomycetes and total biomass (TPLFA) by PLFA. A greater abundance of 16S rDNA was registered for M-T/S-C and S-S, being the copies g dry $soil^{-1}$ of 5,6E+26 and 4,9E+26, respectively. Similarly, the abundance of 18S rDNA was significantly higher for M-T/S-C and S-S, recording both treatments the same value (4.2E+28 copies g dry $soil^{-1}$), overcoming in 90% and 47% the values obtained for the treatments M-T/S and C-S, respectively. Regarding PLFA, a significantly higher percentage of GN bacteria was observed in the M-T/S-C treatment, which registered 26% more than soybean monoculture (S-S). The remaining microbial groups did not show statistically significant differences for the sequences under study. Although TPLFA did not present significant differences for the treatments evaluated, there was a lower percentage in S-S.

Keywords: bacteria, fungi, crop sequences.

(8655 - 2004) Phylogenetic analysis of nitrogen fixing bacteria isolated from leguminous tree species

Anita Fernanda dos Santos Teixeira[1]; Bruna Daniela Ortiz Lopez[1]; Amanda Azarias Guimarães[1]; Marcela de Souza Pereira[1]; Bárbara

Luyse Marques Duarte[1]; Fatima Maria de Souza Moreira[1]
Federal University of Lavras[1]

Sequencing of molecular timers is commonly performed to identify nitrogen fixing bacteria (NFB), mainly through 16S rRNA gene sequencing. However, this is a highly conserved region that do not allow differentiation among these NFB species. In order to obtain a more accurate identification, it is necessary to sequencing other chromosomal DNA genes such as the housekeeping. Therefore, the objective of this work was to identify bacterial strains isolated from nodules of leguminous forest species by sequencing the housekeeping *atp*D and *gyr*B genes. Nine strains available from the NFB collection from the Federal University of Lavras (Brazil) were evaluated. These strains were obtained from nodules of *Machaerium nyctitans* (UFLA01-1164, UFLA01-839, UFLA01-1172), *Ormosia arborea* (UFLA01-1156), and *Platypodium elegans* (UFLA01-1127, UFLA01 - 1134, UFLA01-1129, UFLA01-1137, UFLA01-1128). Sequences of the two genes were individually analyzed and compared in a concatenated phylogenetic tree. Phylogenetic trees were constructed using the Kimura 2-parameter model, using a reliable bootstrap analysis with 1000 replicates. The strains evaluated in this work were compared to sequences of type strains available from GenBank (National Center for Biotechnology Information, NCBI) of similar species to those of this work. From the phylogenetic analysis of the housekeeping genes, five different groups of the species described up to the time of the genera *Rhizobium* (3) and *Bradyrhizobium* (2) were formed. All strains isolated from *P. elegans* belong to the genus *Rhizobium*, with 100% similarity between them and 93.9% similarity to the *Rhizobium tropici* type strain (CIAT 899T). The strain UFLA01-1156 isolated from *O. arborea* and strain UFLA01-1172 from *M. nyctitans* also belong to the genus *Rhizobium*, while the other strains isolated from *M. nyctitans* belong to the genus *Bradyrhizobium*. Considering the high degree of conservation of the nucleotide sequences of the housekeeping genes, it can be inferred that these strains are possible new species.

(5728 - 2471) Response of soil bacteria and archaea communities to long-term crop richness in a no-tillage experiment

Jessica Pereira De Souza[1]; Tatiana Suzin Lazeris[1]; Glaciela Kaschuk[1]; Emanuel Maltempi Souza[1]; Eduardo Balsanelli[1]; Rudimar Molin[2]; Fabiane Machado Vezzani[1]
Federal University of Paraná[1]; ABC Foundation Experimental Center for Agricultural Technical Assistance and Advisory Services[2]

The organic compounds enter the soil ecosystem mainly via crops and therefore the microbial population is selected accordingly. This study aimed identifying the response of the structure and diversity of bacteria and archae communities to long-term crop richness in relation to the growing crop in a no-tillage experiment. Long-term experimental plots were settled in Ponta Grossa, Brazil considering crop systems of wheat-soybean and vetch-corn-wheat-soybean. Soil samples were collected from 0.05 to 0.15 m depth in two moments: before wheat harvesting and at soybean flowering. The structure and diversity of soil bacteria and archae communities were analyzed by extracting the DNA and sequencing the V4 region of the 16SrDNA gene, and soil metabolic diversity was assessed with substrate induced respiration using 11 different substrates. Permutational multivariate analysis of variance was performed to determine changes in the structure of bacteria and archae communities due to crop richness (crop systems) and to growing crop. Distinct genera or group of genera from each season were assessed by the IndVal test. Although the crop richness (p= 0.234) over time did not modify the bacteria and archea communities in no-tillage soil, the growing crop (p=0.001) modulated the soil microbiome. Indicative genera before winter harvesting were: *Candidatus Nitrososphaera, Catellatospora, Devosia, Dokdonella, Geodermatophilus, Hyphomicrobium, Kaistobacter, Methylibium, Mycobacterium, Nitrospira, Nocardioides, Pseudonocardia, Rhizobium* and *Streptomyces*; during soybean flowering: *Candidatus Xiphinematobacter, Candidatus Koribacter, Rhodoplanes* and *DA101*. Diversity indexes for bacteria and archae genera were higher before winter harvesting than at soybean flowering. No difference was observed in the metabolic diversity (p = 0.200) of the edaphic microbiota. The changes in structure and diversity of bacteria and archaea communities were probably due to the diversification of the organic composition of the soil. The crop individually is responsible for modulates the bacteria and archaea community in long-term no-tillage soil and not the crop richness over time. Nevertheless, the results do not invalidate the role of a diverse crop system, as each crop at time may affect soil ecosystem in different ways.

(4010 - 2320) Responses of maize to drought stress when inoculated with diazotrophic bacteria and small rnas regulation

Urquiaga, MC[1]; Da Silva, HAP[1]; Thiebaut, F[1]; Carvalho, TLG[1]; Hemerly, AS[1]; Ferreira, PCG[1]
Instituto de Bioquímica Médica, UFRJ[1]

Plants have a complex mechanism of gene expression regulation that influences their response to biotic and abiotic interactions. Small RNAs (sRNAs) have been described as a regulators of gene expression. The role of sRNAs in the grass-diazotrophic bacteria interaction has been described, however their roles when the interaction occurs under drought stress is not well understood. Maize is a worldwide-cultivated crop and suffers often harvest losses due to drought. Also, maize is a good model to study the interaction with diazotrophic bacteria, once it develops a successful association with beneficial bacteria. Moreover, the induction of tolerance to drought stress mediated by *Gluconacetobacter diazotrophicus* PAL5 bacteria has been described for s sugarcane. In this work, we want to understand the effects of the association between diazotrophic bacteria and maize (Zea mays – hybrid UENF 506-11) in a hydric deficit situation. Initially, an experiment was carried out with plants grown in pots, after inoculation with *G. diazotrophicus*. After an acclimatization period of eight days, plants were divided in four groups, based on plants with normal watering and under water depletion. For each condition, roots and shoots were harvested to analyze the bacterial colonization by confocal microscopy, before water deficit starts and five and eight days after the stress. In addition, phenotypic changes of maize plants were monitored along the experiment and a fourth group of plants were grown for additional 22 days. Our preliminary results suggest that *G. diazotrophicus* cannot improve drought tolerance in maize, as observed in sugarcane. However, the acclimatization period before drought stress may be compromising the effect of the inoculation on the tolerance improve, once the late start of the drought in the fourth group of plants showed a remarkable tolerance phenotype in inoculated plants. In the next step, a new experiment will be conducted, starting drought stress in plants with a more advanced growth stage and with a well-established plant-bacteria association. Our perspectives include evaluation of the expression profile of sRNAs involved in responses to abiotic stresses. These analyses will allow us to confirm the hypothesis that maize can trigger specific responses when plants interact with microorganisms to establish a beneficial association, conferring drought tolerance.

(7985 - 931) Silvopastoral systems drive soil´s total bacteria community.

Felipe Martins do Rêgo Barros[1]; Victor Lucas Vieira Prudêncio de Araújo[1]; José Petrônio Mendes Júnior[1]; Tiago de Oliveira Santos[1]; Giselle Gomes Monteiro Fracetto[1]; Felipe José Cury Fracetto[1]; Mario Andrade Lira Junior[1]

Universidade Federal Rural de Pernambuco[1]

Intercropping tree legumes with forage grasses in a silvopastoral system can avoid the pastures degradation and recover them. This soil management has been successfully used in the recovery and maintenance of degraded pastures, with known results on the soil chemical quality, but without information about their influence on the soil microbial communities. We investigated the influence of the silvopastoral system on the community structure from soil total bacteria. The study area is located at the Experimental Station from Instituto Agronômico de Pernambuco (IPA), in Itambé municipality (Pernambuco state, Brazil). The experiment had nine plots of one hectare with tree legumes Sabiá *(Mimosa caesalpinifolia*) and Gliricidia (*Gliricidia sepium*), and a single Brachiaria (*Brachiaria decumbens*), in a randomized block design with three treatments: B + S (Brachiaria intercropping Sabiá); B + G (Brachiaria intercropping Gliricidia) and B (single Brachiaria), containing three replicates. The soil samples were collected at 0.20 m of depth, in June 2016 (winter season). In B+G and B+S the samples were collected at zero (0 m), four (4 m) and eight meters (8 m) from the legumes, while in B the samples were randomly collected. The structure of the total bacteria communities was evaluated by DGGE (Denaturing Gradient Gel Electrophoresis). The differences in structure of the total bacteria communities among the treatments have been assessed by similarity analysis (ANOSIM). The structure of the total bacteria communities was significantly influenced by silvopastoral system. The results of the ANOSIM pairwise test showed significant differences between B + S (collected at 4 m and 8 m) and B (R Statistical = 0.61 and 0.85, respectively; $p < 0.05$) and between B and B+G at all distances evaluated (R Statistical > 0.75; $p < 0.05$), indicating distinct bacterial communities. The analysis among the distances showed significant differences between 0 and 8 meters. Bacterial communities are stimulated by higher enzymatic activity and higher C and N concentration below the canopy of the trees, forming "hotspots". Furthermore, tree legumes in silvopastoral system influence the grazing intensity in the grass, promoting changes in the microbial community, explaining the differences between B + G (collected at 8 m) and B and B + S (collected at 8 m) and B. However, silvopastoral sytems with tree legumes drive the soil community structure of total bacteria.

(6582 - 996) Soil Bacterial and Archaeal community largely reflects changes in soil properties induced by sheep grazing in an arid shrubland of Patagonia

Magali S. Marcos[1]; Mónica B. Bertiller[1]; Nelda L. Olivera[1]

IPEEC - CONICET[1]

The aim of this study was to analyze the diversity of Bacteria and Archaea in arid soils from the Patagonian Monte under different sheep grazing pressures, and their relation with soil physicochemical properties. Upper soil samples associated to vegetated patches (P) and inter-patches (IP) were collected at a grazed site (G) and a non-grazed site (NG) within the field “San Guillermo” (42˚51’S, 64˚54’W). Aliquots of the soil samples were used to determine soil moisture, pH, texture, organic C, total N, C/N ratio, and the concentration of ammonium, nitrate and nitrite. The diversity and community structure of Bacteria and Archaea in DNA extracted from soil samples was analyzed by MiSeq sequencing of 16S rRNA genes. Bioinformatic analyses were performed in QIIME2 software and sequences were classified using the Greeengenes database. Soil moisture was low (< 3.6%), pH varied between 7.8 and 8.3, and texture was sandy loam. Soil organic C, total N, ammonium and nitrite concentrations were higher ($p < 0.05$) at NG (C: 5.79 ± 0.66 mg/g; N: 0.50 ± 0.03 mg/g; NH_4^+: 2.25 ± 0.12 µg/g; NO_2^-: 0.30 ± 0.03 µg/g) than at G (C: 3.29 ± 0.68 mg/g; N: 0.30 ± 0.05 mg/g; NH_4^+: 1.80 ± 0.16 µg/g; NO_2^-: 0.16 ± 0.03 µg/g), but nitrate concentration and the C/N ratio did not differ significantly among samples ($p > 0.05$). Two-way nested analysis of similarities based on the Bray Curtis index detected differences in microbial community composition at G and NG (global R: 0.59, significance 0.3%), and this result was also supported by cluster and MDS analyses. The families with higher contributions to these differences (> 1%) were Gaiellaceae and Rubrobacteraceae (Actinobacteria), Nitrososphaeraceae (Thaumarchaeota), and unclassified families of the phyla Euryarchaeota, Acidobacteria, Proteobacteria and Actinobacteria. Four soil physicochemical variables (moisture, clay percentage, organic C and nitrite concentration) showed the highest correlation (Rho: 0.71, significance 1%) with the Bray Curtis resemblance matrix based on microbial community composition. No differences were detected between P and IP in physicochemical properties, nor in microbial community composition ($p > 0.05$). In this study, grazing disturbance exerted a major effect shaping soil Bacterial and Archaeal community, through their response to changes in soil physicochemical properties, both in vegetated patches and in bare soil areas.

(4758 - 1434) Structure of the microbial community in a saline soil from semi-arid region of Pernambuco.

Emanuelle Maria da Silva[1]; Maria Betânia Galvão dos Santos Freire[1]; Giselle Gomes Monteiro Fracetto[1]; Josimar Gurgel Fernandes[2]; Alcione Guimarães Freire[1]; Felipe Martins do Rêgo Barros[1]

UFRPE[1]; IPA[2]

The knowledge of the microbial communities present in saline soils could represent a biotechnological potential for applications in the improvement and conservation of saline environments. Some research has focused on the isolation and characterization of these organisms, but more extensive studies have been needed on their ecology, structure, diversity, and functionality. In this study, the structure and diversity of the microbial communities were evaluated along a salinity gradient (High salinity - 17 dS m^{-1}, Average salinity - 8 dS m^{-1}, Low salinity - 4 dS m^{-1}, Native forest - 0.6 dS m^{-1}) in a degraded pasture area, unused for about 20 years, in the municipality of Caruaru (S 08° 15'00.4 "and WO 35° 52'38.0"). At each salinity level, three samples were collected in the 0-20 cm layer, 2.5 m apart. DNA extraction from the soil was performed with the PureLink ™ Microbiome DNA Purification Kit (Invitrogen). Bacterial communities were analyzed by the 16S rRNA gene using the 341f-GC and 518r primers and for the fungi, the ITS1 region of the 18S rRNA gene was amplified using primers EF4, ITS4, ITS1-F-GC and ITS2. DGGE was performed with a denaturing gradient of 30 to 60% for the 16S rRNA gene, from 30 to 55% for ITS. The similarity index was obtained by the analysis of similarity (ANOSIM). The diversity of the communities was evaluated by Shannon’s diversity index (H') and Simpson’s dominance index (D). ANOSIM pointed out that the four areas were not different from each other, indicating that the salinity was not determinant for the differentiation of the community structure. It is possible that the high variability of the areas has prevented the detection of differences between them. By the factorial analysis by main components, there was a positive correlation between EC and SAR with D index, and

negative correlation with H' index, for the fungal community. This indicates that increasing salinity may reduce fungal diversity, although it has not been sufficient to differentiate the areas from each other. Although there was no statistical difference between the areas, the Mata area presented a higher bacterial richness and higher H' index, followed by the high salinity area, indicating that the molecular diversity of the bacteria does not decrease along the salinity increase gradient and it is possible to maintain a high level in extremely saline environments.

(2032 - 2456) Survey of the bacterial community in soils of fruit orchards from all over Japan.

Andre Freire Cruz[1]; Atsushi Nakao[1]; Junta Yanai[1]
Kyoto Prefectural University, Graduate School of Life and Environmental Sciences, Japan[1]

The characterization of the bacterial community is essential at the ecological point of view, as microbes can strongly affect the soil nutrient biodynamics. In order to assess the bacterial community in fruit orchards soils of Japan, 68 soil samples were collected from the surface layer (0–10 cm) all over Japan from each prefecture, taking into consideration the most important fruit in all places. In total 13 kinds of fruits were evaluated in this survey. Based on the 16S RNA genes the soil bacterial community was characterized using the Illumina MiSeq 250bp techniques. The dominant taxonomic groups present in most of the samples were the *Betaproteobacteria*, *Planctomycetes*, *Choloflexi*, *Bacteriodetes*, *Actinobacteria*, and *Acidobacteria*. Although these overarching dominant taxa had occurred, the abundance, diversity, and composition of bacterial communities were sometimes specific according to the fruit type. With special regard to the Mango orchards, it was characterized by a higher abundance of *Actinobacteria* and *Firmicutes*. In most of the cases, the estimated bacterial diversity was generally higher in fruits from northern regions (Cherry and Apple) than in those from southern regions (Mandarin, Pineapple, and Mango). In addition, the Shannon-Wiener index, an indicator of diversity, was positively correlated with pH, extractable Ca and Mg. Such data suggest that soil bacterial community in fruit orchards of Japan depend on land use (fruit species) and may be related to soil chemical properties.

(5875 - 2489) The microbiome of the high-alpine permafrost and its response to warming

Beat Frey[1]; Carla Perez Mon[1]; Theo Smits[2]; Beat Stierli[1]; Aline Frossard[1]
Swiss Federal Reseach Institute WSL[1]; University for Applied Sciences Wadenswil[2]

Permafrost represents 20-25% of the world land area and harbor a largely understudied genetic resource. Thawing of permafrost with global warming will not only promote microbial carbon turnover with direct feedback on greenhouse gases, but also unlock an unknown microbial diversity. Pioneering metagenomic efforts have shed light on the permafrost microbiome in polar regions, but temperate mountain permafrost is largely understudied. The response of the permafrost microbiota to the predicted rising temperatures in alpine regions may be an important part of the ecosystem ability to deal with climate change. Here, we present a unique experimental design coupled to high-throughput sequencing to characterize the microbiota at the long-term alpine permafrost study site in eastern Switzerland with an approximate radiocarbon age of 12 000 years. Compared to the active layers, the permafrost community was more diverse and enriched with understudied phyla having no cultured representatives. Based on these results, we established an *in situ* experiment in which permafrost soils at a depth of 1.6m were placed into the surface active layer in order to simulate thawing of permafrost as a consequence of warming. Similarly, to evaluate the potential of the permafrost microbiome to adapt to warming we set up a microcosm experiment with permafrost soils and active soil layers incubated at increasing temperatures. Collected soil samples have been evaluated for the changes of the bacterial and fungal communities and its functional abilities by measuring respiration, enzyme activities and carbon utilization patterns. Efforts were also made to recover viable cells from permafrost. Some isolates in particular *Collimonas* sp. showed interesting features (e.g. anti-fungal activity, production of violacein). These data yielded an unprecedented view on microbial life in temperate mountain permafrost, which is increasingly important for the understanding the biological dynamics of permafrost in a warming world and its implications for the C- and N-cycles in high alpine soils.

(9069 - 2323) Toward a development of bacterial colonization modelling of soil particles: Effect of humic acids on the formation of nitrogen-fixing bacteria biofilms

Manuel Palencia[1]; María E. Berrio[1]; Sixta L. Palencia[1]
Universidad del Valle[1]

Soil physical, chemical, and biological factors have been shown to affect root colonization, but the detailed mechanisms associated with the adequate colonization of root and microorganisms are not completely understood. Quantitative studies on the distribution of root colonies in time and space are needed to develop mathematical models that describe and predict the root colonization process; being a important factor, to know the effect of inorganic and organic fractions of soils on the ability of microorganisms to form these colonies. Here a methodology to the study of interaction between microorganisms and surface is described and its application for the study of the description of interaction and colonization mechanism between nitrogen-fixing bacteria and particle of soils is shown, special attention is directed toward the effect of humic acids on formation of biofilms. For this, humic and fulvic acids were extracted from two types of soil samples and characterized by infrared by attenuated total reflectance (ATR), thermogravimetric analysis (TGA), contact angle (AC) and volumetric titration (VT). Humic substances were deposited on cellulose previously activated with spectral marker for the mid-infrared and anew characterized. Later, the bacterium *Azotobacter chroococcum* (nitrogen-fixing bacterium) was deposited on the surface by direct contact and in aqueous dispersion. End surfaces were analyzed by ATR, TGA, AC and VT. Analyses by scanning electron microscopy of surfaces were performed. Differentiation between affinity of humic and fulvic acids respect to affinity to be colonized by nitrogen-fixing bacterium were not identified; however, results suggest that different mechanisms associated with nature of surface could be described. It is concluded that the the use of instrumental technique and physicochemical modelling of surface interactions is a promissory tool for the description of process of microbial colonization of soils.

Keywords: Infrared spectroscopy, nitrogen-fixing bacteria, humic substances, biofilm

(7733 - 217) What controls the spatial distribution of microbial communities in agricultural fields?

Bernie Zebarth[1]; Claudia Goyer[1]; Sara Neupane[1]; Sheng Li[1]; Aaron Mills[1]; Sean Whitney[1]; Athyna Cambouris[1]; Isabelle Perron[1]

AAFC[1]

Soil microbial communities mediate many important soil processes in agricultural fields, however their spatial distribution is poorly understood. This study examined the soil physico-chemical properties and topographic features controlling the spatial distribution of soil microbial communities in commercial potato fields in eastern Canada using next generation sequencing and PLFA analyses. Soil was collected from two sites: site 1 was a transect with 83 sampling points approximately 1100 m long in a landscape with rolling topography; and site 2 was a grid with 154 sampling locations in a field with limited topographic variation. Diversity of soil bacterial and fungal communities was evaluated by sequencing the bacterial 16S rRNA gene and the fungal Internal Transcribed Spacer (ITS) region of ribosomal DNA using the Illumina MiSeq system. Sequence analysis was performed in Mothur and Qiime software platforms using the Ribosomal Database Project (RDP) and Unified system for the DNA based fungal species (UNITE) reference databases for bacterial and fungal communities, respectively. At site 1, a significant negative correlation (r = -0.73) between soil pH (range 4.3-7.0) and slope gradient (range 2-12 %) was observed, a finding attributed to greater soil erosion on steep slopes resulting in exposure of low pH subsoil. Proteobacteria, Actinobacteria and Acidobacteria were the three most abundant bacterial phyla, with average relative abundance of 32, 21 and 15%, respectively. Bacterial diversity at the phylum level was found to be primarily related to soil pH. Ascomycota and Basidiomycota were the most abundant fungal phyla, with average relative abundance of 69 and 15%, respectively. Fungal diversity at the phylum level was primarily related to soil organic carbon concentration and soil pH. Semivariogram analyses revealed that the bacterial α-diversity, the relative abundance of most bacterial and fungal phyla, PLFA profiling, pH and slope gradient showed strong to medium spatial autocorrelations with a range between 30 to 92 m. In field site 2, two soil management zones were identified based on apparent soil electrical conductivity that differed in soil texture. The spatial pattern of bacterial diversity in the landscape was closely related to the soil management zones. The soil microbial communities varied in a systematic and predictable pattern in agricultural fields in response to variation in soil physico-chemical properties and topographic features.

C2.3.3 - Rhizosphere mineral dynamics: soil-plant-microorganism

(1047 - 2728) Abundance of N-fixing and nitrifying microorganisms in soybean rhizosphere under the influence of soil cronossequences

Luis Fernando Merloti[1]; Alexandre Pedrinho[1]; Mariley de Cássia da Fonseca[1]; Tsai Siu Mui[1]
CENA - USP[1]

Soil microorganisms play a fundamental role in terrestrial ecosystem due to their participation in processes such as nutrient cycling, biological nitrogen fixation (BNF), nitrification, denitrification, and other processes present in biogeochemical cycles. However, land intensification can promote various impacts on soil microbial communities over time, as well as influence the functions performed by soil microorganisms. Thus, elucidating the changes on soil microbial community is fundamental to optimize the biological diversity in land areas and to contribute to the functioning of land system. The aim of this work was to identify the key genes associated with BNF and nitrification processes in soybean rhizosphere under different land use sequences. The experiment was performed in a greenhouse at CENA-USP, under controlled conditions, in mesocosms containing RR soybean plants, whose soils were sampled in Santarém-PA, from deforested areas, later converted into land areas following the 2, 5 and 20 years chronosequence. The rhizospheric soil samples were collected at the beginning of soybean pre-flowering stage. After sampling, DNA from microbial community was extracted from soil using *PowerSoilLyzer* DNA kit and absolute quantification of *16S rDNA* from *Bacteria* and *Archaea*, *AOA, AOB* and *nifH* genes were determined by real-time PCR (qPCR) technique. Statistical analysis was performed by analysis of variance (ANOVA) using Tukey test (p = 0.05). The results showed that for the *nifH*, *AOA* and *AOB* genes, no significant differences were observed between the 2, 5 and 20 years treatment (p <0.05). However, a greater number of copies of *AOA* gene (6.04 × 102 ng µL of DNA) than the *AOB* gene (1.43 × 101 ng µL of DNA) were observed, both responsible for nitrification process in soil. For *16S rDNA gene* from *Bacteria* (1.75 × 106 ng µL of DNA) and *Archaea* (8.16 × 103 ng µL of DNA), a larger number of copies were observed for the 20-year treatment (p = 0, 05). In this way, it can be concluded that the rhizosphere of the land with 20 years presented a greater abundance of microorganisms, indicating that areas with a more established land systems can contribute with the increase of soil microbial community. Oxidizing ammonia archaeas indicated to be an important group of microbial community responsible for nitrification process in soil.

Keywords: *Bacteria*, *Archaea*, Nitrification, FBN

(3237 - 2891) Aggregation of soil is influenced by the use of inoculants with arbuscular mycorry fungi?

Marisângela Viana Barbosa[1]; Andy Bernal Fundora[2]; Ramón Rivera Espinosa[2]; Orivaldo José Saggin Júnior[3]; Marco Aurélio Carbone Carneiro[1]
Universidade Federal de Lavras - UFLA[1]; Instituto Nacional de Ciências Agrícola - INCA[2]; Empresa Brasileira de Pesquisa Agropecuária - Embrapa[3]

Intensive use and inadequate management of grazing areas cause degradation of the soil structure, reducing its productive potential and pasture yield. Adoption of alternative technologies is necessary to improve the capacity of use and management of soil, making this system more sustainable. In this context, the objective was to evaluate the inoculation of different species of arbuscular mycorrhizal fungi (AMF) in *Urochloa* híbrido stability of aggregates in a ferruginous nodular Gley soil in Cuba. The experiment was conducted out in the Pastures and Forages Station of Cascajal Villa Clara Province, Cuba, using híbrido *Urochloa* cv. CIAT BR 02/1752, inoculated with three strains of AMF EcoMic® (*Glomus cubense*, *Funneliformis mosseae* e *Rhizophagus intraradices*). The design was in randomized blocks, in a factorial scheme 4x2 with inoculation and not inoculation treatement , four replicates and two times. Soil samples were collected at (end of rainy season (2014) and beginning of rainy season (2017) in the 0-10 cm layer, being evaluated the number of spore (NE), the production of glomalin-related soil protein (PSRG), the quantification of extra-radial mycelia (EM), the coefficient of structural stability of the soil through dry sieving (Kes) and immersed in water (Keh) and the Soil Structural Stability Index (Ie). Greater stability of the aggregates Kes was verified at 140 and 876 days of cultivation, however, there was influence of the inoculation only at 876 days. On the other hand, the lower stability was verified for the water-immersed aggregates Keh, showing the influence of the moisture "kinetic energy" of the water on the soil structure. These results indicate that dry soil aggregates in this study were less susceptible to erosion. Effect of inoculation on the soil aggregates is certainly associated with the observed increases for the 140 days that have a cumulative and cementitious character in the soil and the greater EM observed in the 876 that act on the targeting and folding of the mineral particles and soil organic matter, favoring aggregation. AMF inoculation associated with *U.* híbrido roots contributed to the best le at 876 days of cultivation, with emphasis on *G. cubense* species. Which was also more competitive over time, being verified higher NE

when compared to the other inoculated species. These results showed the importance of inoculation and/or management of the native AMFs for formation and stability of the soil physical structure.

(1228 - 2839) Alelopatic effect of aqueous extracts from pig bean plants on the mamone seed germination

Janildes de Jesus da Silva[1]; Caliane da Silva Braulio[1]; Andreza de Jesus Correia[1]; Maria Santos Conceição[1]; Luciano da Silva Souza[1]
Universidade Federal do Recôncavo da Bahia[1]

The castor bean (*Ricinus communis* L.) is a plant belonging to the family Euphorbiaceae, also known as castor bean, carrapateira, tick and castor, the its main product is castor oil, also called castor oil. Used in popular medicine as purgative, possessing large employment in the chemical industry, due to its use. Allelopathy is related to the release of chemicals capable of naturally stimulating or inhibiting the development of plants and organisms. Thus, the objective of this work was to evaluate the efficiency of the addition of aqueous extracts from leaves, stems and roots of bean from pigs in the germination of castor bean. The experiment was carried out in a greenhouse at the Federal University of Recôncavo da Bahia, Cruz das Almas campus, latitude 12º39'11 "S, longitude 39º07'19" W and altitude of 212 m, hot and humid tropical climate region, and soil of the type Yellow Latosol Distrocoeso. For the evaluation of the bean extracts in the germination of castor bean plants, the experimental design was completely randomized, in a factorial scheme 3 x 4 + 1, being three types of extracts (leaf, stem and root), four concentrations (25%, 50%, 75% and 100%) and one control (without extract) with five replicates. To obtain the extracts the parts of the plants were ground separately in a 10% (w/v) mill (10 g of the dried water sample 100 mL^{-1} of water) and then placed in amber glass vials with 1 L and kept at rest for 24 h at room temperature (28°C), protected from light. After 24h the solution was macerated in mortar, filtered on Whatman nº 1 paper and centrifuged at 2000 rpm for 15 minutes to remove traces of fragments, obtaining the extract by maceration at 10% (w/v). During the first 15 days (stage V0 - V2) the germination speed was evaluated. After germination, the following variables were used: germination percentage (%G), germination speed (VG), germination rate (IG), and mean germination time (MGT). The aqueous extracts and their concentrations influenced ($p<0.01$) the variables VG, IVG, TMG of the seedlings of *Ricinus communis* L. The extracts of bean of pig indicate the existence of allelochemical effect in the germination of castor bean, characterizing beneficial allelopathic effect.

(3510 - 3097) Allelopathic extracts of Canavalia ensiformis in the Emergence of Ricinus communis L.

Andreza de Jesus Correia[1]; Maria Santos Conceição[1]; Caliane da Silva Braulio[1]; Janildes de Jesus da Silva[1]; Luciano da Silva Souza[1]
Universidade Federal do Recôncavo da Bahia[1]

Ricinus communis L. is an oleaginous, is resistant to drought, but very demanding in nutrients. Thus, one of the ways to improve the conditions of the soil, for its cultivation, is the consortium with legumes. One of the alternatives is the cultivation in consortium with Canavalia ensiformis. However, it presents an allelopathic principle at its roots capable of benefiting or inhibiting other plants.The allelopathic effect may inhibit the emergence, germination and development of Ricinus communis L. Thus, the objective of the research was to evaluate the allelopathic interference of aqueous extracts of Canavalia ensiformis in the emergence of Ricinus communis L. The experiment was carried out in a greenhouse at the Federal University of Recôncavo da Bahia - UFRB, at the CCAAB campus, located in the municipality of Cruz das Almas. The experimental design was completely randomized, with a factorial scheme 3 x 4 + 1, composed of three types of extracts (leaf, stem and root), four concentrations (25%, 50%, 75% and 100%), a control and five replicates. The soil was collected in the UFRB layer from 0 to 20 cm, placed in plastic bags with a capacity of 3 kg. Five seeds of Ricinus communis L. were placed in each bag. To obtain the extracts, the plants of Canavalia ensiformis were divided into leaves, stem and root, placed to dry in a greenhouse with ventilation at 65 ° C, for 72 hours. Afterwards, they were ground in the proportion of 10% (w / v) (10 g of the dried vegetable sample 100 mL-1 of water), then placed in amber glass flasks with a capacity of 1 L, and kept at rest at ambient temperature (28 ° C), protected from light. After 24h the solution was macerated in mortar, filtered on Whatman n 1 paper and centrifuged at 2000 rpm for 15 minutes to remove traces of fragments, obtaining the extract by maceration at 10% (w / v). To obtain the concentrations the extracts are diluted in water. After sowing, 50 ml of the extracts were applied per replicate and started evaluating the emergence. This evaluation was performed during the first 15 days (stage V0 - V2). With these data, the following variables were calculated: emergency percentage (% E), emergency speed coefficient (CVE), emergency speed index (IVE). The results were submitted to analysis of variance using the statistical program "R". it is concluded that the aqueous extracts of Canavalia ensiformis provided a beneficial allelopathic effect in the emergence of Ricinus communis L.

(8747 - 2924) Allelopathy of aqueous extracts of *Canavalia ensiformis* on initial growth of *Ricinus communis* L.

Caliane da Silva Braulio[1]; Janildes de Jesus da Silva[1]; Andreza de Jesus Correia[1]; Maria Santos Conceição[1]; Luciano da Silva Souza[1]
Universidade Federal do Recôncavo da Bahia[1]

Ricinus comuninis L. presents a high socioeconomic value for the Northeast Region, as it has products and by-products used in the chemical industry, being a family subsistence medium, in addition to its potential as a biofuel, through which biodiesel is obtained through the extraction of oil of its seed. The allelopathic effect may generate physiological disturbances in the cells of other plants, inhibiting or influencing their initial growth. The objective of this experiment was to evaluate the allelopathic interference of different extracts of Canavalia ensiformis in the initial growth of Ricinus communinis L. The experiment was carried out in a greenhouse at the Federal University of Recôncavo da Bahia. The soil used in the experiment was the Yellow Latosol Distrocoeso, fertilized with NPK according to the necessity of the cultivation of Ricinus comuninis L. The experimental design was entirely at random, in a factorial scheme 3 x 4 + 1, being three types of extracts , stem and root), four concentrations (25%, 50%, 75% and 100%) and one control (without extract) with five replicates. The plants of Canavalia ensiformis were collected at Embrapa Mandioca and Fruticultura. To obtain the extracts, the plant parts were separately ground in a 10% (w / v) mill (10 g of the dried water sample 100 mL^{-1} of water), placed in amber glass bottles and kept standing for 24 h at room temperature (28 °C), protected from light. The solution was macerated, filtered on Whatman n° 1 paper and centrifuged at 2000 rpm for 15 minutes, the extract being obtained by maceration at 10% (w / v). After fifteen days of germination, thinning was done leaving only one plant per bag, after which 50 ml of the extracts of Canavalia ensiformis were applied. Two more applications were carried out within the interval of fifteen days. The data were submitted to analysis of variance by the statistical program "R", according to the level of significance was applied the test of Tukey to 5% of probability. The aqueous extracts and their doses influenced (p

<0.01) the variables stem diameter, root length and stem dry mass of the Ricinus communis L. seedlings. The highest concentrations of the extracts increased the dry mass of the shoot and the diameter of the stem of plants of Ricinus communinis L. The roots of plants are more sensitive to the allelochemical effects, as the concentrations of the extracts of Canavalia ensiformis was increasing the root length was reducing.

(6085 - 700) An analysis of nematode communities in three habitats invaded by *Fallopia japonica*.

Andrea Čerevková[1]; Lenka Bobuľská[2]; Dana Miklisová[1]; Marek Renčo[1]
Institute of Parasitology, Slovak Academy of Science, Košice, 040 01, Slovakia[1]; Department of Ecology, Faculty of Humanities and Natural Sciences, University of Prešov, Prešov, 080 01, Slovakia[2]

This study determined the hypothesis whether invasive and native plants have different effects on nematode communities and soil microbial indices. Three natural ecosystems were compared: forest, grassland and wetland in the native conditions with adjacent areas mostly monospecific invaded by *Fallopia japonica* (Hout.) R. Decr. The results showed that in the invasive plant *F. japonica* had a considerable effect on abiotic factors as soil moisture content and soil reaction and biological properties represented by soil microbial biomass carbon and soil basal respiration. The effect of *F. japonica* on soil nematode communities was also observed, resulting in a decrease of the abundance and diversity of nematode species.

Keywords: Soil nematode communities, soil characteristics, biological parameters, *Fallopia japonica*, soil disturbance and ecology

(9545 - 2002) Arbuscular Mycorrhizal Fungal Diversity in Sugarcane Plantations under Different Management Systems

Rosalba Ortega Fors[1]; Itamar Garcia Ignácio[2]; Eliane M. Ribeiro da Silva[2]; Ricardo L. Louro Berbara[1]; Orivaldo J. Saggin Júnior[2]
Universidade Federal Rural do Rio de Janeiro[1]; Embrapa Agrobiologia[2]

Brazil is the main sugarcane producer worldwide with approximately nine million hectares planted with this crop. Arbuscular mycorrhizal fungi (FMA) (Phylum Glomeromycota) are considered indicators of soil quality. The present work aimed to evaluate the AMF communities associated with different sugarcane management systems. Pre-planting and post-harvest AMF surveys were carried out in sugarcane renovation areas (rotated –RA– or not –MA– with *Brachiaria ruzizensis*) and in a sugarcane expansion area (EA) (previously under pasture). Five composed soil samples were collected in each of the areas and seasons, totalizing 30 samples. AMF spores were extracted from soil by wet sieving and decanting. For each sample, spore density and species richness in 50 cm^3 of soil were evaluated. Identification of the AMF species was based on the morphology of the spores. In total, 21 AMF species were identified, distributed in six families and ten genera, with *Acaulospora* and *Glomus* accounting for the highest number of species. Nine species (43%) were considered exclusive, being seven of them from the EA. Generalist species, present in all the areas and seasons, were *Diversispora tortuosa*, *Acaulospora scrobiculata*, *Racocetra fulgida*, *Gigaspora* sp., *Glomus clavisporum,* and *Ambispora leptoticha*. The species richness was higher in the EA with 18 species, followed by the RA and MA, with 13 and 11 species, respectively. These results might be due to differences in soil fertility. Soil environment conditions resulting from monoculture, such as high P concentrations and changes in soil structure, negatively affect AMF species richness. Rotation with *B. ruziziensis* did not influence the species richness in the MA. Changes in AMF communities depend on the disturbances, considering intensity, frequency, spatial extent, and duration. Spore density (SD) showed variations between the three areas and seasons, with the highest values detected in the EA and after the sugarcane harvest. Variations in water availability between seasons and/or changes in the physiological state of sugarcane plants, as well as seasonal changes in the sporulation of each fungal species, may have led to these differences. It was concluded that prolonged monoculture of sugarcane affects the diversity of AMF communities, as well as their spore density. In addition, rotation with *B. ruziziensis* after years of sugarcane monoculture does not imply short-term recovery of AMF communities.

(1678 - 3003) Arbuscular mycorrhizal fungi and rhizobium is important during Vinhático seedling production

Paulo Prates Júnior[1]; Sandro Lúcio da Silva Moreira[1]; Tomas Gomes Reis Veloso[1]; Emanuelle Burgos Cardoso[1]; Thuany Cerqueira Jordão[1]; Bruno Coutinho Moreira[2]; Marliane de Cássia Soares da Silva[1]; Raphael Bragança Alves Fernandes[1]; Maria Catarina Megumi Kasuya[1]
Universidade Federal de Viçosa (UFV), 36570-900, Viçosa-MG, Brazil[1]; Universidade Federal do Vale do São Francisco, 56300-990, Petrolina, PE, Brazil[2]

The production of seedlings of native forest tree species is an issue that requires more research, especially for species such as Vinhático (*Plathymenia reticulata* Bentham), which presents low survival in the nursery. There is a gap in the knowledge about microorganisms species associated to this plant, and they may be important for its survival and growth. The objective of the present study was to evaluate the growth of the seedlings of Vinhático inoculated with arbuscular mycorrhizal fungi (AMF) and *Bradyrhizobium* sp. in different substrates and to identify the microorganisms present in the substrates. The experiment was carried out during 180 days in plots with the following treatments: (T1) 100% commercial substrate, (T2) commercial substrate plus soil filtrate, (T3) 2/3 commercial substrate and 1/3 soil, (T4) 1/2 commercial substrate and 1/2 of soil, (T5) 1/3 commercial substrate and 2/3 of soil, and (T6) 100% of the soil. The soil used was sampled from root system of an adult plant of Vinhático. All treatments were inoculated with a mixture of AMF spores (*Rhizophagus clarus*, *Claroideoglomus etunicatum*, *Gigaspora albida*) and *Bradyrhizobium* sp. Data of growth measures and diversity indexes were submitted ANOVA and the means compared by Tukey test ($p<0.05$). DNA from the rhizosphere was evaluated by amplicon sequencing (Illumina) and canonical correspondence analysis (CCA) was performed using substrate physical and chemical characteristics. Seedlings of treatments T1 and T2 did not survive and these treatments were disregarded from the following analyzes. Biomass of the shoot and nodulation of treatments T3, T4 and T5 were higher than in T6 treatment. The CCA showed that the community of Fungi (ITS), Bacteria, and Archaea (16S) were correlated to pH, CTC and electrical conductivity of the substrates. The richness of Fungi was (T3 and T4) > (T5 and T6) and the diversity in (T3, T4 and T5) > (T6), while Bacteria and Archaea richness and diversity were (T3, T4 and T5) > (T6). The results revealed the important implications of the physical and chemical characteristics of the substrates on Vinhático growth and the relevance of its association with soil microbiota. We conclude that there is a positive plant-soil feedback, since the addition of soil from an adult plant of Vinhático to the commercial substrate, as well

the inoculation with microorganisms, such as AMF and rhizobium, can guarantee its better survivor and growth.

(1096 - 2849) Arbuscular Mycorrhizal status of representative plant species growing in different ecoregions of the Atacama desert, Tarapacá region.

Christian Santander[1]; Pablo Cornejo[1]

Universidad de La Frontera[1]

The symbiosis formed between plant roots and arbuscular mycorrhizal fungi (AMF) has great interest because of its influence on ecosystem processes, its role in determining plant diversity in natural communities and the ability of AMF to induce a wide variety of responses in the plants. The AMF are distributed worldwide as one major component of the natural ecosystems, including arid ecosystems, in which AM symbiosis highlight as the most important biotic components, because AM has an essential role in the survival of plants. In this way, when the desert plants form AM symbiosis have a greater probability of survival to several kind of stress, due to the enhanced nutrient and water acquisitions provided by means of AM symbioses. Based on the above. the objective of this study was to characterize the AM status of representative species of the native flora in different bioclimatic areas of the Atacama Desert, Tarapacá Region. To accomplish this objective, rhizosphere soil was sampled from three ecoregion of Atacama desert: desertic, pre-Puna and Puna ecoregions. In the soil samples was analyzed chemical parameters as pH, electrical conductivity, organic matter and soluble cations. In roots was determined the percentage of AM colonization by the gridline intercept method and staining with trypan blue. In rhizosphere soil was determined the spore density, the mycelium length, and total Glomalin-related soil protein. Of the 48 species sampled, in the 100% was determined presence of AMF propagules. The results showed high rates of mycorrhizal plants (from 12 to 87%), fungal mycelium densities of 0.13 to 20 m g^{-1}, spores densities between 43 and 8500 per 100 g of soil, and T-GRSP contents varied between 0.7 and 9 mg g^{-1}, under natural conditions. The highest spore density and length of mycelium in rhizosphere soils were associated to *Baccharis scandens*, *Werneria pinnatifida*, *Deyeuxia curvula* and *Festuca orthophylla*. The electrical conductivity and soluble cations were positively related with spore density and length of mycelium. These results showed high dependence of plants by the mycorrhizal symbiosis, under the limiting conditions of soil and climate in which are growing. In the same way, the AMF propagules seems to be playing an important role for coping with the salt stress trough the accumulation of toxic ions in fungal structures that deserve to be deeply studied.

(3110 - 2245) Bacterial community assemblages associated with the phyllosphere, rhizosphere and leaf litter of *Amphyrrox longifolia* in the Amazon forest

Julio C. F. Moreira[1]; André A. Souza[1]; Silvia E. Barrera[1]; Mauro Brum[2]; Lidiane C. Almeida[3]; Luciana F. Alves[2]; Rafael S. Oliveira[2]; Bruno H. P. Rosado[3]; Marcio R. Lambais[1]

Departamento de Ciência do Solo, ESALQ/USP, Piracicaba, SP[1]; Departamento de Biologia Vegetal, UNICAMP, Campinas, SP[2]; Departamento de Ecologia, UERJ, Rio de Janeiro, RJ[3]

Bacterial communities associated with tree species of the Atlantic forest have been shown to be specific to their hosts and the plant microenvironment (phyllosphere, dermosphere or rhizosphere), suggesting that plant species-specific traits may drive the selection of microbial populations that comprise their microbiomes. Whether this is true for tree species in the Amazon forest is not known. In order to determine whether the bacterial communities associated with trees in the Amazon forest are specific to the plant microenvironment, we sampled the phyllosphere (Phy), rhizosphere (Rhi) and leaf litter (Lit) of *Amphyrrox longifolia*, a very abundant understory tree species broadly distributed in a pristine east-central Amazon forest (Tapajós National Forest, Brazil). Leaf samples were collected from branches at different points in the canopy. Rhi soil samples were collected under the projection of the tree canopy, at 0-10 cm depth. The Lit samples were collected with a 25x25 cm frame positioned at the same site of Rhi soil sampling. Ten individual trees were sampled. To study the bacterial communities, we sequenced the V4 region of the 16S rRNA gene using the Illumina MiSeq platform. A total of 2,934,907 sequences were obtained and processed using the pipeline of the Brazilian Microbiome Project. Sequences were clustered into 26,323 Operational Taxonomic Units (OTUs), and affiliated to taxonomic groups using the Greengenes database as the reference. The structures of the bacterial communities in the Phy were significantly different from that in Rhi soil and Lit ($P<0.05$), whereas no significant differences were observed between Rhi soil and Lit ($P>0.05$). The Phy harbors most of the unique OTUs, whereas the Rhi soil and Lit share most of the OTUs. The Shannon index indicates a diversity of approximately 666, 578 and 436 OTUs in the Phy, Rhi and Lit, respectively. At the class level, the most abundant OTUs in the Phy were assigned to Betaproteobacteria and Gammaproteobacteria, whereas in the Rhi the most abundant OTUs were assigned to DA052 and Acidobacteria, and in the Lit to Gammaproteobacteria and Betaproteobacteria. Our results indicate that the bacterial communities in the Rhi of *A. longifolia* in the Amazon forest is not as diverse as in the Phy, and suggest that different metabolic functions take place in the Phy, Rhi and decaying leaves, which may have specific contributions to the functionality of the forest.

Inoculation of crops with plant-growth promoting rhizobacteria (PGPR) is a promising biotechnology for reducing the environmental and economic costs of N and P fertilization, especially in tropical environments, where these nutrients are the major limiting factors for plant growth. In this study, we evaluated the ability of five phosphate-solubilizing strains of *Burkholderia* spp. to promote the growth of brachiaria grass (*Brachiaria decumbens* Stapf.) and three crops –

common bean (*Phaseolus vulgaris* L.), cowpea (*Vigna unguiculata*), and maize (*Zea mays*) – under axenic (Leonard jars) and non-axenic (pots filled with nonsterile soil) conditions in two greenhouse experiments. In both experiments, the plants inoculated with PGPR were fertilized with low-solubility P forms: $Ca_3(PO_4)_2$ (applied at 93 mg P_2O_5 per jar) for the experiment with Leonard jars; and Araxá rock phosphate (600mg P_2O_5 per pot) for the experiment with soil. For the experiment with Leonard jars, plants were grown for 40 (maize and common bean), 45 (cowpea), or 105 days (brachiaria grass). For the experiment with soil, cowpea, common bean and cowpea were grown for 50 days; whereas brachiaria and maize were grown for 90 and 30 days, respectively. Under axenic conditions, the total dry matter (TDM) of common bean increased significantly ($P < 0.05$), in relation to the control without inoculation, after inoculation with strain UFLA 04-21 (54% increase) or UFLA 04-155 (21% increase), but neither maize nor brachiaria responded to PGPR inoculation, whereas the root dry matter of cowpea was reduced after inoculation with strains UFLA 04-217, UFLA 04-21, and UFLA 04-195. Under non-axenic conditions, maize was the most responsive species to PGPR inoculation, with significant increases of up to 109% in root, shoot, or total dry matter when inoculated with UFLA 04-233, UFLA 04-21, UFLA 04-195, or UFLA 04-155. The inoculation of cowpea with UFLA 04-217 significantly increased the SDM by about 113% under non-axenic conditions and, although not statistically significant ($P > 0.05$), a similar effect was observed when this crop was inoculated with UFLA 04-155. Also under non-axenic conditions, inoculation of brachiaria with UFLA 04-21 significantly increased the SDM by about 16%. All the tested *Burkholderia* spp. strains were able to promote plant growth to some extent, but among them the strain UFLA 04-21 was the most versatile, increasing the growth of brachiaria, common bean, and maize.

(9780 - 1797) CAS-Selected Metagenomics: Soil Microbial Mechanisms Involved in Grapevine Micronutrient Nutrition and Chlorosis

Lee Opdahl[1]; Ricky Lewis[1]; Anjuman Islam[1]; Joan Davenport[1]; Tarah Sullivan[1]

Washington State University[1]

Grapevine chlorosis is a common problem in many grape-growing regions of the world, particularly in alkaline soils, often causing reduction in grape yield and quality. While the role of soil microbial communities in plant health and nutrition is indisputable, the precise microbial mechanisms involved in mediating grapevine chlorosis are not yet characterized. Microbes have evolved strategies to increase Fe acquisition (siderophore/organic acid production) that also increase plant Fe uptake when Fe availability is limited. A better understanding of siderophore producing soil microbes could aid efforts to combat Fe deficiency and chlorosis in grapevines. A high-throughput chrome azurol S (CAS) assay was used to isolate siderophore producing bacteria from soil (pH ≥ 8.3) collected from the rooting zone of chlorotic grapevines in a central WA vineyard. DNA was extracted from samples exhibiting strong siderophore production, and next-generation sequencing (NGS; Illumina MiSeq) was used to conduct a metagenomic analysis of CAS-positive soil microbial communities. Seven distinct genomes were assembled from the samples using metaSPAdes in the Department of Energy Systems Biology Knowledgebase (KBase) with between 90-100% completeness. Phylogenetic analysis indicates all genomes most closely related within the *Pseudomonas* genus, including *Pseudomonas* sp. PTA1 and *Pseudomonas* sp. GM78. Genome annotation (RAST) and comparison revealed a total of 3,484 core protein families (2,629 core functions) shared between the seven newly constructed genomes, using *Pseudomonas* sp. PTA1 as a reference genome. Furthermore, nine classes of siderophore-related genes were identified in all seven genomes including siderophore-specific ABC transporters, iron-siderophore receptor/sensor proteins, and siderophore biosynthesis proteins. Five other siderophore-related genes were found in two genomes and included siderophore-specific ABC transporters, siderophore biosynthesis genes, and TonB-dependent siderophore receptors. In this study, the genomes of seven potential siderophore producing bacteria were sequenced, and key genes involved in plant and soil health were identified. Future work should examine the relationship of these novel bacteria with grapevine health status to determine plant growth-promoting potential. Examining the functions of the bacteria in soil Fe cycling could provide additional insight into strategies to alleviate chlorosis in many perennial fruit crops.

(9938 - 2334) Characterization of rhizobacteria producing Exopolysaccharides (EPS) and Biofilm in sugarcane (*Saccharum officinarum L.*).

Yamina Coentro Montaldo[1]; Crísea Cristina Nascimento de Cristo[2]; Tania Marta Carvalho dos Santos[1]; Beatriz Paes Duarte Brandão[1]; Sybelle Geogia Mesquita da Silva[1]

Universidade Federal de Alagoas[1]; Universidade Federal de Alagoas / Instituto Federal de Alagoas[2]

The improvement of crops under stress conditions can occur with the use of technologies such as the application of bacteria capable of promoting plant growth or beneficial physiological changes to plants. The production of exopolysaccharides (EPS) and biofilm formation are examples of the capacities developed by these microorganisms that allow the adaptation of plants to environmental stresses. The objective of this study was the isolation of rhizospheric soil bacteria in sugarcane cultivation areas for the production of microbial inoculants with the capacity of producing EPS and biofilm. Soil samples were collected in areas of sugar and alcohol plants in the State of Alagoas, from April to June 2016. Twenty-four collections were made, and a soil sample for each sugarcane plant. The samples were sent to the laboratory de microbiologia agrícola at Centro de Ciências Agrárias – Universidade Federal de Alagoas, The bacteria were isolated, identified and passed by qualitative and quantitative evaluation to test the potential for EPS production and biofilm formation on abiotic surfaces, in addition to quantification of the biofilm formed. At the end of the evaluations, it was verified that all the isolates were able to produce EPS, with variation depending on the carbon source used, as well as, the isolates presented biofilm formation capacity. Concluding the isolates have potential for use as a bioinoculant that help increase growth rates and crop yield, even under stress.

(6514 - 2522) Co-inoculation of common bean with plant growth promoting microorganisms

Raysa Marques Cardoso[1]; Enderson Petronio de Brito Ferreira[2]; Matheus Messias de Oliveira[2]; Marcos Antônio Rodrigues de Oliveira[2]

UFG[1]; Embrapa[2]

The use of plant growth promoting microorganisms has been a viable alternative for increasing agricultural production without the total dependence of fertilizers and agrochemicals. The diazotrophic

bacteria promote the biological fixation of nitrogen and are an example of this interaction. The objective of this assay is evaluate the interaction of *Azospirillum*, *Rhizobium* and *Trichoderma* co-inoculation in the common bean, considering that this association may result in not only productive but also ecological gains. The assay was implemented in the city of Cristalina, located in the state of Goiás using the cultivar Pérola. The experiment was in randomized complete blocks with four replicates. The plots were composed of 6 lines of 4 m in length, spaced at 0.45 m and having as treatments: 1- Absolute Witness; 2- Rhizobia; 3-Rhizobia and azospirilla; 4- Rhizobia, azospirilla and trichoderma; 5- Rhizobia and azospirilla + N according to NSI (Nitrogen sufficiency index) in V4; 6- Rhizobia, azospirilla and trichoderma + N according to NSI at R5; 7-120 kg ha-1 of N (45 kg ha-1 at the base); 8- 80 kg ha-1 of N + N according to NSI no V4; 9- 80 kg ha-1 of N + N according to NSI no R5; 10- 150 kg ha-1 of N at 10 days after emergence (45 kg ha-1 at the base). In the inoculated treatments the seeds were treated at the planting with a mixture of rhizobia, SEMIA 4077, 4080 and 4088, at the dose of 10 g of the inoculant per kilogram of seed and with Trichoderma sp. in the same dosage. The application of Azospirillum brasiliense was between phenolic stage V2 and V3 of the bean at the dose of 300 ml ha-1. The source of nitrogen used was urea. For the number and weight of nodules, the plants with the best averages were those of treatments 9 with 23.08 nodes plant-1 and 26.49 mg plant-1 and 2 with 22.83 nodes plant-1 and 34.16 mg plant-1. The treatments 6 and 7 obtained the highest averages of relative nitrogen content with 51.65 and 51.35, in V4. The R5 stage the highest averages were treatments 10 and 7 with 55.6 and 54.48 respectively. As for productivity per area, treatments 3, 2, 10 and 1 presented the highest yields, being 243.08 g/m², 247.98 g/m², 251.80 g/m² and 254.02 g/m², respectively. The effect of nitrogen fertilizer use was clear on nodulation, resulting in the lower mean number of plant nodules-1. For the production we observed that the greater the nitrogen attachment, being it by BNF or by fertilization, the higher the productivities.

(3256 - 1402) Dark septate endophitic fungi as plant-growth-promoting

Peter Medeiros[1]; Carlos Vergara-Júnior[1]; Carlos Inácio[1]; Jean Araújo[2]; Jerri Zilli[2]

University Federal Rural of Rio de Janeiro[1]; Embrapa Agrobiology- RJ[2]

The dark septate endophytic fungi (DSEF) are widely distributed in nature by colonizing plant roots and are often isolated from environments with strong abiotic stress. They represent a broad group of microorganisms that are still under-researched in tropical conditions and have significant potential for applicability in agriculture, since they are recognized as plant growth promoters similar to arbuscular micorrhyzal fungi. However, depending on the specific treatment conditions, DSEF may exhibit beneficial, neutral or pathogenic behavior. This work aimed to avaluate new five isolates DSEF strains deposited in collection of mycorrhizal fungi of Embrapa Agrobiology (COFMEA), Seropédica, RJ., concerning to pathogenic characteristics. Under greenhouse conditions, the DSEF strains named AM 101, AM 102, AM 103, AM 104 and AM 105 isolated from rice roots (*Oryza glumaepatula*) were tested compared to ten distinct agricultural crops such as soybean, cowpea, sorghum, tomato, rice, maize, common bean, pumpkin, lettuce and papaya. Prior the test, in the laboratory, the seeds were tested for their germinative ability. For the pathogenicity test in greenhouse, the methodology of the colonized toothpick was carried out. Subsequently, a study was conducted *in vivo* to avaluate whether DSEF isolates would be able to influence seed gemination. Our preliminar results show that neither DSEF isolates presented pathogenicity behavior in any of the cultures, and seeds inoculated with fungal suspension showed no significance, straigtening the hypothesis that these DSEF isolates do not present genotipic pathogenic charachteristics. Others study are being conducted to prove this hypothesis.

(3812 - 2971) Edaphoclimatic effects on native rhizobial populations in a tropical semiarid zone, Brazil

Vanessa Dina Cavalcante Barros[1]; Mario de Andrade Lira Junior[1]; Aline Medeiros De Arruda[1]; Mércia Virginia Ferreira Dos Santos[1]; Antônio Félix Da Costa[2]; Clayton Albuquerque De Sousa[3]

Universidade Federal Rural de Pernambuco[1]; Instituto Agronômico de Pernambuco[2]; Instituto Federal da Paraíba[3]

Regional climatic characteristics and soil heterogeneity are important agents in the establishment of native rhizobial populations. This study compared rhizobial populations from Neossolo Litólico, Luvissolo and Argissolo Vermelho Amarelo collected each in from three to five points in each of Bom Jardim county, a transition area humid and drier regions and Serra Talhada, a typical semiarid area with low and spatially and temporally irregular rainfall and high day temperatures. Most soil samples were sandy-loam with CEC greater than 27 cmol kg^{-1}, alkaline to slightly acidic with pH in water between 6.3 and 8. However, Serra Talhada soils were closer to neutrality.There also low Na^{+} contents whose higher values were for the Luvissolos of Serra Talhada (0.52 cmolc dm3) which also had the higher P (182 mg dm^{-3}) contents. Total C-organic content ranged between 6.3 and 8.5 g kg^{-1} for all soils, except for Serra Talhada Neossolo Litólico that presented higher C.O., Ca^{+2} and K^{+}. The samples were used to inoculate cowpea (Vigna unguiculata) as bait crop. The nodules were used for rhizobial isolation and morphological characterization followed by grouping with 100% similarity groups using PAST 2.09 Jaccard coefficients and UPGMA method. 479 isolates were obtained, of which 334 were fast growers perhaps as a survival mechanism due to the very short rain season.There were 100 and 175 100% similarity groups in Bom Jardim (244) and Serra Talhada (235), whose higher diversity may be due to the more drastic rainfall deficit under the latter conditions leading to higher microenvironments diversity when combined with soil conditions. Luvissolos had the lowest group-isolate ratio (0.47) with 85 of the 88 groups, maybe due to the higher clay content presented by these soils, since Argissolo vermelho amarelo also had the second lowergroup-isolates ratio (0.70) and second higher clay content. Our results indicate it is probably worthwhile to further investigate these environments as possible sources of new genetic material, since higher overall diversity may lead to higher diversity in rhizobial efficiency, and thus a higher chance of finding superior materials for inoculant production.

(7714 - 1700) Effect of indigenous and introduced arbuscular mycorrhizal fungi on growth of *Allium fistulosum* under field conditionEffect of indigenous and introduced arbuscular mycorrhizal fungi on growth of *Allium fistulosum* under field condition

Keitaro Tawaraya[1]; Takumi Sato[1]; Weiguo Cheng[1]

Yamagata University[1]

Phosphorus (P) is one of the essential elements for plant growth and often the first limiting nutrient in soils due to its low availability. Rock phosphate is the raw material of P fertilizer and it is estimated that the world's reserve would last for only 90 years. It is necessary to develop sustainable echnologies for the use of P resources. Arbuscular mycorrhizal (AM) fungi promote the growth of many plants by

enhancing P uptake. However, little is known about effect of AM fungi on growth of crop plant under filed conditions. The purpose of the present study was to investigate effect of indigenous and introduced AM fungi on the phosphorus uptake and growth of *Allium fistulosum* under field condition. The field soil was sterilized with application of fumigant dazomet at the rate of 2000 kg ha^{1}. Superphosphate was applied at the rate of 0, 500, and 1000 kg ha^{-1}. *A. fistulosum* was inoculated with AM fungus, *Glomus* R-10 and grown in a glasshouse. Non-inoculated plants were grown as control. Inoculated and non-inoculated seedlings were transplanted to sterilized and unsterilized field. This field experiment was repeated in 2015, 2016 and 2017. AM colonization, shoot P concentration, and shoot growth were measured. AM colonization in unsterilized field ranged from 37% to 76% in uninoculated plant and from 45% to 86% in inoculated plant at 35 days after transplanting, and was not different between inoculated and uninoculated plants until final harvest. AM colonization in sterilized field ranged from 1% to 19% in uninoculated plant and from 45% to 84% in inoculated plant and was mostly higher in inoculated plant than uninoculated plants until final harvest. Shoot growth of inoculated plant was not different from uninoculated plants in unsterilized field, but shoot growth of inoculated plant was higher than uninoculated plants in sterilized field. This result suggested that dazomet treatment suppressed indigenous AM fungi and introduced AM fungi promoted growth of *A. fistulosum* under sterilized field condition.

(1664 - 800) Effect of soybean inoculation and nitrogen fertilization on microbiological activity in a sandy soil

Guilherme Dias Batista[1]; Carlos Felipe dos Santos Cordeiro[1]; Bruno de Senna e Silva[1]; Fábio Fernando Araújo[1]; Fábio Rafael Echer[1]
Universidade do Oeste Paulista (UNOESTE)[1]

Sandy soils under high degree of degradation have low microbiological activity due to the low soil organic matter content, which also impairs the establishment of nitrogen fixing bacteria (N) in soybean crops. The objective of this work was to evaluate the microbiological activity of the soil in response to soybean inoculation and nitrogen fertilization. The experiment was conducted in two fields (first and second year of cultivation) in Presidente Bernardes-SP, Brazil, in the randomized block design in a subdivided plot scheme with 4 replications. In the plots the inoculant doses (0, 4, 8 and 12 ha^{-1}) were allocated and it was applied in the sowing furrow, and in the subplot N fertilization (ammonium nitrate) (0, 25, 50 and 100 kg ha^{-1}) in R1 stage. The density of a dose of inoculant was 5 $x10^{11}$ UFC. Soil was sampled at 0-10 cm depth in the R4 stage to quantify soil respiration, enzyme dehydrogenase activity and nitrogen and carbon in the microbial biomass. The statistical analysis consisted of analysis of variance and regression ($P < 0.05$). There was no interaction between treatments on soil respiration and the average of the first and second year fields was 5.8 and 4.6 mg CO_2 kg^{-1} soil day^{-1}, respectively. The enzyme dehydrogenase showed higher activity in the combinations of 12 doses of inoculant and 50 kg ha^{-1} of N on first year field (3.63 µg TTF g^{-1} soil) and 4 doses of inoculant without N application in the second year field (3,58 µg TTF g^{-1} soil). Microbial nitrogen biomass had a linear growth as a response of N rates increase on 8 and 12 doses of inoculant, in both fields. Microbial carbon biomass (C_{bio}) had a linear growth at 12 doses of inoculant and quadratic for the dose 0 in response to N increase in the first year field. In the second year field the application of 12 doses of inoculant without N or 8 doses of inoculant with 100 kg ha^{-1} of N provided the highest values of C_{bio}. In conclusion, nitrogen fertilization and inoculation do not affect soil microbial respiration, but an increase on inoculant rates improves the dehydrogenase activity on the first year field and nitrogen fertilization increases the N content of the microbial biomass associated with 8 and 12 doses of inoculant in both fields and the association of these doses with 100 kg ha^{-1} of N increases the carbon of the soil microbial biomass on first year field.

(4354 - 3029) Effects of different extracts and neem concentrations in microbiological activity and corn-mycorrhizal relationship cultivated in a soil of the "Sertão do Inhamuns" – Ceará, Brazil

Emanuel Dias Freitas[1]; Dayanne Camelo[1]; Leila Maria de Sousa Tavares[1]; Paulo Furtado Mendes Filho[2]
IFCE[1]; UFC[2]

Neem (Azadirachta indica A. Juss) is a rustic plant species adapted to different regions of the world. Its use is related to insecticidal action, wood production, landscaping and even minimizing problems caused by desertification and soil erosion. Of all the utilities attributed to neem, the insecticidal action is the most documented. However, the results of studies of the action of neem aqueous extracts on edaphic microbial activity is still rather scarce and controversial. This study aimed to evaluate the effects of different extracts and neem concentrations in microbiological activity and corn-mycorrhizal relationship cultivated in a soil of the "Sertão do Inhamuns" – CE. The experiment was conducted in the experimental area of the Instituto Federal do Ceará campus Crateús in a completely randomized design following the factorial arrangement 2x3 + 1. The treatments were: control (T1), leaf extract of neem to 5% (T2), 10% (T3), 20% (T4), seed extract of neem to 5% (T5), 10% (T6), 20% (T7) concentration. Each treatment had 5 replications, totalizing 35 plots. Soil basal respiration, soil microbial biomass carbon, total organic carbon, metabolic quotient, microbial quotient, mycorrhizal colonization in the root cortex and spore density were analyzed. Basal respiration and total organic carbon were higher for soils receiving seed extracts than those receiving extracts from neem leaves. It was observed higher values of metabolic quotient for the concentrations containing 20% of neem seed (T7) when comparing the leaf extracts. The microbial quotient was higher for the treatments with concentrations of 5%, 10% and 20% of leaf in relation to those of seed. The aqueous extract containing 20% of neem seed (T7) was the one that most stressed the microbial activity of the soil, because it reduced the carbon content of the soil biomass (CMS), raised the basal respiration and the metabolic quotient (qCO_2). However, this treatment promoted a higher spore density of arbuscular mycorrhizal fungi in the soil. The mycorrhizal colonization in the root cortex did not differ statistically in the different treatments.

(4751 - 2510) Effects of inoculation on vegetative development of corn

Vinicius Leite[1]; Gustavo Benincá Rodrigues[1]; João Vitor Berner Pereira[1]; José Filipe dos Santos Maciel[1]; Mauricio Rosa Magro[1]; Ana Rosa da Silva França[1]; Camila Köche Wibbelt[1]; Julio Cesar Ariati[1]; Renan Adamcheski[1]; Sonia Purin da Cruz[1]
Universidade Federal de Santa Catarina[1]

Current scenario of agronomy in Brazil raises concerns related to environmental sustainability due to intensive use of chemical fertilizers. Inoculation is an alternative to reduce the amount of fertilizers applied. This technique is based on using plant growth-

promoting bacteria that mainly produce hormones, resulting in higher yield and optimized cost-benefit ratios. The aim of this study was to verify the effects of inoculants on plant height, ear insertion height and stem diameter of corn (*Zea mays*) at R1 stage. The experiment was carried on in Frei Rogério – SC/Brazil, at Salto Correntes. Corn was sown in November 2017, following and completely randomized block design with nine treatments and six repetitions. Plots measured 6.5x4.0m. Treatments included levels of nitrogen ranging from 0%, 75% and 100%. Inoculation treatments included different species of bacteria and fungi. Data were submitted to analysis of variance and no statistical difference was observed among treatments for any studied variable. Based on our findings, we may state that inoculation is not mandatory in order to improve vegetative development of corn. However, further yield analyses are to be conducted to verify feasibility of inoculation as a recommended practice.

Keywords: Keywords: inoculants, *Zea mays*, tratamants.

(5905 - 1279) Effects of wheat-white lupin intercropping on chemical and microbiological properties of soil related to N and P cycles

Ana Beatriz De Oliveira[1]; Philippe Hinsinger[2]; Mustapha Arkoun[3]; Edith Le Cadre[4]
INRA / AII[1]; INRA[2]; AII (Agro Innovation International)[3]; AGROCAMPUS OUEST[4]

Intercropping is a cropping system in which several species are growing in a field during a significant period of their life cycle. This cropping system becomes a promising alternative to intensive agriculture in many countries due to ecological regulations. While benefits of mixed cropping are listed in a large body of literature, only scarce studies focused on the long term consequence of such systems and especially in terms of soil quality. In this study, we estimated if crop association can modify the soil functioning through modifications of the nitrogen (N) and phosphorus (P) cycles. We hypothesize that crop associations can shape microbial activity through plant exudation or litterfall. A pot experiment (pots of 4L with 2,2 kg of soil) was conducted from September 2017 to December 2017 on a calcareous soil with white lupin (*Lupinus albus* var. Feodora) and wheat (*Triticum aestivum* var. Lennox) in both mixing and respective sole crops at three nitrogen levels (N0 = 61 mg kg^{-1} soil; N1 = 92 mg kg^{-1} soil; N2 = 124 mg kg^{-1} soil) to influence plant interactions with seven replicates. At flowering, we measured the nitrogen, phosphorus content of plants (root and shoot) and soil chemical variables (mineral nitrogen, labile phosphorus content after Olsen extraction method and pH) but also soil biological variables (total microbial biomass, abundance of ammonia-oxidizing bacteria (AOB) and archaea (AOA) and microbial carbon, nitrogen and phosphorus contents (MBC, MBN and MBP)). As preliminary results, we measured greater values of MBC, MBN and NH_4^+_N content in rhizosphere compared to bulk in all treatments as expected from other studies. But surprisingly, we measured a significant NO_3^-_N level in the rhizosphere of sole lupin treatment compared to others treatments while NH_4^+_N were similar to mixing crops. We hypothesize that nitrification rate can be modified in the lupin rhizosphere compared to others treatments. Plant and molecular biology analyses planned will confirm this interpretation. If confirmed, it will be interesting to investigate if this nitrification potential is maintained after several cycles of mixing cropping.

(8397 - 2937) Efficiency of Streptomyces spp. in growth, nodulation and productivity of cowpea beans

Albert Lennon Lima Martins[1]; Edvaldo Vieira Pacheco Sant'Ana[2]; Rodrigo Silva de Oliveira[1]; Juliana Mariano Alves[3]; Fred Newton da Silva Souza[3]; Weslany Silva Rocha[1]; Thadeu Teixeira Júnior[4]; Weder Ferreira dos Santos[1]; Lillian França Borges Chagas[1]; Aloísio Freitas Chagas Júnior[1]
Universidade Federal do Tocantins[1]; Instituto Federal de Educação, Ciência e Tecnologia do Tocantins[2]; Universidade Estadual do Tocantins[3]; Secretária do Desenvolvimento da Agricultura e Pecuária do Tocantins[4]

Cowpea is a very important food crop; however, it has low productivity due to the level of the technological level. And to achieve better productivity, several studies related to the selection of micro-organisms have been observed. Thus, the present work aimed to select, through agronomic efficiency studies, strains of *Streptomyces* ssp. know as inoculants for a bean cowpea crop in the region and to evaluate the effect of the doses on a crop. A selection of isolates was conducted in a greenhouse with an inoculation of nine isolates of *Streptomyces* ssp. in cowpea beans. Two evaluations were performed without experience, at 20 and 45 days after emergence (AED). After that, the effect of different doses of *Streptomyces* ssp., both in the greenhouse and in the field, was evaluated. A cultivar of Sempre Verde BRS Rouxinol cowpea was used and the treatments consisted of five inoculant doses (0, 100, 200, 300 and 400 mL of *Streptomyces* ssp. inoculant, for each 50 kg of seeds), being reviewed in 20, 50 and 75 DAE in greenhouse and at 20, 50 and 77 DAE in the field. Regarding the evaluation of the selection of the isolates, it was observed that UFT-St06 (4.48 mm) and UFT-St07 (4.17 mm) strains were distinguished for the stem diameter parameter. In addition, UFT-St03, UFT-St06 and UFT-St08 strains showed a better relative efficiency of the isolates (ER), with 23, 30 and 21%, respectively. As for the effect of doses, in greenhouse as better doses of 300 and 400 mL/50 kg seeds for all parameters. And the best observation efficiency with 300 mL treatment in both evaluations (20 and 50 DAE). The field dose experiment confirmed the results obtained without greenhouse experimentation, and a higher grain yield was obtained with a dosage of 300 ml (1.113,5 kg ha^{-1}). Thus, one can observe the genus *Streptomyces* is a promising agent due to the production of several metabolites of interest.

(4674 - 2609) Environmental Remediation Potential of Biological Nitrogen Fixation and Its Application

Ying Teng[1]; Xiaomi Wang[1]; Lingjia Zhu[1]; Wenting Ma[1]; Yongming Luo[1]
Key Laboratory of Soil Environment and Pollution Remediation, Institute of Soil Science, Chinese Academy of Sciences, Nanjing 210008, China[1]

Biological nitrogen fixation is a significant source of nitrogen in agricultural ecosystems, thus playing an important role in agricultural sustainable development. The key to biological nitrogen fixation lies in the resources of nitrogen-fixing microbes. It has been found that nitrogen-fixing microbes are widely distributed in host plants such as leguminous plants and non-leguminous plants, and even exist in some extreme environments. At present, the nitrogen-fixing resources which are widely used in agricultural production include rhizobium-legume symbiosis system, Frank actinomycetes-(non-leguminous) symbiosis system, diazotrophic cyanobacteria-azolla symbiosis system, etc. Among them, the rhizobium-leguminous

symbiosis system is the most classic biological nitrogen fixation system, which has the strongest nitrogen fixation ability. With the deepening of research, researchers also find that biological nitrogen fixation plays an important role in ecological environment restoration. Numerous studies have shown that nitrogen-fixing bacteria not only have prominent abilities in resisting heavy metals and degrading organic pollutants, but also can assist phytoremediation. In addition, the presence of nitrogen-fixing bacteria can also directly or indirectly affect the microbial community in soils, thus promoting the restoration of soil ecological function. Thus, the function of biological nitrogen fixation in environmental remediation should also attract global attention and need further development. This paper summarized the concept, types and principles of biological nitrogen fixation. The emphasis focused on the roles of biological nitrogen fixation in the remediation of ecological environment and its related mechanisms. In addition, current application of biological nitrogen fixation in the field of environmental remediation was introduced. Some suggestions are further put forward to strengthen the potential of biological nitrogen fixation in environmental remediation. We hope that it could provide some green techniques and basis for improving agricultural sustainable development and ecological environment.

(5950 - 2490) Evaluation of corn diameter in response to different inoculation treatments through Balanced Incomplete Block Design.

João Vitor Berner Pereira[1]; Gustavo Benincá Gustavo Benincá[1]; José Filipe dos Santos Maciel[1]; Maurício Rosa Magro[1]; Ana Rosa da Silva França[1]; Camila Köche Wibbelt[1]; Júlio César Ariati[1]; Renan Adamcheski[1]; Vinicius Leite[1]; Crysttian Arantes Paixão[1]
Universidade Federal de Santa Catarina[1]

The randomized complete block design – RCDB is commonly adopted when establishing field experiments. This design is based on blocking experimental units that receive studied treatments. Blocks, by definition, must have homogeneous conditions throughout their entire area. In Soil Microbiology, experiments with inoculation are usually carried on with many treatments, which demands large blocks. Therefore, the size of experimental areas is big and hence the possibility of error increases. This causes heterogeneity of environmental conditions and makes adoption of RCBD not feasible. The use of a balanced incomplete block design – BIBD reduces these problems and allows testing of several treatments as it keeps homogeneous blocks characteristics. Rather than disposing all treatments in one block, only a few are disposed and hence experimental areas are also reduced in size. The aim of this study was to evaluate the response of corn (*Zea mays*) diameter when submitted to treatments of inoculation with growth-promoting rhizobacteria. The experiment was carried on in 2017 in Frei Rogério/SC, Brazil. Ten treatments were studied, with 6 repetitions, resulting in fifteen blocks. Treatments included one control and nine different inoculation methods or bacterial species. Each block had 4 experimental units (6.5 m x 4.0 m), hence the disposal efficiency was 83.33% compared to RCDB. Sampling was performed at V3, with 6 plants per experimental unit. Data were submitted to ANOVA at 5% significance level. No statistical difference was detected among treatments. We conclude that inoculation practices here tested are not mandatory in order to improve early development of corn plants.

(1423 - 3046) Examining the Influence of Wheat Genotype on Root Exudate Composition and Microbiome Recruitment

Ricky Lewis[1]; Jade Ermita[1]; Scot Hulbert[1]; David Gang[1]; Tarah Sullivan[1]
Washington State University[1]

In wheat (*Triticum aestivum*, L.) growing regions of the world, varieties are bred to address specific regional issues including drought, disease, and nutrient deficiencies or toxicities. However, the full environmental implications of traits allowing sufficient yields under these adverse biotic or abiotic conditions are not fully understood, particularly within the wheat microbiome. Given that many wheat genotypes have the capacity to select specific soil microbiomes, examining the role of genotype-specific root exudates in recruitment of microbiomes is critical to understanding and manipulating the mechanisms governing this process. Our work uses the most advanced techniques in root metabolomics, in combination with next generation sequencing (Illumina MiSeq) of the microbiome in order to understand the composition, function, and mechanisms of recruitment within the wheat phytobiome. Six wheat genotypes were targeted for their resistance to soil acidity and aluminum toxicity. A method was developed to culture wheat plants aseptically in bioreactors for up to a month and wheat root exudates were sampled directly from the bioreactors. Exudate samples were then derivatized and subjected to metabolomic analysis via GC-MS and LC-MS-MS. Initial root metabolomics have revealed 54 basic root metabolites including organic acids, amino acids, and sugars in a wheat genotype that demonstrates aluminum tolerance and forms a genotype specific root microbiome in multiple soils from Washington, USA. *Rhizoctonia* (a root-born disease, prevalent in our area) pathogenicity is suppressed in soils associated with additional genotypes that will be assessed in ongoing studies. Our work aims to elucidate the relationship between wheat genotype, root exudate composition, and soil microbial communities in a manner which may inform the understanding of Al tolerance mechanisms in wheat and assist future endeavors in generating and utilizing pathogen suppressive soils.

(3761 - 1110) Factors affecting the nematode community and microbial activity in the soil

Marek Renčo[1]; Andrea Čerevková[1]; Erika Gömöryová[2]; Gabriela Barančíková[3]; Erika Tobiašová[4]
Institute of Parasitology SAS, Hlinkova 3, 040 01 Košice, Slovakia[1]; Faculty of Forestry, Technical University in Zvolen, TG Masaryka 24, 960 53, Zvolen, Slovakia[2]; National Agriculture and Food Centre, Soil Science and Conservation Research Institute, Gagarinova 10, 827 13 Bratislava, Slovakia[3]; Slovak University of Agriculture, Department of Soil Science, Tr. A. Hlinku 2, 949 76 Nitra, Slovakia[4]

Nematode and microbial communities are integral parts of soil and their activity is very important to the functioning of soil. Both have a high level of species number and diversity, which is determined by set of environmental conditions. A better understanding of community characteristics among major ecosystem types is necessary before these can be applied to environmental analysis in regional and global scale. Nematode communities and microbial activity were thus measured in the three main soil types Cambisol (CS), Chernozem (CZ) and Stagnosol (SS). Soil samples were collected from undisturbed forests (F), relatively undisturbed permanent meadow (M) and disturbed agricultural lands (A) of all soil types three times per year. Seasonal fluctuation within communities was thus also investigated. The objectives of this study were to: 1) determine the variability in soil properties among and within forest, meadow and agricultural

ecosystems; 2) compare nematode communities and microbial activity among and within ecosystem and soil types; 3) determine if nematode community composition or community indices are able to differentiate soil and ecosystem types; 4) identify seasonal changes of nematode communities and microbial activity within ecosystem and soil types. Overall, the highest nematode numbers had CZ followed by CS and SS. Total nematode abundance differs among soil type within particular ecosystems as well among sampling time within ecosystems. In CZ, the highest nematode number was detected in A followed by F and M ecosystems; in CS (A, M and F); in SS (M, F and A). Results point out that ecosystem type was more important factor affecting nematode species occurrence and diversity than soil type. Different aspects of the presence and activities of microorganisms in the soil e.g. soil respiration, N mineralisation, microbial biomass carbon, catalase activity as well soil properties (pH, C, N content, C/N ratio) also demonstrated significant effect of ecosystem, soil type and season to communities.

(5137 - 1196) From barley to maize: Exploiting the potential of genotype selection to optimize root-soil interactions

Lumbani Mwafulirwa[1]; Liz Baggs[1]; Joanne Russell[2]; Tim Daniell[3]; Jill Cairns[4]; Christian Thierfelder[4]; Nick Morley[5]; Eric Paterson[2]

University of Edinburgh[1]; The James Hutton Institute[2]; University of Sheffield[3]; CIMMYT Zimbabwe[4]; University of Aberdeen[5]

Root-soil interactions are central to C- and N-cycling in soil, and thus to greenhouse gas fluxes and nutrient supply supporting plant productivity. In our previous work on barley, we assessed the potential of root trait selection to promote C-storage and sustainable nutrient supply in soil. In planted experiments, using barley recombinant chromosome substitution lines developed using a wild donor and an elite cultivar, we demonstrated barley genotype-specific impacts on mineralization of native soil organic matter and crop residues mixed in soil, with direct impacts on N-uptake by plants. We also demonstrated a variation in root-C deposition, relative stabilization of this root-derived C in soil, and a strong plant genetic control and heritability of traits mediating the functioning of the barley microbiome. Furthermore, we have started to resolve the bases of genetic control of soil processes in barley, as a first step to manipulate C and N dynamics through germplasm selection and plant breeding. In combination these findings suggest strong potential for genotype selection and variety improvement in crop plants to support sustainable production systems. This concept was developed in a successful proposal to the UK Global Challenges Research Fund and we are now working to further exploit the potential of genotype microbiome interactions to promote sustainable soil health in the context of maize germplasm in southern Africa. Here we present key findings in barley and ongoing research in maize.

Keywords: Carbon and nitrogen cycling; sustainable soil health; root-soil-microbe interactions; variety selection

Financial support: Work in barley was funded by a James Hutton Institute international PhD studentship awarded to LM. Ongoing work in maize is supported by the UK BBSRC under the Global Challenges Research Fund.

(9306 - 941) Growth of *Cymbopogon citratus* inoculated with arbuscular mycorrhizal fungi *Rhizophagus clarus* and *Claroideoglomus etunicatum* under phosphorus levels

Caroline Lermen[1]; Rayane Monique Sete da Cruz[1]; Carlos Henrique de Souza Gonçalves[2]; Glaucia Leticia Sete da Cruz[2]; Giovana Penteado Amaral da Silva[2]; Luiz Renato Marques das Almas[2]; Odair Alberton[3]

Programa de Pós-graduação em Biotecnologia Aplicada à Agricultura; Universidade Paranaense – UNIPAR; Praça Mascarenhas de Moraes; 4282; 87502-210; Umuarama – PR – Brazil.[1]; Graduate students, Universidade Paranaense – UNIPAR; Praça Mascarenhas de Moraes; 4282; 87502-210; Umuarama – PR – Brazil.[2]; Programa de Pós-graduação em Biotecnologia Aplicada à Agricultura; Universidade Paranaense – UNIPAR; Praça Mascarenhas de Moraes; 4282; 87502-210; Umuarama – PR – Brazil, (presenter e-mail: odair@prof.unipar.br)[3]

Cymbopogon citratus Stapf (lemon grass) has high biological potential, which is availed by the perfume, food and pharmaceutical industries. Various factors may affect the metabolism of this plant, such as associations with arbuscular mycorrhizal fungi (AMF) that contribute to increases in water absorption and nutrient uptake (especially phosphorous – P). This study aimed at assessing the AMF symbiotic effect on nutrient uptake and growth of *Cymbopogon citratus,* inoculated with AMF *Rhizophagus clarus* and *Claroideoglomus etunicatum* under different levels of P in the substrate. Treatments were prepared with sterile substrate with high (200 mg kg^{-1}) and low (20 mg kg^{-1}) P levels and with and without AMF inoculation in a greenhouse experiment for six months. A 3 x 2 (3 mycorrhizal x 2 levels of P) factorial experiment in a completely randomized design (8 repetitions) was used in this study. Spore density and root AMF colonization, basal soil respiration (BSR), microbial biomass carbon (MBC), shoot dry matter (SDM), root dry matter (RDM), total dry matter (TDM), N content in the plant (N) and P content in the plant (P) were the variables and parameters analyzed in this assessment. Regardless P levels, no significant AMF symbiotic effect ($p > 0.05$) on the lemon grass growth was observed. The contents of P and N on the shoot and P total increased in the treatments with AMF and high P level, being more evident for the inoculation with *R. clarus*. Spore density, root colonization and MBC were higher with AMF inoculation. The AMF inoculation increased the contents of P and N in the *C. citratus*, but did not affect plant growth.

(4442 - 676) Growth, nodulation and nutrient concentrations of lucerne in response to inoculation of abscular mycorrhizal fungus and rhizobium

Jianguo Huang[1]; Ling Yuan[1]

Southwest University[1]

Tropical and subtropical soils in South China are often acidic and nutrient deficient due to strong leaching and intensive cropping. Inoculation of rhizobia and arbuscular mycorrhizal fungi could be considered as one of important strategies to improve the growth and quality of lucerne in artificial cultivation. Therefore, a greenhouse pot experiment was conducted to evaluate the effects of rhizobial and mycorrhizal inoculation on growth, nodule formation, and nutrient uptake with lucerne (cv. Victoria) in an acid soil (pH 5.5). The experiment treatments included seedling alone (control, CK), *Sinorhizobium meliloti* inoculation (SM), *Glomus intraradices* inoculation (GI), and mixture inoculation of SM and GI (SM+GI) with factorial design with 6 replications. Lucerne showed the highest mean shoot biomass of about 28 g in SM+GI, followed by SM (24.5 g), GI (22.3 g), and CK with about 20 g $seedling^{-1}$ (fresh weight). There were no nodules found on the roots of seedlings in both CK and GI, but more nodules formed in SM+GI than SM, implying the promotion of nodule formation by GI at the presence of SM. Phosphorus concentrations in lucerne shoots varied in the sequence: GI and SM+GI > MS > CK (no significant difference between GI and SM+GI), which confirmed the fact that mycorrhizal infection increases phosphors uptake. Compared with other treatments, lucerne shoots contained the highest N in

SM+GI, indicating higher protein content. Therefore, mixture inoculation could be a better strategy than either *G. intraradices* inoculation or *S. meliloti* to enhance Lucerne yield and quality in acid soils.

Keywords: rhizobia,abuscular mycorrhial fungi, lucerne

(7980 - 1991) Hydric stress resistant bacteria associated with Pitaya plants rhizosphere (Hylocereus undatus)

Silva, E.L.D.[1]; Isidio, E.L[1]; Freitas, C.G.G[1]; Carvalho, A.S[1]; Teixeira, M.F[1]; Silva, J.M.M[1]; Amorim, A.S[1]; Kuklinsky-Sobral, J[1]
Federal Rural University Of Pernambuco / Garanhuns Academic Unit (Av. Bom Pastor, Cep: 555292-270, Garanhuns-Pe, Brazil).[1]

For the establishment of sustainable agriculture, we need to better understand the dynamics of the relationship between micro-organisms, soil and plant. As water is a fundamental resource, both for plant and for micro-organisms, providing their biochemical activities, and the scarcity of it can become a problem for the production of food. Some plant cultures, such as Pitaya (Hylocereus undatus), have developed evolutionary mechanisms to withstand under water deficit conditions. It is speculated that bacteria present in soil microbiota, or in interaction with the plant, can contribute to plant development, including in these stressful situations, and may be important in the survival and growth of plants in dry environments. Therefore, the present work aims to isolate and evaluate the bacterial population density, total and resistant to the hydric stress, associated to Pitaya plants. Experiments were carried out to isolate bacteria from the rhizosphere and endophytic of cladodes in TSA 10% culture medium and amid hydric stress (plus sorbitol, providing water activity of 0.963 Aw, at 25 °C). Three Pitaya plants were used, cultivated in Garanhuns, Pernambuco, Brazil, and three homogeneous composite samples were collected from the rhizosphere and a cladode of each plant. Population density was estimated after 15 days of cultivation of isolation. It was observed that Pitaya plants present association with rhizosphere bacteria resistant to the hydric stress, with high indices of population density (10^8 to 10^{10} UFC.mL^{-1}), not differing between the means of culture medium used. However, in the cladodes samples evaluated, there was no bacterial growth wit h the methodology used for the isolation of endophytic bacteria. The refore, rhizosphere bacteria associated with Pitaya present potential for future studies of hydric stress.

(4367 - 677) *In vitro* effect of berberine on soil nitrification

Ling Yuan[1]; Jianguo Huang[1]
Southwest University[1]

Coptis chinensis is a medicine herb in family Ranunculaceae which has been used traditionally as bactericides to treat intestinal infection of human and animals for many centuries in East and Southeast Asia. This medicine plant is now grown commercially but cannot be grown successively in same soil due to autotoxicity and serious diseases. During the growing period, *Coptis chinensis* released numerous allelochemicals into soils. Berberine is the largest contributor of these chemicals, accounting for about 80% of the total allelochemicals entering soils. Thus, a purplish soil was incubated to compare microbial biomass, dehydrogenase activity, nitrification, and bacterial community structures with different concentrations of berberine (without berberine, CK; 10 mg/kg soil, LB; and 20 mg/kg soil, HB). This compound, particularly at HB, decreased significantly soil microbial biomass carbon and nitrogen, dehydrogenase activity, and nitrate content after 4 week incubation. Addition of berberine into soil solutions also decreased the nitrate concentration but showed relatively more nitrate accumulation in soil solution with potassium nitrite than with ammonia sulphate, implying stronger inhibition of ammonia-oxidizing bacteria or ammonia-oxidizing archaea than *Nitrobacter* or *Nitrospira*. The nitrification inhibition could thus be one of mechanisms for the obstacles produced by the cultivation of *Coptis chinensis*. There were 13012, 10657, and 9005 16S rDNA sequences picked up from soils of CK, LB, and HB, respectively, by high throughput sequencing, which were attributed into 562 (CK), 405 (LB), 314 bacterial phylotypes (HB). Berberine could inhibit growth, reproduction, and activity of some bacteria, including those responsible for nitrification. Soils received berberine showed lower bacterial richness and diversity indexes than CK. Less group and number of bacteria present in soils could encourage over reproduction of any single bacterial taxon and thus increase the risk of plant disease occurrence in successive *Coptis chinensis* cultivation.

Keywords: *Coptis chinensis*; berberine; allelochemicals; bacteria; nitrification

(7681 - 2332) Isolation and characterization of rhizobacteria solubilizers of inorganic phosphates in sugarcane (*Saccharum officinarum L.*).

Crísea Cristina Nascimento de Cristo[1]; Yamina Coentro Montaldo[2]; Tania Marta Carvalho dos Santos[2]; João Manoel da Silva[2]; Jose Ubaldo Lima de Oliveira[2]
Universidade Federal de Alagoas / Instituto Federal de Alagoas[1]; Universidade Federal de Alagoas[2]

Phosphorus is one of the elements most required by agricultural crops, however the availability of this nutrient in the soil for plants is limited, requiring the addition of a large amount of synthetic fertilizers, which in addition to the high cost lead to the degradation of environmental resources, contributing to an agriculture that is increasingly dependent on inputs. Considering the concerns inherent in the production of food with less harmful managements in the environment, the objective of this study was to isolate plant growth promoting bacteria from the soil present in the sugarcane rhizosphere to produce microbial inoculants capable of solubilizing phosphate. Soil samples were collected in areas of sugar and alcohol plants in the state of Alagoas, from April to June 2016. Twenty-four collections were made, and a soil sample for each sugarcane plant. the samples were sent to the laboratory de microbiologia agrícola, at the Agricultural Sciences Center – Universidade federal de Alagoas, Bacteria were isolated, identified and underwent qualitative and quantitative evaluation in order to test their potential for solubilization of inorganic phosphates ($Ca_3(PO_4)_2$). The results demontrated that the isolates, with the exception of isolate 4, presented characteristics for the availability of inorganic phosphorus, promoting plant growth, which suggests the biotechnological potential of these isolates. The use of these isolates may reduce or avoid the use of synthetic fertilizers and should be considered future inoculation tests in plants.

(7130 - 2930) Legume-nodulating rhizobia are maize endophytes in Brazilian Semi-Arid

Maria Idaline Pessoa Cavalcanti[1]; Dalila Ribeiro Rodrigues[2]; Adailson Pereira de Souza[3]; Paulo Ivan Fernandes-Júnior[4]
Universidade Estadual da Paraíba/Universidade Federal da Paraíba[1]; Universidade Estadual da Paraíba[2]; Universidade Federal da Paraíba[3]; Embrapa Semiárido[4]

The isolation and characterization of plant growth promoting bacteria (PGPB) for maize (*Zea mays*) are important for the obtainment of efficient bacteria that can be used as new inoculant strains. The isolation and selection of PGPB for non-legumes have been carried out worldwide using the standard N-free semi-solid media, allowing the obtainment of efficient diazotrophic isolates. In the last few years, new approaches have been developed to obtain and characterize other cultivable endophytic bacteria. There is the evidence for the existence of endophytic rhizobial communities in maize roots. To evaluate if in soils from Brazilian Semi-Arid the field-grown maize is colonized by legume nodulating rhizobia, we carried out the isolation of maize endophytic rhizobia (MER) by means of inoculation of surface-disinfected plant extracts on cowpea (*Vigna unguiculata*) seeds in axenic conditions. The maize roots were surface-disinfected with NaClO (2% v/v) and washed eight times in autoclaved water. The last water was inoculated in YMA culture medium to assure the absence of of surface contaminants. The disinfected roots were crushed in NaCl 0.85 % (w/v) and inoculated in surface-disinfected cowpea (BRS Pujante) seeds sowed in sterilized sand. Cowpea was grown for 35 days and were harvested. The rhizobia were isolated in a standard YMA medium and identified through the sequencing of 16S rRNA. The absence of nodules in the control treatments end the negative growth bacteria in the wash water inoculated in YMA medium indicated that the nodules observed were induced by the bacteria from inhabiting the inner of maize roots. A total of 13 bacteria were isolated, and among them, 10 isolates was fast growing and 3 was slow growers with typical rhizobial colonies characteristics. The 16S rRNA sequences showed that the fast growers were classified as *Rhizobium*, mainly within the *R. tropici* clade, close to *R. calliandrae*. The and slow-growing bacteria belonged to *Bradyrhizobium* genus within *B. japonicum* clade. These results indicate the endophytic colonization of maize roots by legume-nodulating rhizobia.

(7154 - 435) Lima bean nodulates efficiently with *Bradyrhizobium* strains isolated from diverse legume species

Elaine Martins da Costa[1]; Paula Rose de Almeida Ribeiro[2]; Wellington de Lima[2]; Thiago Palhares Farias[2]; Fatima Maria de Souza Moreira[2]
Federal University of Piaui[1]; Federal University of Lavras[2]

Lima bean (*Phaseolus lunatus* L.) is an important legume species that establishes symbiosis with rhizobia, mainly of the *Bradyrhizobium* genus. The aim of this study was to evaluate the efficiency of rhizobia of the genus *Bradyrhizobium* in symbiosis with lima bean, in both Leonard jars and in pots with a Latossolo Amarelo distrófico (Oxisol). In the experiment in Leonard jars, 17 strains isolated from nodules of the three legume subfamilies, Papilionoideae (*Vigna unguiculata*, *Pterocarpus* sp., *Macroptilium atropurpureum*, *Swartzia* sp., and *Glycine max*), Mimosoideae (*Inga* sp.) and Caesalpinioideae (*Campsiandra surinamensis*) and two uninoculated controls, one with a low concentration (5.25 mg L^{-1}) and another with a high concentration (52.5 mg L^{-1}) of mineral nitrogen (N) were evaluated. The six strains that exhibited the highest efficiency in Leonard jars, isolated from nodules of *Vigna unguiculata* (UFLA 03-144, UFLA 03-84, and UFLA 03-150), *Campsiandra surinamensis* (INPA 104A), Inga sp. (INPA 54B) and *Swartzia* sp. (INPA 86A), were compared to two uninoculated controls, one without and another with 300 mg N dm^{-3} (NH_4NO_3) applied to pots with samples of an Oxisol in the presence and absence of liming. In this experiment, liming did not affect nodulation and plant growth; the INPA 54B and INPA 86A strains stood out in terms of shoot dry matter production and provided increases of approximately 48% in shoot N accumulation compared to the native rhizobia populations. Our study is the first to indicate *Bradyrhizobium* strains isolated from the three legume subfamilies are able to promote lima bean growth via biological nitrogen fixation in soil conditions.

(6016 - 1115) Microaerophilic iron-oxidizing bacterial community in the bulk soil and rhizosphere of paddy field

Kento Kato, Tatsushi Naruse[1]; Yoshinori Ban[2]; Tomofumi Yoshida[2]; Taketo Funao[2]; Takahiro Kato[2]; Mari Namikawa[3]; Tomoki Takahashi[3]; Mizuhiko Nishida[3]; Susumu Asakawa[4]; Takeshi Watanabe[4]
School of Agricultural Sciences, Nagoya University, Nagoya 464-8601, Japan[1]; Field Crop Division, Aichi Agricultural Research Center, Anjo, Aichi 446-0066, Japan[2]; Tohoku Agricultural Research Center, NARO, Daisen, Akita 014-0202, Japan[3]; Graduate School of Bioagricultural Sciences, Nagoya University, Nagoya 464-8601, Japan[4]

Redox cycling of iron (Fe) is the central processes in the biogeochemistry of paddy field soil. Although redox process of Fe is mediated by both abiotic and biotic reactions, significance of biotic Fe oxidation had not been recognized in paddy field soil. However, we previously observed Fe-oxides deposited microbial colonies on paddy soil surface under microaerobic conditions, in which microaerophilic Fe-oxidizing bacteria (FeOB) related to *Gallionella ferruginea* and '*Sideroxydans*' spp. were enriched. We recently isolated a novel microaerophilic FeOB in the family *Gallionellaceae*, *Ferrisolum kumadai* An22, from a paddy field. These findings suggested that *Gallionella*-related FeOB have a potential to participate in the Fe-oxidizing process in paddy field soil. However, their diversity and community dynamics have been unknown. The present study investigated the community structure of *Gallionella*-related FeOB in the bulk soil and rhizosphere of paddy field soils. A primer set targeting 16S rRNA gene of *Gallionella*-related FeOB was successfully developed for the qPCR and PCR-DGGE analyses. Bulk soil samples, which were periodically collected from two paddy fields, rhizosphere soil and roots samples from a paddy field were subjected to the analyses. DGGE analysis of the bulk soil community of two paddy fields showed seasonal shifts of the patterns, that is, the community structures were changed after flooding and drainage. All of the DGGE bands were affiliated within the *Gallionellaceae*, some of which were related to known microaerophilic FeOB, *G. ferruginea*, *F. kumadai*, '*S. lithotrophicus*' and '*S. paludicola*'. qPCR analysis detected 10^5–10^8 copies of the 16S rRNA gene g^{-1} dry soil and the numbers were negatively correlated to the abundance of acetate-extractable ferrous Fe in the soils during the rice cultivation period. The community structure of rice rhizosphere soil was not largely different from that of the bulk soil and didn't change between the tillering and flowering stages, while some FeOB predominantly inhabited the roots. The numbers of 16S rRNA genes were ca. 10^6 copies g^{-1} dry soil in the both bulk and rhizosphere soils in the both stages, while the number was ca. 10^8 copies g^{-1} dry roots. These results indicated inhabitance of considerable number of diverse *Gallionella*-related FeOB in the paddy fields and their involvement in the Fe-oxidizing process, especially during the rice cultivation period.

(7659 - 3178) pH and extracellular flux of protons in hyphae of *Pisolithus albus* and *Pisolithus tinctorius* grown at different doses of solid particulate iron material

Isabelle Faria Matos[1]; Vivian Ribeiro Pimentel[1]; Alessandro Coutinho Ramos[1]

State University of Northern Fluminense[1]

Due to the large amount of ores exported from the country, there is an intense production of residues such as solid particulate matter (SPM), which consists of a substance subdivided into tiny fractions, small enough to be suspended and carried by the wind in the form of aerosol. The solid particulate material of Fe (SPMFe) affects plants either by physical mechanisms, by disturbing the radiation balance, or by chemical mechanisms, by leaching nutrients from leaves and by affecting pH, nutritional status, and microbiota from soil. In places where acid rain occurs, the availability of Fe2+ increases, leading to a higher accumulation of this metal in the plant tissue. Mycorrhizae are symbiotic fungi that can protect plants against metal toxicity due to their tolerance mechanisms. These fungi also promote plant growth, as they provide plants with a greater ability to obtain nutrients and water. In view of these and other characteristics, mycorrhizal fungi are organisms with a great bioremediation potential, allowing the recovery of areas contaminated with SPMFe. In this context, the objective of this work was to evaluate the proton flux and surface pH in the mycelium of two species of ectomycorrhizal fungi exposed to SPMFe. The ectomycorrhizal fungi, *Pisolithus tinctorius* and *Pisolithus albus*, were grown for 5 days in MMN medium with agar addition, containing three concentrations of SPMFe: 0.0; 4.0 and 8.0 g L-1. Then, the proton extracellular flow and the pH in the fungal mycelium were measured using a proton-selective vibrating microprobe system. In addition, the same fungi were also grown in MMN medium, without agar addition, in the presence of the same concentrations of SPMFe, for 25 days and, afterwards, the dry mass of the fungal mycelium and the profile of organic acids exuded in the culture medium were analyzed. The species presented antagonistic responses in relation to the proton flux, as well as in relation to dry biomass, showing that although they belonged to the same genus, the species present different responses in the stress condition by SPMFe.

(1262 - 2268) Phosphate solubilization by fungi under saline stress

Laura Vieira Xavier[1]; Glécia Junia dos Santos Carmo[1]; Kamila Fernanda Rossati[1]; Larissa Lara Rocha[1]; Vinícius Amaral[1]; Gilberto de Oliveira Mendes[1]

Universidade Federal de Uberlândia[1]

Phosphorus (P) is a limiting nutrient in tropical croplands due to the high P-fixing capacity of most soils in these areas. Phosphate-solubilizing microorganisms (PSM) can improve P availability to plants by releasing acids in the soil and, thus, solubilizing sparingly-soluble phosphate minerals. However, the continuous application of mineral fertilizers in croplands can increase soil salinity and possibly impair the activity of PSM. Thus, the present work aimed at evaluating the phosphate solubilization by *Penicillium islandicum* and *Aspergillus niger* under distinct levels of salinity. The assay was performed in 250-mL Erlenmeyer flasks with 100 mL of culture medium [50 g $Ca_3(PO_4)_2$, 10 g glucose, 5 g $MgCl_2 \cdot 6H_2O$, 0.25 g $MgSO_4 \cdot 7H_2O$, 0.2 g KCl, 0.1 g $(NH_4)_2SO_4$, 1 L distilled water, pH 7]. Saline stress was imposed by addition of NaCl at concentrations of 0, 2.5, 5, 7.5, and 10% (m/v). The flasks were sterilized by autoclaving, inoculated with three mycelium disks of each fungus, and incubated in an orbital shaker during seven days at 150 rpm and 30 °C. The experiment was set up under a completely randomized design with three repetitions by treatment. After the incubation period, the spent medium was filtered and analyzed for pH and soluble P. *Aspergillus niger* achieved the highest concentrations of soluble P in the medium (1539 mg L^{-1}) and the lowest pH (2.3). However, this fungus was more sensitive to increasing salt concentrations (Soluble P = 1539 – 127 [NaCl], R^2 = 0.77) than *P. islandicum* (Soluble P = 711 + 33.8 [NaCl] – 6.8 [NaCl]², R^2 = 0.92). Salt concentrations of up to 5% did not decrease significantly the concentration of P solubilized by *P. islandicum*, and pH of the medium was similar for all salt concentrations (4.4 on average). At the highest salinity level (10%), the solubilization was decreased by nearly 80 and 50% for *A. niger* and *P. islandicum*, respectively. These data suggest that *P. islandicum* could be a promising option for the development of PSM inoculants for saline soils or even for direct mixture with mineral fertilizers.

Universidade Federal Rural de Pernambuco - Unidade Acadêmica de Garanhuns[1]

The existing microorganisms in the soil are responsible either directly or indirectly, by numerous biological processes with great importance for the functioning and productive capacity of terrestrial ecosystems. The phosphorus is the second most important element for plants. However, the brazilian soil has a deficiency of soluble phosphorus. The use of phosphate by plants can be leveraged with the activity of phosphate-solubilizing bacteria (PSB), contributing in this way to plant growth. Therefore, the objective of this work was to isolate and evaluate the total bacterial population density and PSB in soil without cultivation, with cultivation and rhizosphere of cassava (*Manihot esculenta*). Were used three cassava plants, cultivated in Garanhuns, Agreste Pernambucano, Brazil. Three homogeneous samples were collected from the rhizosphere, soil cultivated in the spacing of planting and soil without cultivation of nearby area without the presence of culture. The bacteria were isolated in culture medium containing calcium phosphate insoluble and the population density was estimated after 15 days of cultivation of isolation. It was observed that the cultivated soil and rhizosphere showed the highest population densities of bacteria (10^8 to 10^9 CFU.mL^{-1}), including the able to solubilize phosphate. However, the soil without manioc cultivation also exhibited phosphate-solubilizing bacteria, at a density of 10^9 CFU.mL^{-1}. Therefore, the bacteria isolated from soil under cultivation of cassava and from rhizosphere have potential for studies of plant growth promotion.

(3020 - 1799) Phosphorus spatial distribution and speciation using low energy µ-XRF and µ-XANES in the rhizosphere of an artificial soil experiment

Luis Carlos Colocho Hurtarte[1]; Andreas Kling[2]; Markus Drechsler[3]; Thomas Huthwecker[4]; Jurgen Thieme[5]; Jorg Prietzel[1]

Technische Universitaet Muenchen[1]; Ludwig-Maximilians-Universität München[2]; Universitaet Bayereuth[3]; Paul Scherrer Institut[4]; Brookhaven National Laboratory[5]

Phosphorus (P) is an essential element for life, with cellular functions ranging from energy transport to being a structural and genetic material component. In many terrestrial ecosystems around the

world, P is a limiting factor for plant growth and biomass productivity, thus ultimately influencing the global carbon balance. Plants can thrive in many terrestrial ecosystems by mining and cycling organic and inorganic P forms in soils. There is still a substantial gap of knowledge with respect to the major pathways of P mobilization from soil minerals and aggregates by plant roots, which handicaps a thorough understanding of the P dynamics in the rhizosphere. The gap is due to the difficulty of accurately probing the rhizosphere, as traditional techniques are unable to resolve the distribution of different P forms and at the same time identify major P-bearing compounds in the soil matrix with high spatial resolution. In this work, we address these gaps by analyzing the soil-root interface of microaggregates of an artificial soil experiment in which *Picea abies* seedlings were grown. The artificial soils were composed of Al saturated Montmorillonite (Al-MT), Calcite, hydroxyapatite or a mixture of either Al-MT and Calcite or Al-MT and apatite, these mixtures where diluted to 5% w/w. Thus, recreating artificial soils derived of calcareous material. The seeds of Picea abies were sown in the artificial soils, with 7 repetitions of each treatment, including a non-planted treatment. After 4 months, the seedlings were cut and the above ground biomass grinded in N2 and analyzed for major elements. The soil solution was sampled and analyzed for organic acids and the root arquitecture analyzed using WhinRhizo. Sections of the root were cryo-freezed by High Pressure Freezing and sectioned. The thin sections were later taken to the PHOENIX X07MA/B beamline at the Paul Scherrer Institut where low energy µ-XRF and µ-XANES spectroscopy at low temperatures was carried out. We analyzed regions of interest (ROIs) of 40 x 40 µm² previously selected. The ROIs were scanned across the energies of C, Si, P, Al, Ca ("element mapping"). Overall, we have observed distinct P spatial distribution and speciation on the different artificial soils through µ-XRF and µ-XANES, mainly due plants actively affecting its surrounding soil. Low-energy µ-XRF and µ-XANES allowed simultaneously localize C and P in the soil matrix and the speciation of P in points of interest.

(7944 - 2411) Poor seed germination and seedling emergence of wet-direct seeded rice seeds are partly induced by several aromatic carboxylic acids produced in the submerged soil

Shinsuke Mori[1]; Futa Sakakibara[2]; Kenichi Yamazaki[2]; Kazuhiro Takagi[2]; Gen Ishioka[1]; Kazuo Soeno[1]; Daigo Abe[1]
NARO WARC[1]; NARO NIAES[2]

Among the systems for cultivating rice (*Oryza sativa* L.), the direct seeding method is becoming more popular globally than the seedling transplant method due to lower labor and time requirements. However, this cultivation technique has experienced limited use in Japan due to poor seedling emergence and establishment. Our previous results suggested that poor seed germination and seedling emergence of rice plants are induced by the drastic decrease in the soil oxidation-reduction potential(ORP) around direct-seeded rice seeds under the submerged soil conditions with organic matter. However, its precise inhibition mechanisms have not elucidated yet. Here, we report that several aromatic carboxylic acids produced under low ORP conditions can be inhibitors of seed germination and seedling emergence of the wet-direct seeded rice seeds. The objectives in this study were as follows: (1) to reexamine seedling emergence under submerged soil conditions with or without straw. (2) to identify several aroma carboxylic acids produced in the submerged soil. (3) to examine effect of several aroma carboxylic acids on seed germination and coleoptile elongation. When rice seeds were directly sown at 1cm depth under the submerged soil conditions with or without straw, the seedling emergence rate were approximately 10% and 60%, respectively. Furthermore, seed germination and coleoptile elongation were also inhibited by the solution extracted from submerged soil incubated with straw, compared with that without straw. These results suggested that some chemical substances produced in submerged soil incubated with straw inhibited seed germination and seedling emergence. Several unknown organic acid peaks in the soil solution were detected by TQD-UPLC-MS/MS analysis. We finally identified several organic acids as benzoic acid, salicylic acid, phenyl lactic acid, phenyl acetic acid, 3-phenylpropionic acid and others. Additionally, our results elucidated that some aroma carboxylic acids delay seed germination and coleoptile elongation and other organic acids promote seed germination and coleoptile elongation. We will discuss presumed inhibition mechanisms of seed germination and seedling emergence of the wet direct seeded rice.

(8103 - 1331) Soil carbon cycling enzymes in ectomycorrhizal fungi under heavy metal stress

Gilka Rocha Vasconcelos da Silva[1]; Vinicius Henrique De Oliveira[2]; Mark Tibbett[2]

Centre for Agri-Environmental Research, School of Agriculture, Policy and Development, University of Reading, Whiteknights, PO Box 217, Reading, Berkshire, RG6 6AH, United Kingdom (g.r.v.dasilva@pgr.reading.ac.uk)[1]; Centre for Agri-Environmental Research, School of Agriculture, Policy and Development, University of Reading, Whiteknights, PO Box 217, Reading, Berkshire, RG6 6AH, United Kingdom[2]

Ectomycorrhizal fungi extend from root to rhizosphere and into the bulk soil. Despite receiving carbon from the autotrophic partner, these fungi have the capacity to access carbon and associated nutrients and from soil by decomposing soil organic residues. As the balance between heterotrophic fungi and these root symbiotic fungi is predicted to shift under climate change scenarios, we were interested to investigate capacity to degrade carbonaceous compounds found in soils. Hence, our objective in this study was to identify the most prolific soil carbon degrading exo-enzymes produced by ectomycorrhizal fungi, which are exuded into the soil solution. We were interested in the relative activities of enzymes that are involved in the breakdown of a range of soil carbon compounds, under unstressed and stressed conditions. The key carbon cycling enzymes we measured were cellulase, cellobiohydrolase, xylanase, mannisidase, galactosidase, arabinosidase, manganese peroxidase and lignase. Enzymes assays were conducted on 12 strain of ectomycorrhizal fungi of species from the basidiomycota and the ascomycota. Fungi were subjected to stress with the amendments of metals (Zn, Cd) at sub-lethal but toxic concentration. The results showed a differential responses of different fungal species to carbon cycling enzymes. Heavy metal stressed ectomycorrhizal fungi had a tendency to produce different amounts of enzyme to unstressed treatments, and enzyme activities were typically repressed under stressed conditions. These finding are discussed in the context of soil carbon cycling in soils and the interactions with metal contaminants.

(9404 - 698) Soil chemical changes after annual pasture species cultivated as mono- and intercrop and in response to phosphorus fertilization

Ana Cristina Martins Boucho[1]; Corina Carranca[1]; Manuel V. Madeira[2]
INIAV[1]; ISA/UL[2]

In Mediterranean areas, sustainable production of rainfed pastures is associated with plant species which withstand low soil fertility and variable annual drought conditions, phosphorus (P) being the primary

limiting nutrient for legume growth and N_2 fixation. A study was undertaken to compare the response of subclover and a new pasture legume (pink serradela) to P supply, in terms of biomass, nodulation pattern, N_2 fixation, P use efficiency and soil chemical changes, using a moderately acid soil, very poor in extractable P. Three pasture species (ryegrass, suclover and pink serradela) were cultivated in pots, under controlled environmental conditions, as monocrop or intercrop and fertilized with four P rates (P0 = 0; P1 = 30; P2 = 60; P3 = 90 kg P ha^{-1}), with four replicates. In the present study, results regarding changes in soil chemical properties are shown. After 103 days of growth (beginning of flowering by pink serradela), a declining of soil pH and exchangeable base cations (Ca^{2+} and Mg^{2+}) was observed, especially under the well nodulated pink serradela. The decreasing of soil pH was accompanied by the increase of legumes biomass, nodules number, N_2 fixation and P-uptake. Unlike, soil organic C decreased after sole and intercrop pink serradela cultivation possibly by its greatest mycorrhization and N_2 fixation rate compared to subclover, with a consequent lower root C exudation. Soil acidity and the level of base cations, and the extractable P concentration revealed to be good indicators for assessment of soil quality status following the installation of improved pastures (with leguminous species). On the contrary, total soil N and non-humified C fraction did not vary with crop species, cultivation system, and P fertilization. Results suggest that more productive and efficient N_2-fixing plants have stronger negative effects regarding soil acidity and base status. Future research, including long-term field studies in different environmental conditions are recommended to confirm present findings, by the presence of studied and other pasture legumes.

(9226 - 926) Soil macrofauna in arboreal caatinga area managed at the southwest of Bahia

Priscila Silva Matos[1]; Patrícia A. Bittencourt Barreto-Garcia[2]; Rafael Nogueira Scoriza[2]; Mariana dos Santos Nascimento[2]
UFRRJ[1]; UESB[2]

Forest management can lead to numerous changes in the composition and diversity of soil organisms as a result of changes in habitat, food supply, microclimate and intra and interspecific competition. Among the most affected soil organisms, the set of invertebrates that belongs to the macrofauna plays an important role in the system's functionality. These organisms act mainly in the fragmentation of organic matter, nutrient cycling and physical structuring of the soil. In this context, the objective of this study was to evaluate the influence of different types of forest management on the edaphic macrofauna community. The experiment was carried out at National forest Contendas do Sincorá, located at the Southwest region of the state of Bahia. The experimental area consisted of 32 plots of 20 x 20 m, consisting of eight replicates of the following treatments: shallow cut, selective cut of trees with diameter at breast height ≥ 5 cm), selective cut of three species (*Commiphora leptophloeos*, *Pseudobombax simplicifoliu* and *Jatropha mollisima*) and control (unmanaged caatinga). The edaphic macrofauna was sampled by the soil monolith method, in two seasons of the year. The densities, total number of individuals, total wealth, average wealth and the rates of Shannon and Pielou were estimated. The macrofauna of the soil showed to be sensitive to the different practices of forest management, evidencing that the selective cuts are more conservationist systems of use of the Caatinga. Among these, the selective cut by species is more favorable to the maintenance of the fauna of the soil. Both in the Caatinga managed as in the control, the predominant groups in the edaphic fauna were Isoptera, Formicidae, Coleoptera and Chilopoda larvae.

(5982 - 1995) Solubilization of inorganic phosphate by the bacterium UAGF14 *Pseudomonas mosselli* under hydric stress, saline stress and different carbon sources.

Silva, J.M.M.[1]; Teixeira, M.F.[1]; Freitas, C.C.G.[1]; Silva, E.L.D.[1]; Isidio, E.L.[1]; Carvalho, A.S.[1]; Amorim, A.S.[1]; Kuklinsky-Sobral, J.[1]
Universidade Federal Rural De Pernambuco - Unidade Acadêmica De Garanhuns / UFRPE-UAG[1]

Brazilian agricultural soils are subject to adverse conditions, such as water deficit, salinity, nutritional deficiency, decreasing the production of agricultural crops. Some nutrients, such as phosphorus, are essential for plant development, but they are not always assimilable in the soil for plants. Several bacteria of the genus *Pseudomonas*, when associated with plants, have the ability to solubilize inorganic phosphates, making phosphorus available to plants. Therefore, the present work aimed to analyze the bacterium *Pseudomonas mosselli* UAGF14, sugarcane endophytic, as to its capacity to solubilize inorganic phosphate under hydric stress, saline stress and in different carbon sources. For analysis of phosphate solubilization (PS) under hydric stress, the bacterial strain was inoculated in culture medium containing insoluble calcium phosphate (MP) with 285 $g \cdot L^{-1}$ of sorbitol, providing water activity of 0.963 A_w at 25°C. For the SF under saline stress, MP was supplemented with 0%, 1%, 2.5%, 5.0%, and 7.5% NaCl. For the SF under different sources of carbon, the MP was added 1% of: glucose, sucrose and mannitol, regardless. The treatments were incubated at 25ºC for 17 days, totalizing 5 readings. Then, the solubilization index (SI) was calculated, expressed by the ratio of the mean diameter of the solubilization halo to the mean halo diameter of the colony. It was observed that the UAGF14 strain of *P. mosselli* was not able to solubilize the inorganic phosphate under conditions of hydric stress. However, under saline stress, the bacterium presented prominence in the concentrations of 0%; 1% and 2.5% NaCl. Regarding the different carbon sources, UAGF14 presented SI in the presence of glucose and mannitol. However, when sucrose was used, the strain was not able to solubilize. From mode, concludes that the UAGF14 *P. mosselli* presents variations in the expression of the capacity to solubilize inorganic phosphate as a function of the available carbon source, and responds well to saline stress but not to hydric stress. Therefore, the UAGF14 strain may be better exploited for experiments to promote plant growth under saline stress conditions.

(7529 - 2676) Symbiotic capacity and plant growth promotion by bacteria isolated from nodules of Mimosa spp. in ultramafic soils

Kelly Alves de Sousa[1]; Leide Rovenia Miranda de Andrade[2]; Iêda de Carvalho Mendes[2]; Fábio Bueno dos Reis Junior[2]
União Pioneira de Integração Social -UPIS[1]; Embrapa Cerrados[2]

Ultramafic soils are characterized by excess of potentially toxic heavy metals, such as cobalt, chromium, copper and nickel, as well as low availability of nutrients, such as calcium, phosphorus and nitrogen, resulting in a strong mineral imbalance. In Brazil, ultramafic massifs from the state of Goiás (GO) have great economic importance due to the intense mining activity in these areas. These mining operations result in degradation of extensive areas of native vegetation. Studies on the occurrence and characterization of diazotrophic bacteria in symbiosis with native legumes from this environment may be an important part of strategies to be applied in programs that aim at environmental conservation and recovery of degraded areas, as is

already being done in areas from the Amazon and the Atlantic forest. For Cerrado conditions, especially in mining areas, there are very few studies in this field. The objective of this work was to evaluate the symbiotic capacity and plant growth promotion potential of bacteria isolated from nodules of Mimosa spp. from the ultramafic massif of Barro Alto (GO). Bacteria were isolated from nodules of native plants (M. clausenii and M. somnians) growing in previously selected areas, which were divided into two categories according to the Ni concentration and its bioavailability in soil. A greenhouse experiment was carried out and 13 different bacterial isolates were tested. The bacteria were inoculated in seeds of M. pudica and after a period of 60 days the dry mass of nodules and the increment of roots and aerial part dry matter were evaluated. The inoculated plants were compared with controls without inoculation and with nitrogen fertilization. Isolates of Paraburkholderia tuberum, a beta-rhizobium, showed symbiotic capacity and differential growth promotion potential. Isolates W41, W84 and W38 can be highlighted since the plants inoculated with these bacteria produced approximately four times more roots and fourteen times more shoots than the uninoculated control plants. These results suggest that in the future this symbiosis could be used as part of a program for recovery of ultramafic soil areas degraded by mining activity.

(7744 - 2462) The Effects of Plant Growth-Promoting Bacteria (PGPB) on the Initial Development of Corn

Gustavo Benincá Rodrigues[1]; João Vitor Berner Pereira[1]; José Filipe dos Santos Maciel[1]; Mauricio Rosa Magro[1]; Ana Rosa da Silva França[1]; Camila Köche Wibbelt[1]; Julio Cesar Ariati[1]; Renan Adamcheski[1]; Vinicius Leite[1]; Sonia Purin da Cruz[1]

Universidade Federal de Santa Catarina[1]

The use of Plant Growth-Promoting Bacteria (PGPB) is a promising and low-impact technology to improve agronomic efficiency and minimize the use of chemical fertilizers, ensuring high rates of productivity with an excellent cost-benefit ratio. The present study aimed to verify the effects of PGPB-based inoculants on maize (Zea mays), mainly in relation to development and productivity up to stage V4. The experimental plot waz located in the FreiRogério-SC, Brazil (27°11'55.24'' South and 50°43'40.15'' West). The experiment was implemented in November 2017. The experimental design was RBD, with nine treatments and six repetitions. Treatments were: T1: control, 0% N without inoculation; T2: 75% N, without inoculation; T3: 100% N, without inoculation; T4: 75% N + AZOTOTAL inoculant (standard); T5: 75% N + ACCELERATE FERTILITY; T6: 75% N + ACCELERATE EFFICIENT; T7: 75% N + BAFZ + additive; T8: 0% N + product AcRh + additive; T9: 75% of the dose of N + product AcRh + additive. We measured stem diameter, and data were later submitted to analysis of variance (ANOVA) at the 5% probability level. No significant differences were identified among treatments. However, PGPBs comprise a group of microorganisms that can be used as a technological and sustainable alternative and may stimulate plant growth and development at later stages.

Keywords: rhizobacteria, inoculants, corn.

(3208 - 1424) The influence of microbial diversity on maize rhizosphere to phosphorus disponibilization

Yasmin Florentino Rodrigues[1]; Julia Franke Capozzi[1]; Antonio Marcos Miranda Silva[1]; Armando Cavalcante Franco Dias[1]; Fernando Dini Andreote[1]; Simone Raposo Cotta[1]

Department of Soil Sciences, "Luiz de Queiroz" College of Agriculture University of São Paulo - ESALQ/USP[1]

In recent years the paradigm of agriculture has been changing, inserting the concept of sustainability as a central strategy for its development. The use of microorganisms appears in this scenario as an important tool, since these organisms are directly associated with the health of the plant. However, the ecosystem functioning correlated with microbial diversity is still little known. Based on this premise, our hypothesis is that a more diversity microbial community promotes a greater availability of phosphorus to the plants. Phosphorus was used as an experimental model because of its importance in plant nutrition. To test this hypothesis, we developed a gradient of soil microbial diversity using the dilution-to-extinction approach. Microbial communities at different levels of diversity were inoculated into microcosms containing three sources of phosphorus: calcium phytate (FC), Araxá rock phosphate (FA) and triple super phosphate (ST) with and without corn seed. The experiment was conducted in the greenhouse for 30 days and after that period, analyzes were performed regarding plant growth (dry weight, root and shoot measurements) and the microbial community and their activity. In the most available sources of phosphorus (FC and ST), the effect of reducing microbial diversity was more prevalent, where as the diversity is reduced, dry weight (shoot and root) measures decrease. The specific root length (CER) was inversely proportional, where the highest values were found in the less diverse treatments, especially in the AF treatment. In relation to the microbial community and its functions, both acid phosphatase and basic phosphatase activity measurements were reduced in less diverse communities. In addition, abundance of the phoD gene showed a significant positive correlation ($p < 0.05$) with acid phosphatase activity for the rhizosphere environment in all treatments. More studies are being carried out, however, it is possible to observe the importance of the conservation of high levels of microbial diversity for the full functioning of ecosystems, thus reflecting the health of the plant.

(1141 - 1559) Chemical and mineralogical of soils of the metropolitan region of Manaus – Amazonas, Brazil

Matheus da Silva Ferreira[1]; Mauricio Paulo Ferreira Fontes[1]; Anderson Almeida Pacheco[1]; Rafael Biscotto Davila[1]

Federal University of Viçosa[1]

The Metropolitan Region of Manaus is composed of 13 cities that form a large urban complex with a population of more than 2 million people, being the major economic center of the Amazonas state and the northern region of Brazil. However, the demographic occupation of this urban complex has happened in an accelerated way in the last decades, mainly in the cities of Manaus, Iranduba, and Manacapuru where it is concentrated around 90% of the population. Given the national importance of this urban complex and the efforts for the maintenance and preservation, this study aimed to characterize soils collected in natural and urban environments of Manaus, Iranduba, and Manacapuru, to a better understanding of their chemical and mineralogical characteristics. Soil samples were collected at depth of 0-20 cm in urban areas and in representative natural areas, totaling 32 samples. The determination of the soil chemical characterization and mineralogical characteristics were performed. The mean values observed were: 4.4 (pH_{KCl}); 2.73 (Ca^{2+}); 0.21 $cmol_c\ dm^{-3}$ (Mg^{2+});

2.76 $cmol_c$ dm^{-3} (H+Al); 33.03 mg L^- (P – Rem); 1.06 mg dm^{-3} (Cu); 97.81 mg dm^{-3} (Fe); 5.40 mg dm^{-3} (Mn) and 5.53 mg dm^{-3} (Fe). Urban areas have higher nutrient contents than natural soils, but normally the fertility of these soils is low, independent of occupation. The XRD pattern of the clay fraction shown to be composed mainly of kaolinite, gibbsite, goethite, hematite, and smaller proportion of montmorillonite. The presence of 2:1 minerals in amazonian mainland soils are rare and when occurs it is associated with areas with drainage deficiency, constituting an exception in the landscape. Therefore, we conclude that the chemical and mineralogical characteristics is owing to the poverty of the source material and strong weathering conditions of this tropical environment.

(6368 - 233) Contribution of amorphous materials in the cohesion of soils of the Barreiras Formation and correlates

Michele Ribeiro Ramos[1]; Vander de Freitas Melo[2]; Alexandre Uhlmann[3]; Renato Antonio Dedecek[4]; Gustavo Ribas Curcio[3]
Universidade Estadual do Tocantins[1]; Universidade Federal do Paraná[2]; Embrapa Florestas[3]; Pesquisador aposentado Embrapa Florestas[4]

The cohesive Yellow Latosols and Argisols developed from sediments of the Barreiras Group and correlates, are distributed in many areas in Brazil, positioned in the north-south direction, with a width ranging from 20 to 120 km and an altitude of 20 to slightly more than 120 m, framing and often covering lands that mostly have gneiss and granitic rocks In order to understand the processes involved in cohesion, a methodology was developed based on the extraction of minerals from the clay fraction consortium to the physical-hydro analyzes in samples undisturbed soil. For this, undisturbed samples were collected only from the BA horizon of cohesive (Macacu Formation) and non - cohesive soils (São Fidélis Formation) on the upper third of two slopes located at the Rio de Janeiro Petrochemical Complex (COMPERJ), Itaboraí, RJ. In the samples, solutions with potential of extraction of chemical elements present in the fractions of the soils were percolated. The solutions with temperature of approximately 60 ^oC were percolated through drippers (DCB, ammonium oxalate (0.2 mol L^{-1}), NaOH (0.2 mol L^{-1} and 0.06 mol L^{-1})) and water deionized, in an individualized and non-sequential manner. The solutions percolated in the samples were collected, measured their respective volumes and analyzed for their concentrations in silica, iron and aluminum. Subsequently, the samples were saturated in trays with deionized water and subjected to a physical analysis sequence to verify their physical attributes. (The results were: (1) although the extractions were mild, the solutions used extracted significant amounts of silica and (2) the results indicated the presence of some material more easily extractable in the cohesive soil, which is not present in the non cohesive soil, (3) there is a possibility that the presence of amorphous materials associated with cohesion

(3557 - 792) Could 33 years of K fertilization deprivation alter phyllosilicates and K mineral reserve in the clay fraction of an Oxisol?

Ruan Francisco Firmano[1]; Vander de Freitas Melo[2]; Adilson de Oliveira Junior[3]; João Arthur Antonangelo[4]; Luís Reynaldo Ferracciú Alleoni[1]
University of São Paulo - ESALQ[1]; Federal University of Paraná[2]; Brazilian Agricultural Research Corporation[3]; Oklahoma State University[4]

Highly weathered soils from humid tropics generally present low total potassium (K) and no abundance of K-bearing minerals in the clay fraction. However, there is evidence that non-exchangeable forms (NEF) of K can contribute to plant nutrition even in tropical soils. Special techniques such as X-ray diffraction (XRD) and sequential extraction of minerals from clay fraction efficiently allow the investigation of K-bearing minerals in soils. The clay fraction characterization was applied to soil samples collected from an Oxisol under long-term no-till (NT) fertilized for 33 years with KCl and cultivated with soybean (*Glycine max* L.), maize (*Zea mays* L.), wheat (*Triticum aestivum* L.) and oats (*Avena strigose* L.) in southern Brazil. The mineral K-bearing species were quantified, and the changes resulted from the K fertilizer deprivation were also evaluated. The greater part of the K mineral reserve was contained in the soil clay fraction. The K deprivation for 33 years reduced the mineral reserve of the nutrient associated with 2:1 minerals and dramatically reduced illite peaks in the soil clay fraction. Exchangeable and non-exchangeable forms of K were also reduced in comparison to those in which K fertilization was maintained at rates equal to or greater than 120 kg ha^{-1} $year^{-1}$ of K_2O. Oxides and hydroxides as hematite, Gibbsite, Goethite, and phyllosilicates such as kaolinite dominated the mineralogy of clay fraction. Those minerals were not affected by the three decades absence of K fertilization.

(4111 - 2395) Description of the mineralogical profile of Oxisols of the Central Amazonia

Jose Zilton Lopes Santos[1]; Tainah Manuela Benlolo Barbosa[1]; Laercio Santos Silva[2]; Renato Eleoterio de Aquino[2]; José Marques Júnior[2]
Federal University of Amazonas[1]; University of São Paulo[2]

The level of crystallinity, isomorphic substitution (IS) and, specific surface area (SSA) are the especific properties that most influence the mineralogical activity of soils. The aims of this study were identify and characterize the minerals of the clay fraction of Oxisols of Central Amazonia and check the relation of these with the remaining phosphorus (P-rem). Samples from the upper layer (0-20 cm) of 10 Dystrophic Yellow Oxisols, under native forest, in the municipality of Manaus, Iranduba, Manacapuru, Rio Preto da Eva and Presidente Figueiredo, in Amazonas state, Brazil. The soils were ordered in four groups, according to P-rem (index that indicate the retention potential of anions in soil) = 5.6; 14.0; 17.7 and 22.2 mg L^{-1}. Were identified the minerals kaolinite (Kt), goethite (Gt), hematite (Hm) and estimated the mean crystal diameter (MCD), IS of iron for aluminum and, SSA. The presence of intense and characteristic diffraction peaks 0.732 nm in Kt; 0.416 nm in Gt and 0.352 nm in Hm, point to dominance of these minerals in the clay fraction of the studied soils, regardless of the P-rem content. The values of Gt ranged from 14.28 to 51.49 while the values of Hm varied from (5.72 to 32.44 g kg^{-1}), being the highest values of Gt and the lowest values of Hm found in soils with higher values of P-rem (22.2 mg L^{-1}). While the lowest and highest values of Gt and Hm, respectively were observed in soils with 14.0 mg L^{-1} of P-rem. The last P-rem level showed the higher content of Hm in comparasion to Gt. We observe a predominance of MCD (110) in retation to MCD (111), regardless of the mineral. In general, the values of MCD (110) were increased at the highest level of P-rem as much as Gt and Hm. We also observed a narrow amplitude of variation of SSA (47 to 90 m^2 g^{-1}) and of IS (20.5 to 41.0 mol%) and, the highest values

of this variables were comparatively higher in soils with higher P-rem., however, the values of IS was inversely related to values of P-rem (5.6 > 14.0 > 17.7 > 22.2). This Behavior also was observed to (MCD 110) of Gt and Hm minerals. The data presented here show that the mineralogy of clay fraction of the Oxisols of Central Amazonia consist of kaolinite, goethite and hematite. The P-rem show strong relationship with levels of cristalinity of goethite and hematite in DMC 110, SSA, IS. The results implie that in spite of these soils occur under the similar climatic conditions, they may vary in their vocation of use.

(6395 - 2273) Different types of treatment prior to the granulometric analysis of volcanic soils made it possible to determine a regular distribution with other soil properties according to altitude on the western slope of the tropical island of Réunion.

FEDER[1]
CIRAD[1]

Soils on the western slope of the Piton des Neiges (Réunion Island, Indian ocean) showed the following toposequence: Vitric Andosols and Andic Podzols (16001850 m asl and more); Silandic Andosols (10001600 m asl); Andic Umbrisols and Andic Cambisols (9001000 m asl); Haplic Umbrisols and Cambisols (500900 m asl); Haplic Phaeozem and Leptic Cambisols and Phaeozem (below 500 m asl). According to altitude, evolution of soil properties (pH, organic matter content, cationic and anionic exchange capacity, oxalfe, etc.) is regular, except for the particle size distribution analysis (PSDA) performed with the standard method. On these soils, short-range-order minerals (SROM) such allophane and amorphous aluminosilicates and organo-mineral cements such noncrystalline hydrous oxides of Fe and Al, often prevent soil dispersion before the PSDA. The absence of an efficient and common soil method in this toposequence limits the understanding of pedogenetic processes when granulometry is involved (clay illuviation, etc.). We realize different type of treatments before PSDA for the different soils. To quantify clay minerals on andic horizons, we realize 6 successive dissolutions of SROM with ammonium oxalate. To improve particle dispersion, we also use sonication. Within a group of, a priori, similar andosols, the PSDA, after the destruction of the SROM, separates two groups of andosols. The first group raises a strong clay leaching from the surface horizons (0 - 40 cm, on average 25% clay) to the deep horizons (40 - 90 cm, on average 60% clay). The second group has similar clay contents over the entire profile (between 10% and 15%) but high contents of coarse sand (up to 40%) in the deep horizons; that's incompatible with the textural description. Thus, for some andosols, the procedure for dissolving the SROMs is insufficient to obtain a relevant particle size analysis. At the lowest elevations in the slope, non-Andic soils showes a common tendency to increase clay content with the depth of the horizons (extreme values of 45 to 75%) but less marked because of the already very high values in the surface horizons (extreme values of 40 to 75%). These last PSDA results are similar regardless of the method used (with or without sonication or dissolution of SROM). By choosing the most appropriate PSDA method for each soil type, the spatial distribution on the slope according to the altitude of the granulometric analyses is consistent with the other soil properties.

(6628 - 1665) Formation of hydroxy-interlayered minerals (HIMs) in integrated crop-livestock systems (ICLS)

VANESSA THOMA BERTOLAZI[1]; Alberto Vasconcellos Inda[1]; Laurent Caner[2]; Ibanor Anghinoni[1]; Paulo César de Faccio Carvalho[1]
Federal University of Rio Grande do Sul[1]; University of Poitiers[2]

The complexity and diversification of integrated crop-livestock systems (ICLS) generates synergisms between animal, plant, and soil components, like this, the formation of 2:1 hydroxy-interlayered minerals (HIMs) may be affected by accumulation of animal wastes in soil and grazing intensity. The aim of this work was to assess the effect of grazing intensity, in two different treatments [intensive grazing (IG) and no grazing (NG)], on the formation of 2:1 hydroxy-interlayered minerals of an Oxisol in an integrated crop-livestock system in southern Brazil. The main analyzes used were chemical (organic carbon and cation-exchange capacity) and mineralogical analyzes of the fractions of total clay (<2 µm) and fractionated clay in three particle sizes (< 0.05, 0.05–0.1 and 0.1–2 µm). Two different types of HIM were found in intensive grazed areas: one presented aluminization of the interlayer, and the other presented K-saturated interlayers. The higher aluminization of the 2:1 interlayers observed under intensive grazing may induce lower content of exchangeable and available aluminum and subsequently lower toxicity to plants. The occurrence of HIM with K of the interlayer may be associated with the increased nutrient cycling proportioned by bovine manure; the retention of this element within the soil clay mineral fraction may reduce leaching losses and act as a long-term source of K in the ICLS soils. However, these results demonstrate significant, short-term alterations in soil mineralogy, reinforcing the necessity to consider the response to changes in soil management.
Keywords: 2 :1 phyllosilicates ; sub-fractionation ; aluminization.

(1590 - 896) Geotechnical characterization of Vertisols from Bahia State, Brazil

Gustavo Magalhães Nunes Barbosa[1]; Igor Rodrigues de Assis[1]; João Carlos Ker[1]; Eduardo Antônio Gomes Marques[1]; Tony Jarbas Ferreira Cunha[2]; Luciano da Silva Souza[3]; Ullisses Vargas Sobrinho[1]
Universidade Federal de Viçosa[1]; Embrapa Semi-árido[2]; Universidade Federal do Recôncavo Baiano[3]

Despite the existence of vertic soils with predominance of kaolinite is reported around the world, there are few studies shown the influence of this clay mineral in their geotechnical characteristics. The work aimed to perform a geotechnical characterization of Vertisols from Bahia, Brazil, besides understanding the influence of physical, chemical and mineralogical properties on the geotechnical behavior. Three Vertisols were collected in Juazeiro city, in a semi-arid region, one kaolinitic Vertisol and two smectite Vertisols. Other three Vertsols were collected in Recôncavo region, all presented clay mineralogy with codominance of smectite and kaolinite (Sm-K). A geotechnical characterization was carried out in their diagnostic horizons, determining properties such as granulometric curve, clay activity, linear expansion coefficient, compaction capacity, cohesion (c'), and internal friction angle (φ) of saturated soils. We observed that the clay content was the attribute that most influenced the geotechnical characteristics. All soils showed expansion potential above 0.01, considered as very high. The kaolinitic Vertisol showed the lowest clay activity. However, the clay content of 68% contributed to this soil to present an expansion potential similar to the smectite Vertisol with clay content of 35%. The major values of soil compaction were observed for the kaolinitic Vertisol, which presented greater reduction of void ratio and higher density as a function of moisture increase. For this soil, the optimal moisture content (OMC) and maximum dry density (MDD) were 22% and 1.65 g cm^{-3}, respectively. The other soils presented OMC between 18-41% and MDD between 1.75-1.24 g cm^{-3}. These smectite-soils, MDD decreased with increasing of OMC. All soils had low c' values, which is expected for high clay content soils.

The *c*' values increased with increasing of kaolinite and decreased with increasing of clay content. The kaolinite Vertisol showed *c*' of 0.19 kgf cm^{-2}. The *c*' values to Sm-K Vertisols ranged between 0.05-0.11 kgf cm^{-2}. As for smectite-soil, *c*' values ranged between 0.02-0.03 kgf cm^{-2}. Low φ values were observed for all soils, which indicates low shear resistance. In its turn, φ was more influenced by granulometry, in which higher levels of sand and gravel provided higher φ, independently of the type of clay. Vertisols with different mineralogy present different geotechnical characteristics.

(8234 - 2645) Impact of eucalyptus plantation on an Ultisol on chemical properties

Estéfane Chaves[1]; Alberto Vasconcelos Inda Junior[1]; Laurent Caner[2]; Keyrauan Taha[1]

Universidade Federal do Rio Grande do Sul[1]; Université de Poitiers[2]

The current agricultural activity contributed to improve the chemical and physical properties of the soil. However, in some situations some harmful effects, such as soil and ecosystem degradation, are still observed. Recent studies revealed the impact of human activity (e.g. soil management) on physical and chemical properties in cultivated soils. Mineralogy of the clay fraction is an extremely important tool that can help to elucidate the behaviour of soils under different management. Since the forestry sector expanded rapidly in south Brazil, studies viewing actions of preservation and rational use of resources (soil water, fertilizers) and that limit economic and environmental losses are needed. In this context, the goal of the present work was to evaluate chemical and mineralogical changes in soil under eucalyptus plantation in the state of Rio Grande do Sul – south Brazil. Soil samples (yellow Ultisol) were collected in triplicate at the same depth (0-5, 5-10; 10-20, 20-40, 40-60, 60-80 cm) in an eucalyptus plantation with 15 years of cultivation and a control soil as a native meadow. Statistical inferences were made with ASSISTAT version 7.7 pt. and revealed differences between the forest and the native field. To limit acidification and to maintain biomass production the Eucalyptus stand received two cycles of fertilization and liming with application of dolomitic calcareous, natural phosphate, superphosphate and NPK. Chemical analyses showed that pH, sum of bases, exchangeable Ca^{2+} were lower in the eucalyptus soil samples whereas CEC, exchangeable Mg^{2+}, K^{+} and (Al^{3+} + H^{+}) values were higher whatever the soil depths. Liming did not completely limit soil acidification due to litter decomposition and nutrient uptake by eucalyptus trees. Acidification and related release of Al can lead to the formation of hydroxy-aluminum interlayered vermiculite (HIV-Al) from expandable 2:1 clay minerals. For this purpose we have extracted the clay fraction (< 2 µm) and subsequently fractionated it into infra-micrometric subfractions (< 0.05, 0.05 – 0.1 and 0.1 – 2 µm) to study in details the clay minerals by X-ray diffraction. The results of the bulk clay fraction showed abundance of kaolinite and low proportion of 2:1 clay minerals. The study of the subfraction is in progress.

(2584 - 1676) Physiological quality of the first sequeiro of sugarcane in the function of potassic fertilization

Aline Franciel De Andrade[1]; Frederico Simões Raimundo De Lima[1]

UFG[1]

Aline Franciel de Andrade[1]; Frederico Simões Raimundo de Lima[1]; Amanda Magalhães Bueno[1]; Rilner Alves Flores[2]

[1]PostgraduateProgram in Agronomy/UFG, Highway - Goiânia - Nova Veneza Km 0, Goiânia,74690-900, Brazil e-mail: (alineandrade418@gmail.com; fredlimaufg@yahoo.com.br; amanda.mabu@gmail.com); [2] Department of soil UFG - e-mail: (rilner1@hotmail.com) Brazil is the word's largest producer of sugarcane, with an estimated production of 647.6 milion tons (2017/18 harvest). Sugarcane, demands a higt amount of nutrients, which has made the practice of fertilization of great importance in soils cultivated with this crop. Among the nutrients, potassium (K) stands out as the most absorbed by sugarcane, acting in several physiological processes of the plant, such as: enzymatic activator; acts on photosynthesis; maintains the turgor of the cells; opening and closing of stomata; translocation of nutrients in the plant. However, most Brasilian soils are natirally K deficient, requiring supplementation througt fertilization. The objective of this work was to evaluate the effect of potassium fertilization on the physiological quality of the first ratoon sugarcane cultivated under Cerrado soil and these climatic conditions. The research being conducted in an experimental area of the Goiasa Plant, Bom Jesus de Goiás municioality - GO, The experiment carried out in a randomized block desing with fives doses of K_2O (0,50,100,150 and 200 kg ha -1) Five replicates. For the determination of the physiological quality, the stomatal conductance, transpiration, internal CO_2 concentration and liqud photosynthetic rate evaluated at 120 days after the isntallation of the experiment. The evaluations performed using a photosynthetic analyzer system (IRGA-Infraed Gas Analyzer with coupled fluorometer model iFL - Integrated Fluorometer and Gas Exchange System). The results were submitted to analysis of variance by the F test, applying the polynominal regression test to the significant variables. A linear reponse observed for the variables transpiration and photosynthesis as a function of the higher potassium supply in the soil, reaching 5.65 mol m^{-2} s^{-1} and 17.95 mmol m^2 s^{-1}, respectively. In relation to the internal CO_2 concentration, a quadratic response observed, with a dose of 150 kg ha^{-1}, which promoted a higher internal CO_2 concentration. The physiological activity of the ratoon sugarcane is significantly responsive to the application of potassium fertilization.

(2609 - 2082) Potassium release from organic black shales used as remineralizers: effect of size fraction and acid extractors

Jacqueline Kochan Lepchak[1]; Thais Correa de Assis[1]; Gabriel Ramatis Pugliese Andrade[2]; Antonio Carlos de Azevedo[3]

Universidade Estadual do Centro-Oeste[1]; Universidade Estadual do Norte Fluminense Darcy Ribeiro (UENF)[2]; Escola Superior de Agricultura Luiz de Queiroz - ESALQ-USP[3]

The high demand for nutrients by tropical crops is an economical and environmental challenge. Alternatives for new nutrient sources include the use of rock powders derived from mining co-products, which are able to provide major nutrients to plants. In southern Brazil, organic black shale from Irati Formation (Permian Age) are widely known by their high contents of oil, which is explored for fuel production. It also contains high amount of alkali elements, like potassium (K), that make this shale potentially useful as remineralizer. In this preliminary study, we tested the K release from the powdered Irati shale to evaluate its release after five subsequent extractions in pure water, oxalic acid (0.01 M) and citric acid (0.01 M). The tests were performed in polyethylene tubes, in a rock powder/extractor proportion of 1:4, at 120 rpm in a shaker-over-end device for 14 h. Three different size-fractions of the powdered rock were used: coarse sand (CS, 2-0.2 mm), fine sand (FS, 0.2-0.05 mm) and filler (FL, < 0.05

mm). Samples were analyzed in triplicates and K content determined by flame spectroscopy. Oxalic acid was the more efficient extractor for all size fractions, summing up to 65 mg K L^{-1} in FS fraction after five extractions, followed by 46 mg K L^{-1} in FL fraction and 44 mg K L^{-1} in CS fraction. The K releasing curve was positive and linear only for CS fraction (for oxalic and citric acids), whilst a polynomial behavior express the release from the FL fraction. For FS fraction, an unusual behavior was observed for the two acids: there was a steep increasing until the third extraction, followed by a decrease and a new increase in the values (at fifth extraction). This unusual behavior after successive extractions for coarser fractions may be attributed to the likely abrasion among particles at experimental conditions, during shaking procedure. The behavior for FL fraction seems to be more realistic, since K release progressively increases as illite and other K-bearing minerals (like feldspars) disrupt their lattices by the extractors. Although preliminary, these results show the potential use of the Irati black shales as complementary or alternative soil K source, as well as the role of organic acids on the kinetic of element releasing, which must be further tested at field conditions.

(9694 - 2941) soil characterization, classification and formation on sedimentary lithology in Gravatai municipality, Rio Grande do Sul state.

Paulo César Do Nascimento[1]; Tatiana Finato[2]; Alberto Vasconcellos Inda[1]; Luis Fernando da Silva[1]; Augusto Koglin Wink[1]; Jessé Rodrigo Fink[3]; Élvio Giasson[1]

UFRGS[1]; EMATER[2]; IFPR[3]

Metropolitan region of Porto Alegre, although great urbanization process, has some localities that can be defined like rural towns, being Gravatai one of the municipalities with bigger expression of this issue. Natural resources knowledgement is an important aspect for sustainable agricultural production systems. With the aim to characterize, classify and evaluate soil – environment relationships, morphologic description and sample colect were made in four representative soil profiles of sedimentary regions, to chemical, physical and mineralogical analysis. Results showed, with exception of P1, profiles with great pedologic development, expressed by subsurface horizons with higher clay content and hydromorphic features in P2. Organic carbon contents were relatively low, due to sandy texture, with acid pH. Ki index and Fed/Fes relationship showed high weathering degree. Soil distribution in landscape seems to show relief and hidrology as major influences. Soil characteristics indicated Lessivage as the major processes, showed by lower floculation degree in transitional horizons, and increase fine clay:total clay relationship values in subsurface horizons. Ferrolysis and Gleization seems to contribute, specially in P2, as indicated by higher Feo/Fed relationship in E horizon.

Keywords: soil-environment; soil classification, pedogenetic processes

(6761 - 2958) Analysis of the mass attenuation coefficient in granulometric fractions of soils and their effects regarding the mineralogical properties of each fraction

Luis Valério Prandel[1]; Sérgio da Costa Saab[1]; Luiz Fernando Pires[1]; Larissa Macedo dos Santos[2]; André Maurício Brinatti[1]

State University of Ponta Grossa (UEPG)[1]; Federal Technological University of Paraná (UTFPR)[2]

Soils and their granulometric fractions can be characterized using energy dispersive X-ray fluorescence (EDXRF) and the Rietveld Method with X-ray diffraction data (RM-XRD). These results can be correlated to studies on radiation interaction (X-ray and δ) with the matter from the analysis of the mass attenuation coefficient (μ). The measurement of μ from the γ radiation interaction in soils and soil fractions, along with their mineralogical properties, is very relevant since it enables the prediction of physical properties such as total density, water content and porosity. Therefore, the purpose of this research was: to discriminate soil fractions using mineralogical, elemental and physical analyses; and to show, through the use of elemental and mineralogical analyses, which fractions present greater contribution to the characteristics of the γ radiation interaction with the matter. Five soil samples were collected, mashed and sieved (2 mm aperture sieve), dispersed, submitted to coarse sand separation (0.053 mm aperture sieve) and physical fractioning process through sedimentation (Stokes law) to extract the fine sand, silt and clay fractions. Semi-quantitative elemental analysis of the soils was accomplished through EDXRF by using an instrument model EDX-720 (Shimadzu) equipped with an Rh X-ray tube. An XRD diffractometer, model Ultima IV (Rigaku), with CuK_{α} radiation, 40 kV voltage and 30 mA current was employed to collect data for RM-XRD analyses. The μ and other phenomena such as partial cross-sections for Photoelectric Absorption (PA), Coherent Scattering (CS) and Incoherent Scattering (IS) were obtained based on the soil elemental chemical composition through the XCOM software. By using Principal Component Analysis (PCA), PC-1 (57.5 %) and PC-2 (20.9 %), the samples were grouped as a function of their texture, and granulometric fractions were classified in distinct quadrants due to the discrimination between physical, chemical and mineralogical properties. PCA made it possible to discriminate soil fractions through the mineralogical, elemental and textural analyses, correlated with the analysis of μ, photoelectric absorption (PA), coherent scattering (CS) and incoherent scattering (IS).

(9411 - 2945) Elemental release analysis of Polyhalite using micro X-ray fluorescence

Wilfrand Ferney Bejarano Herrera[1]; Kiran Pavuluri[2]; Robert Meakin[2]; Hudson Wallace Pereira de Carvalho[3]; Paulo Sergio Pavinato[1]

ESALQ/USP[1]; Sirius Minerals[2]; CENA/USP[3]

Polyhalite is a mineral to supply four macronutrients, including, potassium (K), calcium (Ca), magnesium (Mg), and sulfur (S), and its single crystal nature could provide a differentiate elemental release compared to other commercial fertilizers. The objectives of this study were to evaluate the release of K, Ca and S from polyhalite and muriate of potassium using micro X-ray fluorescence (μXRF) in an Oxisol and to determine the velocity of the horizontal and vertical movement through the profile. Rhizobox experiment was conducted using a Quartzipsamment and washed sand as a control substrate, arranged in a completely randomized design, with four replications, using K, Ca, Mg, S sources; polyhalite (POLY4) and potassium chloride (KCl) combined with phosphogypsum and kieserite, balancing Ca, Mg and S, supplied by POLY4, to reach the dosage evaluated. Bench-top μ-XRF scans were performed on the applied area and the surrounding region to measure K, Ca and S intensities at 30, 60, 120, 240, 480, 720 and 1440 minutes after application (MAA). The intensity was mapped to observe the dynamics of release for each element and the possible interaction between them. Additionally, a laboratory study using μ-XRF spectroscopy was carried out on POLY4 and KCl granules to observe the spatial distribution of the elements. The results showed that K, Ca and S intensities were influenced by source ($p<0.05$), presenting different dynamics of release. Horizontal and vertical

mobility showed that K, and Ca from POLY4 moved rapidly as MOP and phosphogypsum, however, the lower intensities of K in polyhalite demonstrate that is less soluble and released slower than KCl. On the other hand, vertical mobility of sulfur showed that this element moved rapidly when polyhalite is used, indicating that S from polyhalite is more soluble and released faster than the phosphogypsum. The granule of POLY4 showed that S is located all over the analyzed granule area, whereas K, Ca and Mg are distributed in spots, possibly complexed by S, and KCl presented high intensities of Cl and K in the analyzed region. Thus, the results indicated that µ-XRF is an effective technique for fertilizer analysis and the polyhalite is an alternative slow-release source of K, Ca, and S.

(6369 - 1587) Hematite and goethite proportion in soils of Rio Grande do Sul, Brazil

Keyrauan Taha[1]; Priscila Vogelei Ramos[1]; Alberto Vasconcellos Inda[2]
UFRGS[1]; UFGRS[2]

Iron oxides hematite and goethite are important pigment agents and influence on soil physical and chemical behavior. The aim of this work was to determine soil iron oxides, hematite and goethite, proportion in the Rio Grande do Sul's state, using continuum removal technique, and to establish soils kinds of soils for the hematite/(hematite+goethite) ratio (Hm/(Hm+Gt)). 579 soil samples of the 0-0.20 m layer have been used representing all the physiographic state regions. Samples have been analyzed on a VIS-NIR spectrum with a range from 350 to 2500 nm. For the removal continuum calculations, wavelength between 535-590 nm to hemathite and between 415 –450 to goethite have been selected. From bands intensity relative to each type of iron oxide has been calculated the ratio Hm/(Hm+Gt)*100, for the purpose of classifying RS soils as the ratio obtained. It has been established classes according to the proportion between the two types of iron oxides: goethitic soils = 0-25%; goethitic-hematitic soils = >25–50%; hematitic-goethitic soils = >50–75%; hematitic soils = >75–100%. The results indicate that 22% of RS soils are hematitics, 10% hematitic- goethitics, 13% goethitic-hematitics and 55% goethitics. Its concluded that it is possible to establish, by removal continuum technique, proportion kinds between hematite and goethite, and RS soils are predominant goethitics. In addition, the obtained results in this work could be related to physical (e.g. soil drainage) and chemical attributes (e.g. soil adsorption) of the southern Brazil soils.

Keywords: Iron oxides, soil pigment, soil reflectance.

(5908 - 2448) Iron oxide Nanoparticles in clay fraction of tropical soils from Peru: Study by X-ray diffractometry and Mössbauer spectroscopy

Mirian Mejia S.[1]; Jorge A. Bravo C.[1]
Laboratorio de Análisis de Suelos, Universidad Nacional Mayor de San Marcos, Lima, Perú.[1]

Iron (Fe) is the fourth element in order of abundance in the lithosphere, with an average content of about 5% in the Earth`s crust, and is very common soil mineral component (1-10%). The iron oxide particles are related to soil fertility and plant growth, they often occur as aggregates, minerals nanoparticles or as nanoscale coatings on other grains in the soil of both Fe crystalline and poorly ordered Fe oxide minerals [1]. The aims of this work was to identify and extent characterize the main minerals in the clay fractions of soil samples from the Tropical soils from Peru, with emphasis on the iron oxides and iron-bearing aluminum - silicates minerals; which are transformed to nano-size Fe oxides, via weathering processes in natural environment, using analytical techniques such as X ray diffractometry (XRD), transmission Mössbauer spectroscopy (TMS) at room temperature (RT) and at 110 K to determine their mineralogical composition. This work details the results obtained with two selected samples with contrasting characteristics. Where the effect of intense weathering causes the loss of Si, increasing the concentration of Fe and Al sesquioxides, this could explain the different mineralogical composition of the two soils studied. The main Fe sesquioxides found in the soils studied have been identified as hematite and goethite. (5647 - 2024) Magnetic susceptibility on study of Oxisol derived from sandstone in Brazilian Cerrado

Ronny Sobreira Barbosa[1]; Romário Porto de Oliveira[1]; João de Deus Ferreira e Silva[1]; Erico Vinícius Macêdo de Souza[1]; Raphael Vinicius de Souza Martins[1]; Juvenal Pereira da Silva Junior[1]; Diego Ferreira de Souza[1]; Yuri Jacques A. B. da Silva[1]
Federal University of Piauí[1]

Magnetic susceptibility is a soil property reflected its mineralogical characteristics. It can be defined as being one attribute of simple measure on material magnetized in the presence of a magnetic field. Accordingly, it can be used to indirect determination of some soil attributes that have magnetics interactions. Therefore, the objective of this work was to characterize the magnetic susceptibility relating it wit to the factors and processes of soil formation, and too, check it potential in estimating soil attributes formed in these environments. The study was performed in Palmeira do Piauí municipality (northeast Brazil) located in Cerrado, with Aw type climate according to Koopen classification, with average temperatures of 26.8 ºC and average rainfall of 1054 mm. The predominant soil is Oxisol formed from sandstone (Piauí Formation, Balsas Group) in the Paleozoic era at the top of the landscape (555 m elevation). For the study, were analyzed chemical, physical attributes and the magnetic susceptibility in samples of their different horizons. The data were submitted to descriptive analysis and also to a Pearson correlation analysis of the magnetic susceptibility with all attributes analyzed. Subsequently, pedotransfer functions were calibrate with attributes that showed a significant correlation with magnetic susceptibility. The studied soil showed values of magnetic susceptibility ranging from 1.85 to 2.90 * $10^{-6}m^3kg^{-1}$. Magnetic susceptibility showed significant linear correlation with sand, clay, water dispersed clay, organic matter, cation exchange capacity, aluminum saturation, base saturation and flocculation degree. In all regression models, high determination coefficients were obtained, with R^2 higher than 0.80. The highest values of the magnetic susceptibility found in the surface horizons are possibly dependent on the ferrimagnetic minerals present in the coarse fraction of this soil. It is concluded that the parent material was the most important soil formation factor in the magnetization of this soil and that the magnetic susceptibility can be used in the estimate of chemical and physical attributes in Oxisol of the Brazilian Cerrado.

(2150 - 2113) XANES spectroscopy in the study of iron oxides of an Indian Black Earth, Amazonia – Brazil

Anderson Almeida Pacheco[1]; Mauricio Paulo Ferreira Fontes[1]; Scott Fendorf[2]; Juan S. Lezama-Pacheco[2]; Matheus da Silva Ferreira[1]; João Carlos Ker[1]

Department of Soil Science, Federal University of Viçosa, Viçosa, Minas Gerais, 36571-000, Brazil[1]; Environmental Earth System Science, Stanford University, Stanford, California 94305-4015, USA[2]

The Indian Black Earth (IBE) is a soil formed as result of anthropic activity in pre-Columbian Indigenous settlement areas. These soils show features such as high fertility, high level of organic carbon, anthropic dark-colored epipedon, and the presence of lithic artifacts. Furthermore, the IBE is in contrast to other Amazonian upland soils, which are usually poor in nutrients due to intensive weathering and subsequent leaching under the prevailing humid tropical climate. The strong weathering condition this environment facilitates the genesis of crystalline iron oxides in the soils. Thus, iron form and concentration have long been important indicators for studies of soil genesis and adsorption processes. This study aimed to quantify the crystalline and poorly crystalline iron oxide species present in an Indian Black Earth, Amazonas State-Brazil, using geochemical, mineralogical and Fe K-edge XANES spectroscopy analysis. The location of collection of the IBE profile was in 3°14'11.98"S and 60°13'35.75"W. X-ray diffraction (XRD) analyses were performed using a Panalytical X'Pert (CoKα). The Fe content was measured by X-ray fluorescence spectroscopy (XRF). The Fe K-edge XANES data were collected at beamline 11-2 at the SSRL Stanford - USA. The IBE, with a collected profile of a depth of 100+ cm, showed in the horizons A1 and A2, organic carbon of 2.9; 2.1 %, P contents of 101.7; 176 mg kg-1, and color of 10YR 6/6, respectively. The horizon Bt, P content of 163.3 mg kg-1 and color of 10YR 6/1. The XRD patterns from of the clay fraction shown to be composed mainly of kaolinite, gibbsite, goethite, hematite, and in smaller proportions illite and montmorillonite. The Fe content measured by XRF showed the values of 4, 4.5 and 8 % for their horizons, respectively. The linear combination fitting (LCF) of XANES spectra results for the bulk samples showed iron oxide species as hematite, goethite, and ferrihydrite, based discernible spectral feature of standards. The LCF showed the average amount the 10, 29.5, and 53 %, respectively. We conclude XANES spectroscopy was efficient in the study of iron oxides, and the ferrihydrite, a poorly crystalline species, is present in higher proportion, although the environment presents a high degree of weathering. Thus, this study provides baseline data for future studies that evaluate the importance of the formation and stability of the ferrihydrite and its implications in soil adsorption processes in the tropical environment.

C2.4.3 - Influence of biological process in mineral formation

(4870 - 553) Crystal-chemical transformations and iron reduction in clay minerals of two Brazilian mangrove soils

Gabriel Ramatis Pugliese Andrade[1]; Javier Cuadros[2]; Carmen Partiti[3]; Renato Cohen[3]; Pablo Vidal-Torrado[3]

Universidade Estadual do Norte Fluminense Darcy Ribeiro[1]; The Natural History Museum[2]; Universidade de São Paulo[3]

The formation of clay minerals in mangrove soils is an important key to understand pedogenic and biogeochemical processes. To investigate the chemical transformations and the role of Fe reduction in clays, two Brazilian mangroves were selected: the first in a humid tropical climate in the Amazonian coast (city of Bragança, Pará State - BR), with predominance of kaolinite and pedogenic oxides as deposited minerals; and the second in the semiarid coast of northeastern Brazil (city of Acaraú, Ceará State - AC), where 2:1 clays are also sedimented. Samples of 2-0.2 mm and < 0.2 mm size fractions were studied using modeling of XRD patterns (program ClaySIM®), X-ray fluorescence spectroscopy (XRF) and Mössbauer spectroscopy. There is a mixture of end-member clays and R0 mixed-layered phases in the two size fractions from the two mangroves. The phases are kaolinite-smectite (K-S) with a range of smectite layers (1%, 15-25%, 50% and 80% of S layers), illite-smectite (I-S), Fe-rich illite and Al-rich illite. Kaolinite, smectite and illite layers had high octahedral Fe contents. The 2-0.2 mm size fraction contained more kaolinite-rich K-S and Fe-rich illite minerals, with higher structural order, than the < 0.2 mm fraction, which had more smectite-rich mixed-layered phases. In the AC samples, the Fe-illite content was higher than in BR samples. Fe^{2+}/TotFe proportions, from the combination of XRF and Mössbauer spectroscopy data, is higher in samples of the 2-0.2 mm size fraction (10-16%) than in the < 0.2 mm size fraction (2-3%). The deposited kaolinite is progressively transformed into smectite via K-S. This step includes the formation of a new tetrahedral sheet, gradual substitution of cations in tetrahedral (Al for Si) and octahedral sites (Fe+Mg for Al), and intercalation of cations. It leads to formation of Fe-rich smectite layers. The second step is the illitization of smectite layers, which includes further Fe substitution for Al and and Fe reduction. This is concluded because both total Fe and Fe^{2+}/TotFe proportion in the 2-0.2 mm size fraction correlated very well with Fe-illite contents from XRD. The AC samples have higher Fe-illite content because continental 2:1 clays are deposited in the mangrove and they are transformed more quickly into Fe-illite than kaolinite. We conclude that Fe sequestration and reduction during illitization are important biogeochemical processes operating in mangrove soils.

(9298 - 726) Mineral-life interaction in the soil environment

Javier Cuadros[1]

Natural History Museum, Department of Earth Sciences, Cromwell Road, London, SW7 5BD, UK (j.cuadros@nhm.ac.uk)[1]

Soils first formed perhaps as early as 3,000 My ago, when the first bacteria may have invaded the land. Later, from perhaps 1,300 to 450 My ago the sequential incursion of fungi, algae, lichens, plants, and invertebrates made life's role in shaping soil morphology and mineralogy increasingly important. The physiological drive of living organisms and their ability to generate microcosms of "extreme conditions" is likely to override inorganic processes if living organisms are in sufficient concentration. Physical and chemical processes involved in the formation of soils are generally well characterized and relatively well understood. Biological processes are not. Among living organisms developing on rocks and in soils, microorganisms are the most efficient modifiers of inorganic processes because they are the most abundant. Rock weathering and soil types correlate well with climatic zones, which is interpreted as soil development to be controlled by the physico-chemical conditions generated by temperature and precipitation regimes. However, climate and biological activity are also correlated and we may be underestimating the role of biological activity in soil formation and development. Biological weathering (physical disruption of minerals; dissolution or chemical change of minerals) is faster than inorganic weathering (measurements range from similar to orders of magnitude faster). However, biological protection of minerals has been observed to slow down inorganic weathering. Mineral dissolution rate in nature is orders of magnitude lower than in experiments. Reasons of experimental character are partially responsible for this difference. However, if living organisms always accelerate weathering why do we not ever measure faster dissolution in nature? Biological activity may have a net effect of mineral protection in the long term. Two considerations support this hypothesis: the protective effect of polymeric coatings and the possibility to retrieve inorganic nutrients

from biological litter rather than the inorganic soil. Biological activity can change the direction and products of mineral weathering, and can incorporate entirely new minerals that change the character of the soil (e.g., biogenic carbonate). In all microbial activity "encapsulation" is crucial: mineral-microbial interaction takes place in a small volume controlled by the microorganisms. Otherwise, inorganic physico-chemical conditions prevail.

Keywords: Biological activity; microbial activity; mineral protection; mineral weathering.

(4971 - 1804) Physical and mineralogical changes of the soil by the action of termites

Tatiele Fruett Dos Santos[1]; Alberto Vasconcellos Inda[1]; Antonia Finkler Dias Fernandes[1]; Keyrauan Taha[1]
Universidade Federal do Rio Grande do Sul[1]

Termites are predominant organisms of significant importance in soil. Soil termites are seen as "ecosystem engineers" and some as "keystone species" because they are important for survival and maintenance of other species. They are known for their effects of soil bioturbation, moving particles vertically and horizontally. The objective of the study was to verify physical and mineralogical alterations in the soil of termite mounds in relation to the adjacent soil used for the construction. Samples were collected in four Brazilian states: Rio Grande do Sul (RS), Mato Grosso (MT), Piauí (PI) and Minas Gerais (MG). Soil samples were collected in the 0 to 20 cm layer at adjacente area to termite mounds, under natural vegetation condition and without evidence of visible termite action. The samples of termite mounds were collected in the median and top portions. The samples were air dried and passed through a 2 mm sieve to obtain the air-dried fine soil (ADFS). The particle size analysis was performed by the pipette method and clay was collected for the preparation of slides oriented to the analysis of minerals by X - ray diffraction (XRD). The specific surface area (SSA) of the soil was estimated in the ADFS by the water adsorption method. The magnetic susceptibility analysis was performed in low (χLF) and high (χHF) frequency in magnetometer apparatus with dual frequency sensor (MS2 System). The XRD analyzes did not indicate mineralogical changes between the materials analyzed in the soil and in of termite mounds. However, more intense reflections of quartz were observed in the soil samples in relation to the of termite mounds samples. In addition, were observed in the diffractograms of termite mounds more intense reflections related to kaolinite (RS, PI, MG, MT) and gibbsite (MG). These results indicate a selection / preference of termites for smaller particles. This was confirmed both by the textural analysis, which indicated that termite mounds materials presented higher clay content in relation to adjacent soil samples; as by the SSA analysis, which was higher in the samples collected in térmite mounds. Magnetic susceptibility was higher in soil samples adjacent to termite mounds, possibly due to the higher concentration of magnetite in the coarser fractions of ADFS. However, the content of maghemite was higher in the thermals, where the clay contents were higher.

C2.5 - Soil chemical, physical and biological interfacial reactions

C2.5.1 - Soil interfacial reactions and their control of biogeochemical cycles

(4831 - 2036) A molecular dynamic study of water molecule on mica surface under different surface electrical field strength

Qinyi Li[1]; Gang Yang[1]
Southwest University[1]

The structure and dynamic properties of interfacial water are crucial to many physical chemistry processes in soil, such as adsorption/desorption on mineral surface, ion diffusion in nonpores, etc. Here, we report a molecular dynamic study of interfacial water molecule on mica surface under different electrical field strength. In this study, five different charged mica surfaces implemented by using aluminum atom substitute the silica atom. The result shows that the water molecules near charged surface are highly oriented when the electrical field strength is high, and the dipole orientation of all interfacial water is between 130-150 degrees. This means both hydrogen atoms of water point to the mica surface, so that the water can interact with mica surface directly by forming hydrogen bonds with the surface. When electrical field strength is low, the dipole orientation of water molecule becomes vary which means that the structures of water is less ordered. However, when the mica surface is zero charged, the interfacial water presents a highly ordered situation, while the dipole orientation is around 85 degrees which means that the hydrogen atoms of water are pointed away from the mica surface. This result indicates that the hydrogen atoms of interfacial water will form hydrogen bonds with water molecule other than interact with the mica surface. This is to say that the mica surface becomes hydrophobic when the surface charge comes to zero. The diffusion coefficient of water are also calculated. Under high electrical field strength, water has the lowest diffusion coefficient; and when electrical field strength are zero, the diffusion coefficient of water is a little higher. Nevertheless, when the electrical field strength is low, the water diffusion coefficient are the highest. From those results, we could conclude that the charge on mineral surface may affect the properties of hydrophobic/hydrophilic of the surface. And charges on the surface are not always increase the interfacial water order. It depends on the strength of the electrical field strength near surface. The electrical field strength may make the interfacial water more "active", which to some extent promote the interactions occurred on mineral-water interface.

(3221 - 1101) An improved method to synthesize pure allophane

Yang Li[1]; Tao Wang[2]; Marta Camps-Arbestain[1]; Qinhua Shen[1]; Catherine Whitby[3]
Institute of Agriculture and Environment, Massey University, Private Bag 11222, Palmerston North 4442, New Zealand[1]; Department of Biology, Microbial Ecology Group, Lund University, Ecology Building, SE-223 62 Lund, Sweden[2]; Institute of Fundamental Sciences, Massey University, Private Bag 11222, Palmerston North 4442, New Zealand[3]

Currently, allophane is most commonly synthesised following a 3-step method that includes the production of allophane precursor, its hydrothermal incubation, and the post-treatment of the resultant allophane with sodium chloride at high pH (ca 10). The post-treatment of allophane is generally conducted by dialysis (DI) or repeated washing with deionised water followed by centrifugation (WC). However, these methods have their own drawbacks; for instance, DI is a very time consuming step for the pH adjustment of allophane due to its high pH-buffering capacity, while WC often has a low product recovery resulting from the loss of unsettled allophane nanoparticles. In order to improve the post-treatment, new methods, adding HCl prior to the use of traditional methods, were used and evaluated based on allophane recovery, time demand, and properties of treated allophane and compared with traditional methods. The results indicated that the improved method, combination of HCl addition and subsequent WC (HCl+WC), could achieve not only a high specific surface area, low salt concentration, but significantly greater recovery (> 80%) in a shorter time period compared with traditional methods. Based on the results obtained, we concluded that the improved protocol (HCl+WC) is the most suitable for the batch production of

synthetic allophane.

(5113 - 695) Application of biocomposites with Fe hydroxide and extremophilic red microalgae on Pb removal

Yu-Ting Liu[1]; Yen-Lin Cho[1]

National Chung Hsing University[1]

Due to the tolerance for a wide range of temperature (room temp - 56 ℃) and acidity (pH 0.2 - 5), the Cyanidiales are considered as one of few extremophilic red microalgae. In this study, the tested Cyanidiales were collected from the Yangmingshan National Park in Taiwan. Because of the typical mineralogy, the soils and waters in this area are enriched with As and Pb. Given that their abundance is not dependent on the concentrations of As and Pb, the Cyanidiales are proposed as the potential materials for the remediation of heavy metals, especially in the acidic wastewater and soils that received contaminants from mining and industrial activities. While the Cyanidiales form complex with the environmentally ubiquitous Fe hydroxides, the bonding with surfaces of the Cyanidiales hinders the accumulation of nanoparticles of Fe hydroxides, leading to a promoted removal efficiency for heavy metals. Meanwhile, surface functional groups of Cyanidiales would transfer electrons to Fe atoms and thereby increase the redox activity of Fe hydroxides. This attribute enables Fe hydroxides to detoxify heavy metals by redox transformation during the metal removal process. Collectively, this innovative biocomposite material consisting of Cyanidiales and Fe hydroxides shows the promise the optimize efficiency in the accumulation and redox transformation of heavy metals.

Keywords: Cyanidiales; Fe hydroxide; biocomposite material; heavy metal removal

(2756 - 2420) Availability of phosphorus in Oxisols in function of incubation time and remaining phosphorus

Tainah Manuela Benlolo Barbosa[1]; José Zilton Lopes Santos[1]; Carlos Alberto Franco Tucci[1]

Federal University of Amazonas[1]

Soils developed under similar moisture and temperature regimes can respond differently to phosphate fertilization. The aims of this study were to evaluate the effect of incubation time of phosphate with Oxisols on availability and uptake of phosphorus by sorghum plants. Nine samples of dystrophic Yellow Oxisols were collected in a depth of 20 cm randomly, under native forest, in Amazonas state, Brazil. The soils were arranged in four groups, according to remaining phosphorus (P-rem): 5.6; 12.5; 17.2 and 22.2 mg L^{-1}, which received 455; 385; 320 and 185 mg dm^{-3} of P (KH_2PO_4), respectively. The P was incubed for five periods (0, 15, 30, 60 and 120 days), at the end of each incubation time the recovered P was determined (anion exchange resin). Sorghum was grown for 50 days in a greenhouse pot-culture study and the P content was determined in flag leaf. Soil with higher level of P-rem provided a higher recovery (67.5%) of P to the 30 days compared to other incubation times, however not significantly different ($p<0,1$) from 15 and 60 days. In the other soils (Prem =17.2, 12.5 and 5.6), the higher recovery of P is associated with lowest times of incubation, specialy in soils with P-rem = 12.2 and 5.6 mg L^{-1}, but there was no significant difference in comparison to 0 and 15 days. In relation to shorter contact times, the soils with 12.2 and 5.6 mg L^{-1} of P-rem had a higher rate of recovery of applied P (≈ 60.5%), while the soil with higher P-rem (22.2 mg L^{-1}) had the lowest rate of recovery of P (43.5%). In general, the lowest levels of recovered P were observed in the longer incubation time, especially in soils with higher P-rem. In longer incubation times, the soil lower P-rem (5.6 mg L^{-1}) presented the higher rate of recovery while the lowest recovery rate was observed in soil with 22.2 mg L^{-1} of P-rem. The P content in leaves of sorghum in the soils with 22.2 and 17.7 mg L^{-1} of P-rem not showed statistically significant diference. In the soil with 12.5 mg L^{-1} of P-rem the highest P leaf content were observed in the shorter time of incubation, but opposite behavior was observed in soil with P-rem = 5.6, which presented the highest values of leaf P in longer incubation time. The results confirm that the effect of incubation time in P availability vary among the soils. There is reduction in phosphorus availability in soils in long incubation time. The P uptake by sorghum plants dependend on nutritional requirement not on the absolute concentration of phosphus.

(2111 - 255) Can leguminous trees increase soil phosphorus availability? A link between the P and N cycles in tropical forests and agroforests of Brazil

Antonio Carlos Gama-Rodrigues[1]; Seldon Aleixo[1]; Jan Schripsema[1]; Emanuela Forestieri Gama-Rodrigues[1]

Universidade Estadual do Norte Fluminense Darcy Ribeiro[1]

Understanding the role of leguminous trees for phosphorus (P) and nitrogen (N) cycling in tropical soils is relevant for conservation of natural forests as well as the sustainable management of agroforests with low P input in the Atlantic Forest region of Brazil. We assessed the selected sites: 1) 0% leguminous trees mix cover; 2) 75% leguminous trees mix cover; 3) *Acacia auriculiformis;* 4) *Mimosa caesalpinifolia*; 5) *Acacia mangium;* 6) *Gliricidia sepium*; 7) low input of nitrogen fertilizer; 8) secondary forest; 9) spontaneous vegetation and 10) pasture without grazing. Soil P species (0-10 cm) was extracted with a solution of 0.25 M NaOH + 50 mM Na_2EDTA in conjunction with ^{31}P nuclear magnetic resonance (^{31}P NMR) spectroscopy operating with proton decoupling at 202.446 MHz with a 5 mm probe, using a 6.0 µs pulse (30°), an acquisition time of 0.4 s, an delay time of 0.5 s operating at 21 °C. Approximately 30,000 scans were acquired for each sample. Total soil ^{31}P NMR ranged from 192 to 465 mg kg^{-1} (37-83% of total soil P). Soil organic P (Po) ranged from 49 to 199 mg kg^{-1}, with the predominance of phosphate monoesters (P-monoester) ranging from 42 to 133 mg kg^{-1} (65-85% of total Po), while phosphate diester (P-diester), in the DNA form, ranged from 4 to 17 mg kg^{-1} (6-9% of total Po). The highest concentrations of *myo*-hexakisphosphate (*myo*-IHP) were found in the site with low input of nitrogen fertilizer (85.7 mg kg^{-1}) and all leguminous trees sites (mean of 87.6 mg kg^{-1}). There was a positive correlation between *myo*-IHP and *scyllo*-IHP, and both strongly and positively correlated with inorganic orthophosphate (*ortho*-P), pyrophosphate, glucose-1-phosphate and DNA. *Ortho*-P ranged from 123 to 236 mg kg^{-1} (82-89% of total inorganic P), while pyrophosphate ranged from 19 to 38 mg kg^{-1}. The highest concentration of pyrophosphate was found in the site with low input of nitrogen fertilizer (38 mg kg^{-1}), while for all leguminous trees sites the average concentration of this P species was 34 mg kg^{-1}. In conclusion, the results indicated that leguminous trees can be a suitable tool to increase the concentrations of P species (inorganic and organic) in tropical soils.

(8764 - 2897) Carbon contents in aggregates under black oat cultivation in the municipality of Nova Friburgo RJ

Douglath Alves Corrêa Fernandes[1]; Sandra Santana de Lima[1]; Jayna Eloy da Rocha[1]; Adriana Maria de Aquino[2]; Marcos Gervasio Pereira[1]
Universidade Federal Rural do Rio de Janeiro[1]; Empresa Brasileira de Pesquisa Agropecuária[2]

The growing of black oats promotes the contribution of organic matter in the soil and benefits to its structure. The objective of the research was to evaluate the carbon content in different compartments of organic matter in aggregates biogenic and physiogenic in areas with black oats under different management. The research was carried out in the Municipality of Nova Friburgo-RJ in conservationist production systems, located in an area of mountainous relief. Two areas of study were selected: AV-N area - managed with unfertilized black oats since the second half of 2011. Annually the plowing and the replanting of the oat are done at the end of the winter. Before plowing the oats are desiccated through the application of herbicides; area AV-A - managed with black oats since 2012, being fertilized with NPK formulation 4-14-8 (1 Mg ha^{-1}) and an area of forest - fragment of Atlantic Forest without record of anthropic action in the last 60 years. Soil clusters were collected and from these were separated aggregates of soil in 8 and 9 mm sieves. Subsequently the aggregates were classified according to the biogenic and physiogenic formation pathways. The total organic carbon content (TOC) and the particle size fractionation of the organic matter were analyzed by quantifying the particulate organic carbon (POC) associated with the sand and organic carbon fraction associated with the minerals (OCam) of the silt and clay fractions obtained by difference between TOC and POC. Among the areas, the highest TOC levels were observed in AV-A. Regarding the granulometric fractionation only OCam showed a difference, with the highest values observed in the AV-A area. Among the aggregate classes there was no difference between the biogenic and physiogenic aggregates for the TOC, POC and OCam contents, and the values in the cultivated areas close to those of the preserved forest area. The growth of black oats besides adding organic matter to the system also contributes positively to the soil aggregation and the formation of biogenic and physiogenic aggregates in a similar quantity to the area without anthropic action.

(6952 - 297) CO_2 efflux over a hill with different water contents due to heterogeneities in soil texture

Tiago de Carvalho Pessoa[1]; Vânia da Silva Fraga[1]; Borja Ruiz Reverter[1]; Galileu Medeiros da Silva[1]; Júlia Eudócia de Araújo Monteiro[1]
Universidade Federal da Paraíba[1]

Soil CO_2 efflux is the major component of the carbon released to the atmosphere, but its main drivers and features are still under debate. In our work, we quantified the CO_2 efflux at three different locations over a heterogeneous hill, which presented different water contents due to heterogeneities in soil texture. Static chambers based on absorption by caustic soda (NaOH) were used to collect the CO_2 from soil during 24 horas periods, whose concentration were subsequently determined by acid-base titration. Soil water content was measured by reflectometry at 0-10 cm depth. The soil type of the hill was Acrisol with a clay texture at the shoulder and at the backslope and a sand texture at the footslope. We found that low water contents decrease the carbon releases. In fact, at the shoulder and at the backslope the least carbon emissions (1.5 µmol m^{-2}s^{-1}) were related to 0.05 cm^{3}cm^{-3} of water content and to 0.03 cm^{3}cm^{-3} at the footslope (1 µmol m^{-2}s^{-1}). On the other hand, the highest carbon releases (4 µmol m^{-2}s^{-1} at the shoulder and 5 µmol m^{-2}s^{-1} at the backslope) were found for water contents between 0.11 to 0.16 cm^{3}cm^{-3}, while at the footslope the major carbon releases (7 µmol m^{-2}s^{-1}) took place for water contents between 0.06 and 0.011 cm^{3}cm^{-3}. Maximum carbon emissions were registered for water contents of 0.146 cm^{3}cm^{-3} at the shoulder, 0.107 cm^{3}cm^{-3} at the backslope and 0.068 cm^{3}cm^{-3} at the footslope. These differences in the water content were attributed to soil textures heterogeneities, which influence water retention and water availability for biological activity. Nevertheless, we also found some events of water content above 0.17 cm^{3}cm^{-3} at the shoulder and at the backslope and 0.11 cm^{3}cm^{-3} at the footslope, that decreased the carbon emissions probably due to the filling of the soil pores that, firstly, expel the gases and, second, hinder the CO_2 diffusion. We conclude that heterogeneities in soil texture over our hill influences the content of soil water, which in turn influences carbon emissions, not only by enhancing them, but also by limiting them at high water contents.

(8939 - 769) Differences in surface elemental composition between intact and homogenized soil microaggregates reflect the specific location of elements

Susanne K. Woche[1]; Stefan Dultz[1]; Robert Mikutta[2]; Joerg Bachmann[1]; Georg Guggenberger[1]
Institute of Soil Science, Leibniz Universität Hannover, Herrenhäuser Str. 2, 30419 Hannover, Germany[1]; Soil Science and Soil Protection, Martin Luther University Halle-Wittenberg, Von-Seckendorff-Platz 3, 06120 Halle (Saale), Germany[2]

Soil microaggregates (SMA; <250 µm) are of special interest as they are considered to be more stable than larger structures and thus potentially sequester more organic matter. Formation as well as stability of SMA likely depend on surface properties (e.g., exposed functional groups, surface charge, wettability) of aggregate building units involved such as small minerals or organic matter. Application of X-ray photoelectron spectroscopy (XPS) to water-stable SMA isolated from Luvisols along a clay gradient revealed some differences in the elemental composition of the surface layers as function of SMA origin (free or occluded SMA), size fraction, and bulk soil clay content. To assess the enrichment or depletion of elements within the surface layer in order to gain more insight in SMA functioning demands comparison of the surface element composition with data from bulk analysis. However, element amounts derived from XPS analysis and common bulk analytical techniques such as e.g. chemical digestion followed by ICP analysis or XRF usually are not directly comparable due to different analytical principles. Here, we suggest a different approach by homogenizing SMA manually in a mortar in order to create quasi-bulk material that can be analyzed by XPS along with intact SMA. First results for 53-250 µm-SMA revealed some marked differences between intact and homogenized SMA. The most striking result was a distinctly smaller N content of the homogenized SMA. This may indicate the surface layer to be the preferred habitat of microorganisms. Along with the decrease in N an increase in C content was observed which may point on some enrichment of C within the

SMA that thus may be more stabilized. Further, the content of Na and K was increased for homogenized SMA, probably indicating the presence of alkali feldspar and illite and/or micas rather within SMA where weathering will be delayed. This may be supported by the slightly decreased Si/Al ratio after homogenization, which at the same time, together with a concurrently slight decrease in O content, may indicate quartz to be more prominent within the surface layer. The results so far suggest manual homogenization to be a useful tool to identify differences in element contents between SMA surface layer and SMA bulk composition. Contrary to surface sputtering, where material is removed from the system, homogenization preserves all compounds present and only destroys their original arrangement.

(8433 - 735) Diurnal variation in soil heterotrophic and total carbon dioxide emission

Jesus Rosario Mancilla Huashuayo[1]; Nisa Novita[2]; Louis-Pierre Comeau[3]; Jodie Hartill[4]
MCF Fredericton Canada[1]; Center for International Forestry Research[2]; Agriculture and Agri-food Canada[3]; University of Aberdeen[4]

Assessment of CO2 emissions are usually made by day-time measurements and only a few studies have measured in situ heterotrophic respiration at night. Therefore, current estimates of annual CO2 fluxes based on day-time measurements may have systematic errors. The goal of this study was to measure the diurnal (i.e. day and night) variation of heterotrophic CO2 fluxes and total respiration from the soil surface, and to compare it between ecosystems. The study sites were deep peat coastal in Indonesia, mineral forest soil in Hong Kong and mineral agricultural soil in Eastern Canada. Soil CO2 fluxes were measured with an infrared gas analyzer in dark closed chambers. Measurements were made every 3 h during a 24 h period. The experiments were conducted twice in each ecosystem. Simultaneously with CO2 flux measurements, water table depth, air and soil temperatures were also recorded. A total of 72 measurement spots were studied. The diurnal CO2 flux pattern of each individual collar was analyzed using the Q10 approach and by fitting a 24h cosinor wave curve to determine the circadian oscillation. Overall, only 12/72 and 14/72 measured units displayed a significant diurnal variation using the Q10 and circadian oscillation methods, respectively. The circadian oscillation method had the advantage over the Q10 approach of automatically estimating the diurnal flux amplitudes and peak emission times. In addition, compared to the Q10 approach, the circadian oscillation analyses were not biased due to delays in the microbial activity response to temperature change and other environmental variables that affect CO2 fluxes. The median peak emission time from the fitted circadian wave curve was between 13:02 and 13:34. The average diurnal flux amplitude from the circadian fitted curves was 0.28 (±0.05) g CO2 m2 h-1. Due to the low number of significant measured units, the observed large range of potential peak emission times and the relatively small amplitude in diurnal fluxes, we conclude that for scaling CO2 measurements to represent a daily flux, the widely expressed concern about temporal variability is not particularly pertinent. Therefore, emphasis in sampling schemes should be on a spatial rather than temporal replication.

(3064 - 2008) Dynamics of greenhouse gas emissions during anaerobic soil disinfestation in vegetable soils

Kun Zhu[1]; Chen Wang[1]; Guitong Li[1]
China Agricultural University[1]

Anaerobic soil disinfestation (ASD) is proposed as an alternative to chemical soil fumigation for the control of several soil-borne diseases, plant-parasitic nematodes, and weeds in a variety of crops. Limited information is available on the impact of ASD on greenhouse gas emissions. The current study aims to investigate the effects of ASD applied using crop residues as amendments, on soil oxygen (O_2), pH, temperature, soil nutrient content, and emissions of carbon dioxide, methane and nitrous oxide (CO_2, CH_4 and N_2O). A laboratory experiment and a greenhouse trial were simultaneously conducted. The O_2-specific planar optode system in lab was employed to continuously monitor soil O_2 profile with high spatiotemporal resolution during the ASD period. The stable isotope ^{15}N labelled KNO_3 was applied in the greenhouse trial to monitor the N transformations. Compared with the treatment without crop residue amendments, addition of crop residues resulted in robust metabolic activity, inducing much larger peak GHG emissions, particularly 800 times higher of N_2O peak emission rates during the first week, and 1000 times higher of CH_4 peak emissions rates during the second week. The monitored O_2 profile in soil clearly indicated that a quick shift of the soil environment from aerobic to anaerobic conditions occurred for the initial few days, which stimulated the denitrification processes. The ^{15}N site preference (SP) and $\delta^{18}O$ of emitted N_2O indicated a mixture of production sources during ASD treatment period. Adding crop residue 5 days before ASD treating process significantly immobilized nitrate in soil, therefore reduced the substrate availability of denitrification, consequently mitigated N_2O emissions. Due to the high capacity of labile carbon sorption on biochar particles, crop residue coupled with biochar addition reduced both CH_4 and N_2O emissions. Those results suggest that both pre-immobilization of nitrogen by earlier crop residue addition and co-application of biochar would mitigate GHG emissions effectively, therefore could potentially improve the strategies of anaerobic soil disinfestation.

(3156 - 650) Effect of drought on soil consolidation, and associated changes in decomposition and aggregation

Asmeret Asefaw Berhe[1]; Chelsea Arnold[1]; Teamrat A. Ghezzehei[1]
University of California, Merced[1]

While peatlands are garnering much attention for their greenhouse gas feedback potential in a warming climate, the coupled biogeochemical and hydrological impact of structural and physical changes in these types of systems as a result of drought-induced drying and desiccation has not been studied in detail. The cyclic drawdown/recharge of the water table that exists in most peatland systems impose important controls on organic matter storage and decomposition as well as soil physical properties. In order to better understand how high elevation peatlands will respond to increasingly dry years, we incubated meadow soils collected along a hydrologic gradient at 5 different water potentials and measured the CO_2 flux at intervals for over one year to determine how desiccation of meadow soils (from the Harvey Monroe Hall Research Natural Area at the crest of the Sierra Nevada) influences gaseous fluxes of C, as well as aggregation of the organic-rich soils and distribution of the soil C in different physical pools (macro- vs. micro-aggregate, and silt+ clay fractions). We found that the cumulative carbon mineralization was greatest at the highest (0.1 bar) and lowest (4 bar) water potential,

across all regions of the meadow, indicating the presence of two separate pools of labile carbon that can be accessed only after a threshold of drying is reached in the soil. We also observe important changes associated with aggregate size distributions and fraction of total carbon distributed in three distinct pools.

(3496 - 1575) Effect of long-term organic matter manipulation on soil biological activity in a temperate oak forest

Zsolt Kotroczó[1]; Katalin Juhos[1]; Imre Berki[2]; István Fekete[3]
Department of Soil Science and Water Management, Szent István University, 29-43. Villányi út,Budapest, 1118, Hungary[1]; Institute of Environment and EarthSciences, University of Sopron, Ady u. 5, 9400 Sopron, Hungary[2]; Department of Soil Science and Water Management, Szent István University, 29-43. Villányi út,Budapest, 1118, Hungary; Institute of Environmental Sciences, University of Nyíregyháza, Nyíregyháza, Sóstói út 31/B Hungary[3]

The DIRT treatments are derived from a project started in 1957 in forest and grassland ecosystems at the University of Wisconsin. The Síkfőkút DIRT (Detritus Input and Removal Treatments) Project (Hungary; N 47°55' E 20°26') joined with the American ILTER DIRT network which was organized by the US-ILTER (International Long-Term Ecological Research).According to the FAO World Reference Base, the soils are Luvisols. The site has *Quercetum petraeae-cerris* community. During our examinations, we studied the effects of modified litter production on the organic matter content of soil. It also studies how the modifications, decreases or increases in litter production influence the biological processes of soils.Our examinations were carried out in spring periods, on the permanent experimental parcels which were established in 2000. According to ourresults, the activity of soil enzymes and soil respiration are rather influenced by the drastically decreasing amount of leaf litter than increasing leaf litter production which has surpassed its natural level. pH values of the soil fulfilled our expectations, since leaf litter withdrawal lead to lower (more acidic) pH values (NL=5.41; DL 6.41; Co6.32). After 5 years there was a significant difference between the treatments in soil respiration (p=0.012) and enzyme activity. In the NL plots (22.348 mgC/m^2/h), the CO_2 emission of the soil was significantly lower than that of C (29.832 mgC/m^2/h). However, the effect of the increased amount of litter has not shown the expected results of the DL treatment(28.963 mgC/m^2/h). Treatments with leaf-litter addition samples showed the highest activities, while treatments with leaf-litter withdrawal could be describedsignificantly lower activities. Remarkably, dominancy of DL (which treated with the largest amount of biomass) against Co and DW could not be detected by none of the examined enzymes. There wa sno significant relationship between treatments in case of *ß*-glucosidase enzyme and the soil respiration (p>0.050; R=0.213). The aryl-sulphatase and saccharase activity of soil in the litter withdrawal treatments (NL, NR, NI) showed lower values than in the other three treatments.

(6760 - 407) Effect of soybeans inoculation and nitrogen fertilization on soil nitrogen content in a sandy soil

Carlos Felipe dos Santos Cordeiro[1]; Fábio Rafael Echer[1]
Universidade do Oeste Paulista (UNOESTE)[1]

Nitrogen (N) is the most important nutrient for plants, and for legumes it cames from biological nitrogen fixation (BNF), and also from N availability in the soil. On the other hand, the amount of soil organic matter in sandy soils is low and N content available for plants is very low. The objective of this study was to evaluate the response of soybean to inoculation in interaction with nitrogen fertilization, in an area of first and second year of soybean cultivation. The experiment was carried out in the field in Presidente Bernardes-SP-Brazil. The experimental design was a split plot within a randomized complete block, with four replications. In the plots the inoculant doses were allocated (0, 4, 8 and 12 ha^{-1}) and in the subplots the nitrogen doses (0, 25, 50 and 100 kg ha^{-1}). The inoculation was performed by the spraying in the furrow. The fertilization in the plots that received the nitrogen (ammonium nitrate) was performed at R1 stage. In R4 stage, soil was sampled at depth of 0-20 cm, to determine the amounts of N-organic and N-inorganic (NH_{4+} and NO_{3-}). At soybean physiological maturity, the yield was evaluated, by mechanical harvest of the three central lines of the plot. The statistical study consisted of analysis of variance and regression (P<0.05). In both, first and second year areas of soybean cultivation, the highest N-total contents were achieved with 12 inoculant doses and 100 kg ha^{-1} N, with values of 202 and 234 mg kg^{-1}, respectively. In the control treatment, the N-total content was 45% higher in the older area as compared to the first-year area. NH_{4+} and NO_{3-} contents were similar, representing 6% of N-total. In the first-year area, the highest soil-N contents were achieved with 4 doses of inoculant and 100 kg ha^{-1} of N (NH_{4+} 7.04 and NO_{3-} 6.08 mg kg^{-1}). However, in the second-year area the highest values were achieved with the maximum doses of nitrogen and inoculant (NH_{4+} 9.48 and NO_{3-} 8.72 mg kg^{-1}). The highest yield in the first-year area occurred with application of 12 doses of inoculant and 100 kg ha^{-1} of N (2883 kg ha^{-1}), yet in the second-year area the application of 8 doses of inoculant (2299 kg ha^{-1}) reached the maximum yield. In conclusion, increasing inoculant and nitrogen doses improved soil N-organic and N-inorganic contents in first and second year areas, and enhanced soybean yield in the first-year of cultivation area.

(3668 - 669) Effects of long-term fertilization on the pathways in N supply

Qiang Ma[1]
Institute of Applied Ecology, Chinese Academy of Sciences[1]

Fertilizer N can be conserved through immobilization by microorganisms and fixation by soil clay minerals, and then subsequently remineralized and released. These processes are significantly influenced by soil fertility levels and fertilization history. Based on a long-term *in-situ* experiment, the effects of different fertilization regimes on the seasonal fluctuations of soil microbial biomass N (SMBN) and fixed NH_4^+ were investigated during one maize (*Zea mays* L) growing season, including six treatments, i.e. CK (unfertilized control), M (recycled pig manure), NP (mineral fertilizers N and P), NPK (mineral fertilizers N, P and K), NPK+M (recycled pig manure with mineral fertilizers N, P and K), and PK (mineral fertilizers P and K). The results showed that the response of soil fixed NH_4^+ to chemical fertilizer N application was observed during the growing season. In the treatments containing fertilizer N, the peaks in fixed NH_4^+ achieved after top dressing, accounting for an average of 40.8%

of fertilizer N was fixed by soil minerals. Subsequently, fixed NH_4^+ released slowly and contributed to the N supply. In the treatments receiving fertilizer N, the release of fixed NH_4^+ was 1.1-fold greater on average than the mineralization of SMBN, whereas the latter was 2.3-fold greater than the former in the treatments without fertilizer N. Moreover, the greatest N supplying capacity of SMBN obtained in the M treatment, which received recycled manure alone. Therefore, our study indicates that the pathways in N supply varied according to the fertilization regimes. With N fertilizer application, fixed NH_4^+ pool was the major pathway in N supply, whereas SMBN was the primary approach of N supply when no fertilizer N applied.

(4269 - 261) Effects of rice cultivars on CH_4 emissions and their possible interaction with soil C availability

Weijian Zhang[1]; Yu Jiang[1]

Institute of Crop Sciences, Chinese Academy of Agricultural Sciences, Beijing 100081, China[1]

Breeding high-yielding rice cultivars through increasing biomass is a key strategy to meet rising global food demands. Yet, increasing rice growth can stimulate methane (CH_4) emissions, exacerbating global climate change, as rice cultivation is a major source of this powerful greenhouse gas. Here, we show in a series of experiments that high-yielding rice cultivars actually reduce CH_4 emissions from typical paddy soils. Averaged across 33 rice cultivars, a biomass increase of 10% resulted in a 10.3% decrease in CH_4 emissions in a soil with a high carbon (C) content. Compared to a low-yielding cultivar, a high-yielding cultivar significantly increased root porosity and the abundance of methane-consuming microorganisms, suggesting that the larger and more porous root systems of high-yielding cultivars facilitated CH_4 oxidation by promoting O_2 transport to soils. Our results were further supported by a meta-analysis, showing that high-yielding rice cultivars strongly decrease CH_4 emissions from paddy soils with high organic C contents. Based on our results, increasing rice biomass by 10% could reduce annual CH_4 emissions from Chinese rice agriculture by 7.1%. Our findings suggest that modern rice breeding strategies for high-yielding cultivars can substantially mitigate paddy CH_4 emission in China and other rice growing regions.

(8276 - 1091) Formation and genesis of natural nanoparticles (NNPs) in flooding Pb-Zn mine tailing soil

Kengbo Ding[1]; Miaoyue Zhang[2]; Man Zhao[3]; Can Feng[3]; Xi Zhong[3]; Yaying Li[2]; Erkai He[2]; Yuanqing Chao[2]; Shizhong Wang[2]; Rongliang Qiu[2]

School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou 510275, China (dingkb@mail2.sysu.edu.cn)[1]; School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou 510275, China; Guangdong Provincial Key Laboratory of Environmental Pollution Control and Remediation Technology, Guangzhou 510275, China[2]; School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou 510275, China;[3]

Nanoparticles (NPs) have high affinity to contaminants in the environment. However, research on natural nanoparticles (NNPs), especially their formation mechanisms, has limited attention. Microcosms containing Pb-Zn mine tailing soil and artificial rainwater were therefore prepared in this study to confirm the hypothesis that microbial dissimilatory reduction could induce the formation of NNPs in soil. Porewater in microcosms was obtained by a MircoRhizons sampler in an anaerobic workstation. The concentrations of lithophile elements and metal elements in nanosized and dissolved fraction of porewater, as well as the concentrations of anions in porewater were analyzed by ICP-OES and ion chromatography, respectively. The morphology, elemental composition, and mineral characteristics of the NNPs were observed by transmission electron microscope (TEM). Pyrosequencing analysis was performed on soil samples from the soil microcosm to obtain microbial information. The results showed that flooding induced tailing soil reduction slowly, exhibiting an increase of pH from 4.0 to 5.0 and a decrease of Eh from 250 to 50 mV in 100 days. The concentration of NO_3^- decreased first, followed by Mn and Fe. However, the concentration of SO_4^{2-} remained unchanged. For lithophile elements, the concentration of Mn increased first (Day 4), followed by Si (Day 10) and Fe (Day 40), while the concentration of Al decreased along the whole experiments. The nano-fraction of Mn, Fe, and Si in soil solution has increased compared to the initial status after filtration and ultracentrifugation analysis, indicating the formation of Mn, Fe, and Si containing nanoparticles. All the elements of Pb, Zn, Cu, and Cd existed in the nano-fraction of soil solution, indicating an adsorption or complexation of these metals in the nanoparticles, which was further confirmed by TEM images. Microbial information will be supplemented to link the formation of NNPs and microbial dissimilatory reduction. These findings indicated that NNPs were formed in the flooding Pb-Zn mine tailing soil due to the effect of microbial dissimilatory reduction by a combination of top-down way (breakdown of aggregates) and bottom-up way (nucleation of inorganic ions). More studies on the transport behavior and ecological effects of NNPs should be studied in the future.

(7284 - 3093) Geomorphological control of carbon and nitrogen dynamics in agricultural areas in the Brazilian Central Plateau

Mateus de Alencar Ramos Fernandes[1]; Vinicius Vasconcelos[1]; Ray Pinheiro Alves[1]; Renato Henrique Ferrari[1]; Eder de Souza Martins[2]; Gabriela Bielefeld Nardoto[1]

University of Brasília, Asa Norte, Brasília, 70910-900, Brazil[1]; Embrapa Cerrados, BR-040 Km 18, Planaltina, 73310-970, Brazil[2]

The distribution of organic carbon and nitrogen in tropical soils is influenced by topographic attributes and soil types in the landscape while agricultural management usually intensifies the dynamics of soil organic matter. The differences in the nature and dynamics of soil organic matter were characterized using stable carbon and nitrogen isotopes. In this context, the objective of this work was to understand the dynamics of carbon and nitrogen as function of geomorphological aspects in the Rio Jardim Basin, east of the Federal District, in the Brazilian Central Plateau. The predominant land use in the region is agriculture on a large scale. Four toposequences were selected: two were performed on smooth and gentle ramps and two on partially dissected channels along an interfluve. Soil samples were collected up to 40 cm depth along the gradient. They were air-dried and sieved

with a 2 mm mash, milled and analysed for C:N, $\delta^{13}C$, $\delta^{15}N$ and clay content. Both soil $\delta^{13}C$ and $\delta^{15}N$ values at depth 20-40 cm were greater than 0-20 cm. In the interfluves the soils become shallow towards the central part of the basin, with increasing values of carbon and nitrogen isotopes at that same direction for both depths. The ramps presented higher values of $\delta^{13}C$ and $\delta^{15}N$ compared to the channels. The C:N ratios presented higher values in the channels, because of higher concentration of C when compared to the channels. The dynamics of C and N in these agricultural soils under different position in the landscape is being mostly controlled by the geomorphology of the regions that seems to be related to dissection and deposition processes.

Keywords: Stable isotopes, landscape, topossequence, $\delta^{13}C$ e $\delta^{15}N$.

(9983 - 2995) How soil carbon and nutrient availability in an integrated crop-livestock-forest system are related?

Janaína de Moura Oliveira[1]; Beata Emöke Madári[2]; Marcia Thais de Melo Carvalho[2]
Post-doc, Brazilian Agricultural Research Corporation – National Rice and Beans Research Center, (EMBRAPA/CNPAF), Rod. GO-462, Km 12, Faz. Capivara, Zona Rural, Santo Antônio de Goiás-GO, Zip Code: 75375-000, P.O. Box: 17, Brazil[1]; Reseracher Scientist, EMBRAPA/CNPAF[2]

Cropping systems integrated with trees and livestock is a potent mitigation strategy in tropical agriculture by increasing soil C stock and producing food, fiber and energy on the same area. In integrated systems, nutrient cycling is more complex and behave differently from monoculture due to the increment in biodiversity. In a previous study (Oliveira et al., 2018), we found up to 30% increment of soil organic C (SOC) stock in a 3-year old integrated crop-livestock-forest (iCLF) system compared to a 20-year old pasture under continuous grazing, especially in samples of the 30-100 cm soil depth located at the tree lines. We believe that such fast increment in total C stock was due to healthy conditions of soil chemical properties, since synthetic fertilization and liming were applied for establishment of the iCLF system. Therefore, in this study we aimed to check the correlations between SOC and nutrient availability at the 0-100 cm soil depth of an Oxisol cultivated with the iCLF system. The iCLF system was established in 2009, with rows composed by three lines of eucalyptus spread at each 20 m in a 4.7 ha, under real farm conditions. Details about field design and data collection can be found in Oliveira et al. (2018). The area is located in the southern Amazon ecosystem, North of Mato Grosso State, Brazil. The SOC and nutrient availability were quantified in the same soil samples collected from 15 trenches, each splitted in eight soil layers from 0-100 cm soil depth. Status of nutrient availability in soil was given by the following variables: pH (water), Ca, Mg, P, K, Cu, Zn, Fe and Mn. Correlations between measured SOC and soil nutrient availability variables within 0-100 cm soil depth (n = 120) were determined with Pearson's correlation coefficient. Analyses were performed using the linear mixed model procedure (Proc Mixed) and the correlation procedure (Proc Corr) of the SAS software (SAS Institute Inc., Cary, NC, USA). Results show that there was no significant correlation between SOC and soil pH in water (R^2: 0.15, p-value: 0.09). However, a positive correlation was observed for all other nutrients, wherein (R^2 and p-value) in order of magnitude: Mg (0.78, $p < 0.001$), Ca (0.76, $p < 0.001$), Zn (0.73, $p < 0.001$), P (0.70, $p < 0.001$), K (0.67, $p < 0.001$), Mn (0.65, $p < 0.001$), Fe (0.59, $p < 0.001$), Cu (0.54, $p < 0.001$). Results confirm that the increment of SOC was favored by soil nutrient availability in the iCLF system.

Rewetting of dry soil typically results in a short-term pulse of CO_2 from soil to the atmosphere known as the 'Birch effect'. The displacement of CO_2 air-filled pores with water during wetting has been recognised as one of the sources of this pulse. The Birch effect has been extensively reported under wettable soil conditions but some studies report a lack of such response, suggesting soil water repellency (SWR) as a potential cause. SWR restricts infiltration and affects soil water distribution. Preferential flow paths and increased overland flow are common patterns in water-repellent soils, leaving extensive areas of the soil dry even after substantial rainfall. Future climate scenarios will likely enhance the development and persistence of SWR. Despite this, the effect of SWR on CO_2 efflux after rewetting has never been tested and remains poorly understood. The aim of this research was to test the hypothesis that SWR suppresses CO_2 pulse after rewetting. In the lab, dry homogeneous soils at water-repellent and wettable status were rewetted with different amounts of water. CO_2 efflux in response to wetting was continuously monitored using the LI-COR Li-8100A Soil Gas Flux system. Severely reduced infiltration, overland and preferential flow was observed in water-repellent soils. Typical 'Birch effect' observed in wettable soil was not detected in water-repellent soil. A field study was conducted in a burnt pine stand in Portugal before the first natural rainfall event. Forest fires are known to induce changes in SWR, often increasing its severity and persistence. The study plots were rewetted with water and with water mixed with the wetting agent (Revoltution®, Aquatrols) to simulate inhibited and non-inhibited infiltration, respectively. CO_2 efflux in response to wetting was monitored before and several times after the rewetting event using the soil gas flux system along with changes in soil moisture, infiltration and runoff. The main conclusion from the experiment is that SWR not only affects hydrological relationships but also has an impact on CO_2 fluxes. Hence SWR becomes an important parameter to consider in monitoring and modelling of gas fluxes.

(5491 - 1520) Iron dynamics in replanted mangrove forest (SE-Brazil): preliminary results

Gabriel Nuto Nóbrega[1]; Hermano Melo Queiroz[1]; Tatiana Scacco Pereira[1]; Xosé L. Otero[2]; Tiago Osório Ferreira[1]
Universidade de São Paulo (ESALQ/USP)[1]; Universidade de Santiago de Compostela (USC)[2]

Concerns over the global C cycle, greenhouse gas emissions (GHGs) and their impacts on the global climate change have led researchers and public agencies to create policies aimed to mitigate the increasing concentration of GHGs in the atmosphere. In this sense, mangroves play a significant role in C sequestration, especially in their soils. Thus, the understanding the dynamic of elements which controlling the recovery of C stocks in these ecosystems is essential. This project aims to evaluate the Fe dynamic in replanted mangrove soils, aiming to comprehend the evolution of the processes that rule C dynamic

(sulfidization and gleyzation). In the Guapimirim Environmental Protection Area (state of RJ), four sectors of mangrove forest with different replanting stage (recently re-planted - NV; 3 and 7 years replanted; and established mangrove - V) were sampled for solid-phase Fe partitioning. Additionally, were measured redox potential (Eh) and pH for soil characterization. Higher Eh values were recorded for the established mangrove (average: 180±197 mV), while lowest values were in the recently planted mangrove (+5±25 mV), whereas the pH values were circumneutral (average: 7.3±0.3 and 7.2±0.2 for NV and V). With regard to Fe dynamic, a higher degree of Fe pyritization (DOP), which indicates the intensity of sulfidization, was recorded the older forest (average: 59.2±21.2 %) compared to NV (average: 34.9±27.5 %). Additionally, at the older replanted mangroves (7 and V), higher pseudo-total Fe content were recorded (average for both sites: 1259.2±477.8 mmol kg^{-1}) compared to NV (average: 607.3±405.1 mmol kg^{-1}) indicating mangroves replanting may affect Fe dynamic to coastal waters. In mangrove restoration practices, the soil characteristics are influenced by age of replanted forest since the recovery of the vegetation affects microbial metabolism favoring less energetic metabolic pathways (e.g., sulfate reduction and sulfidization) thus improving C sequestration. The results of this project are expected provide a basis for funding policies to mangrove restoration projects.

(9660 - 2029) Microscopic Mechanisms of Lead Retention on Thermoacidophilic Cyanidiales

Yen-Lin Cho[1]; Pin-Chen Chen[2]; Shao-Lun Liu[2]; Yu-Ting Liu[1]
National Chung Hsing University[1]; Tunghai University[2]

Thermoacidophilic Cyanidiales (red microalgae) are mainly distributed in volcanic areas and capable to survive in extreme environments with wide temperature and pH ranges (25-56℃; pH 0.2-5.0). In this study, the tested Cyanidiales including *Galdieria maxima* (Gm), *Cyanidium caldarium* (Cc) and *Cyanidioschyzon merolae* (Cm) were isolated from the beudantite collected in the Thermal Valley in Taiwan. Due to the tolerance for the concentrated Pb and As, Cyanidiales are suggested as potential materials for heavy metal remediation, especially in the acidic wastewater and soils. Accordingly, we aimed to determine the mechanisms for Pb accumulation on Cyanidiales in terms of sorption capacity, changes of functional groups with algae, and speciation of sorbed Pb. The combination of sorption isotherms and analyses using synchrotron-based spectroscopic techniques including X-ray photoelectron spectroscopy (XPS), X-ray diffraction (XRD), Fourier transform infrared (FTIR), and Pb L_{III}-edge X-ray absorption spectroscopy (XAS) was performed. Results of Pb sorption isotherms showed that the sorption capacity on red algae was in the sequence of Cc (299.36 mg g^{-1}) > Cm (214.04 mg g^{-1}) > Gm (38.20 mg g^{-1}). Possible retention mechanisms of Pb on Cyanidiales are (1) Pb bound with surface functional groups of the algae; (2) Pb complexed with proteins of the algae, and (3) Pb precipitated on the surfaces of the algae. Our collective results indicated that while all three mechanisms controlled Pb retention on Gm and Cm, Pb sorption on Cc was dominated mainly by the formation of organic complexation. The knowledge provided here could improve the application of the Cyanidiales in environmental remediation as an innovative green technology.

Keywords: Cyanidiales, Pb, Sorption, FTIR, XAS.

(4837 - 864) Modelling the potential mobility of heavy metals in red soil in Southern China

Mingxia Wang[1]; Wenfeng Tan[1]; Juan Xiong[1]; Fan Liu[1]
Huazhong Agricultural University[1]

The pollution of heavy metals in soil has become a normalcy of soil in China due to sewage irrigation, heavy metal atmospheric sedimentation, pesticide fertilizer use and industrial sludge and municipal solid waste composting and other human producing activities. The bioavailability and toxicity of heavy metals in soil are not only related to the total amount, but more to the species of heavy metals in soil. The Multi-surface model was used to predict the labile heavy metals and their speciations in the soil. The model considered complexation in solution and interactions with soil organic matter (SOM), a clay mineral and hydrous Al, Fe and Mn oxides. The amounts of reactive metals were derived from extraction with 0.43M HNO_3, and the concentration of free heavy metals in the soil which was measured by Donnan Membrane Technique (DMT) for testing the accuracy of prediction. The prediction results of the Multi-surface model using default parameters were consistent with the actual measured values of free Zn, Cu and Cd in the soil solution, while the predicted value of free Pb was much different from the measured value. By the model optimization, several heavy metal forms in the red soil were well predicted. The predicting results of Multi-surface model showed that the SOM and crystalline iron oxides in the soil played the important role for adsorbing Zn, Cu and Cd, while the content of manganese oxide in soil had a great influence on the adsorption of Pb. The fraction of reactive metals, which were interacted with dissolved SOM according to the modelling, was predominantly < 4% for Pb and Cu, < 0.4% for Zn, and < 14% for Cd. We suggest further quantitative and qualitative investigations on the Multi-surface model to the soils with high iron content in southern China to improve the prediction of the potential mobility of heavy metals.

Keywords: Red soil; heavy metals; SOM; iron oxides; Multi-surface model.

(3683 - 1515) Nitrogen availability to corn as a result of long-term use of organic sources and mineral nutrients

Carina Marchezan[1]; Carlos Alberto Ceretta[1]; Gustavo Brunetto[1]; Paulo Ademar Avelar Ferreira[1]; Cledimar Rogério Lourenzi[2]; Ricardo Fagan Vidal[1]; Rodrigo Krammes[1]; Daniela Basso Facco[1]; Rodrigo Knevitz Hammerschmitt[1]; Yohana Porto Calegari Alves[1]
Universidade Federal de Santa Maria[1]; Universidade federal de Santa Catarina[2]

Animal manures are frequently utilized in agriculture as a source of nutrients, especially nitrogen (N). In the long-term, successive and continuing additions of organic residues augment the content of N mineralization in the soil. However, the composition of these residues is a determining factor upon N release to the soil and its availability to the plants. The present study aimed at quantifying the N content in soil solution during the cultivation of corn in areas fertilized with organic and mineral nutrient sources. The study was conducted from a long-lasting experiment established in 2004 in the experimental area of the UFSM Soil Department. The experiment was set in a randomized block design with 4 replications and plots measuring 25 m^2 (5 by 5 m). The treatments were: Control, chemical fertilization (NPK), pig slurry manure (PSM), liquid cattle manure (LCM) and swine deep bedding (SDB). The soil solution extraction was done *in situ* with the help of porous capsules, installed at 10 cm in depth. The collections of soil solution were conducted 16h after raining or irrigating, in periods before and after manure application at 20, 45 e 80 days after corn emergence (DAE). In the soil solution was determined the content of ammonium (NH_4^+) and nitrate (NO_3^-). The

content of NO_3^- in solution was higher than NH_4^+ in all treatments. The higher NO_3^- availability occurred at 20 DAE and decreased according to the plant growth, reaching values of approximately zero at the flowering period. At 20 DAE, the treatments LCM, PSM, and NPK presented 41, 55, and 57 $mg.l^{-1}$ of NO_3^-, while the treatments Control and CSS presented 21 and 9 $mg.l^{-1}$, respectively, on the same date. The low content of NH_4^+ in solution can be explained by the elevated soil solution pH, which was above 6.3 in all treatments, result from the background animal manure applications. Long periods of application of organic residues increased considerably the content of labile organic matter in the soil. This easy-to-decompose material stimulates the multiplication of heterotrophic microorganisms that consume rapidly NH_4^+ present in the soil and in the animal manure, producing more NO_3^- at the expense of NH_4^+. This phenomenon is more pronounced in residues with high C/N ratios. Application of organic sources, especially LCM and PSM, promote higher availability of N in the soil at the initial crop stage. SDB immobilized N present in the soil solution, resulting in its decreased availability to the plants.

(3716 - 2222) Nitrogen isoscapes along a climatic gradient in Alisols in the Northeastern Brazil

Fabio Luis de Souza Santos[1]; Vinicius Vasconcelos[2]; Gabriela Bielefeld Nardoto[2]; Antonio Felipe Couto Junior[2]; Kennedy Nascimento de Jesus[3]; Everardo Sampaio[3]; Jean Pierre Ometto[4]; Rômulo Simões Cezar Menezes[3]
Universidade de Brasília, Campus Universitário Darcy Ribeiro, Asa Norte, Brasília-DF, Brasil (fabio.luis92@gmail.com)[1]; Universidade de Brasília, Campus Universitário Darcy Ribeiro, Asa Norte, Brasília-DF, Brasil[2]; Universidade Federal do Pernambuco, Av. Prof. Moraes Rego, 1235, Cidade Universitária, Recife-PE, Brasil[3]; Instituto Nacional de Pesquisas Espaciais, Avenida dos Astronautas, 1758 Jardim da Granja, São José dos Campos-SP, Brasil[4]

The climate regime is one of the main factors for the formation of ecosystems and regulates their structure and functioning. Temperature and precipitation affect the natural abundance of stable nitrogen isotopes ($\delta^{15}N$). Soil $\delta^{15}N$ across climate gradients provide key insights into organic matter dynamics in the ecosystems, since it can indicate rates of mineralization, decomposition, fixation of nitrogen and losses for atmosphere. The Brazilian northeast region has a single climate regime that reflects the existence of different physiographic regions. In this context, the objective of this work was to evaluate the $\delta^{15}N$ in Alisols of natural forest (Atlantic Forest and Caatinga) along a climatic gradient in the Brazilian northeast. With these values nitrogen isoscapes for the region were produced using multiple regression equations. Soil samples were collected in the 0-10 and 10-20 cm depth along the gradient, which has moist areas - Zona da Mata (ZM), subhumid areas (AG) and semi-arid areas - *Sertão Leste* (SL) and *Sertão Oeste* (SO). Three replicates were collected in each area. The samples were sieved with a 2mm mesh, milled, and analyzed for $\delta^{15}N$ and the concentrations of N through a mass spectrometer for isotopic ratios coupled to the elemental analyzer. The nitrogen isoscapes presented a $\delta^{15}N$ spatial pattern that is similar to the climatic boundaries. The highest %N in native forest was found in areas with highest average precipitation. Soil $\delta^{15}N$ were inversely related to soil %N and was also inversely related to the precipitation. Therefore, the semi-arid areas had higher values than the humid and subhumid areas. Higher temperatures associated with intense precipitation events might lead to higher soil $\delta^{15}N$ due to the intense N isotope fractionation. This variation of soil $\delta^{15}N$ along the climatic gradient indicates differences in nitrogen dynamics in each mesoregion.

(4146 - 572) Plant growth and plant nitrogen uptake effects on isotopic composition of nitrate leached from pasture systems.

Sephrah Rayner[1]; Timothy Clough[1]; Troy Baisden[2]
Lincoln University[1]; Waikato University[2]

Worldwide there is increasing awareness of the potential risks that pasture grazing systems pose to freshwater, including faecal contamination and enhanced nutrient loadings. Excess nutrient levels, predominately nitrate (NO_3^-), result in a reduction in water quality for recreation, aquifer contamination and reduced drinking water quality, which are costly to mitigate. Attenuation of NO_3^- before it reaches freshwater is a potential management tool in these systems. Dual NO_3^- isotopes signatures ($\delta^{15}N\text{-}NO_3^-$ and $\delta\ ^{18}O\text{-}NO_3^-$) can be used to quantify NO_3^- attenuation, and apparent isotope fractionation factors to differentiate processes such as denitrification and plant/microbial uptake. However, the role that plant growth and associated N uptake plays in the isotopic composition of the NO_3^- from pasture systems is still not fully understood. This study focused on how the presence of plants influenced both the amount of NO_3^- leached from a pastural system and its isotopic signature. Using intact soil columns, the effect of the presence or absence of perennial ryegrass (Lolium perenne L.) under varying rates of bovine urine addition was examined. Drainage volumes, dual NO_3^- isotopes, inorganic N (NH_4^+ and NO_3^-) and dissolved organic C (DOC) were monitored over a 10-month period. Under bovine urine the presence of perennial ryegrass reduced the cumulative leaching of NO_3^-, with the rate of bovine urine significantly affecting the concentration of NO_3^- in drainage. Results for the $\delta^{15}N\text{-}NO_3^-$ and $\delta\ ^{18}O\text{-}NO_3^-$ values under the various treatments will be presented and the implications discussed. This research will help to enable the key effects of plant growth and N uptake, which potentially influence temporal and spatial change in NO_3^- isotopic signatures, to be linked to NO_3^- attenuation models within the landscape. The use of dual NO_3^- isotopes allows the quantification of N attenuation in the landscape and primary N source identification, which can provide a tool for farm management and policy to reduce nutrient loading and retain nutrients on farm.

(7553 - 2947) Podzolization processes of Yellow Latosols of tablelands conditioned by neotectonism

Claudia Csekö Nolasco de Carvalho[1]; Fábio de Carvalho Nunes[2]
Universidade Estadual de Alagoas[1]; Instituto Federal de Educação, Ciência e Tecnologia Baiano[2]

The process of transformation of the Yellow Latosoil - Spodosoils with high contents of organic matter were the subject of this study. They developed on the Barreiras Group sediments, in a Recôncavo Baiano tablelandstop located in Santo Amaro county, Brazil of. The starting

point was the toposequencial soils analysis which were characterized regarding the morphology, micromorphology and physical, chemical and mineralogical attributes. The pedological system is complex, showing depressions related to faults and/or fractures crossing that indicate the neotectonism how started process of transformation. The relationships between the oxic and the hidromorphic domain point to Latosoil transformations linked to conditions of cyclic hydric saturation and to the action of organic composites of low molecular weight. The high contents of organic matter accumulated by reduction of mineralization under acids conditions and temporary anaerobiose propitiate the evolution of humus with the formation of mobile organic composites and acids which act on the transformation of the Latosol, through the installation of processes of podzolisation with partial acidolysis, acting from downstream to upstream in the versant. On the pedogeochemical aspect the destruction of primary minerals and the disorganization of the secondaries, indicate a route predominantly organic in the transformation, process, under the influence of reducing environments.

(3890 - 1012) Rare-earth-element geochemistry in soils developed in different geological settings of Cuba

Ygor Jacques Agra Bezerra da Silva[1]; Clístenes Williams Araújo do Nascimento[1]; Caroline Miranda Biondi[1]; Yuri Jacques Agra Bezerra da Silva[2]; Adriana Maria de Aguiar Accioly[3]; Mirelys Rodríguez Alfaro[4]; Alfredo Montero[4]; Olegario Muniz Ugarte[5]; Juan Estevez[4]
UFRPE[1]; UFPI[2]; EMBRAPA[3]; Instituto de Suelos MINAG[4]; CEADEN[5]

The increased exploitation of rare-earth elements (REEs) over the past few decades and the disposal of various products containing these elements have prompted numerous environmental studies and the need to establish regulatory guidelines. We determined the concentration of REEs in topsoil samples of 33 soil profiles collected from areas of different geological settings in Cuba. The average REE concentrations revealed the following chemical abundances in decreasing order: Ce > Nd > La > Pr > Sm > Er > Yb > Dy > Tb > Lu > Ho > Gd > Eu > Tm. The significant variation in REE levels reflects the geological diversity of Cuba. The highest REE concentrations were observed in Typic Rhodudalf and Rhodic Eutrodox, which are derived from hard limestone. In contrast, the lowest REE concentrations were detected in the Typic Kandiustalf, which originated from mica schist. The lower light REE (LREE) contents in Cuban soils compared with soils from other countries is related to the low abundance of felsic rocks on the island. We also observed a strong positive correlation between REEs and some major elements in soils. This finding implies that the distribution of REEs in soils is partly governed by phosphates and aluminosilicates. The low fractionation between LREEs and heavy REEs is likely related to the predominance of soils developed from carbonates. This finding was also supported by the low LaN/SmN and GdN/YbN ratios and principal component analysis. The spatial distribution of REEs normalized to Upper Continental Crust coupled with univariate and multivariate statistical techniques indicated that parent materials control the prevalence of REEs in Cuban soils. The data presented here represent the first national-wide survey of REEs in Cuban soils.

(4975 - 1620) Relationship between the content of steviol glycosides in *Stevia rebaudiana* Bert., and edaphologic offer of five regions of Colombia

Enrique Combatt Caballero[1]; Jaime Hernández Burgos[2]; Alfredo Jarma Orozco[1]
Universidad de Córdoba, Colombia[1]; Universidad Nacional Abierta y a Distancia[2]

In Colombia for determine the effect of the nutritional status of the soil and the leaves of Stevia rebaudiana Bert on the concentration of the main steviol glycosides. Were established Investigations in five locations: Montería-Córdoba; Campamento-Antioquia; Palmira-Valle del Cauca; Fonseca-Guajira y Valledupar-Cesar. In each locality two levels of radiation were used, at 100 and 50% of the incident radiation, to evaluate the growth of the crop under the offer of radiation and edaphic conditions. In each locality two levels of radiation were used, at 100 and 50% of the incident radiation, to evaluate the growth of the crop under the offer of radiation and edaphic conditions. A randomized complete block design was carried out in each of the localities. In each locality and level of radiation, five plants and three soil samples of 0 to 20 cm were collected; with the objective of determine the relationship between the nutritional contents in leaves and soil of the following essential and nutritional elements: N, P, S, Ca, Mg, K, Na, Cu, Fe, Zn, Mn and B. In addition, the contents of rebaudioside A and stevioside contained in the leaf. The data were analyzed by analysis of variance combined, for the contents of total glycosides (GT) and the foliar contents of the different nutrients. Also, were analyzed the correlation, between foliar contents and nutrient soil contents and finally multiple linear regression analysis of the foliar contents with the contents of GT, RebA and Stv. The results indicated that the cultivation of stevia tends to adjust the assimilation of nutrients such as N, Ca, Na, Mn and B, the according with environmental and soil factors, different of the radiation and nutrient content in the soil. Likewise the linear regression determined the following models: GT= 63.64N**+13.83S°°+10.72Ca*-26.97Mg*-1,37K*+0.28Zn*+0.08Mn°°+0.75**; RebA=56.24N**+6.55Ca°°-17.42Mg°+0.39Zn**+0.79B°°-0.01Fe°°; Stv=1.11P°+0.66Ca°+0.71B**. The participation of all the elements in the models of the evaluated variables indicates that Stevia needs complete nutrition, to achieve good yields and leaf quality, adjusting the nutrient doses according to the environmental conditions and edaphic of each locality.

(2575 - 2213) Removal of HCH from aqueous solutions and soils using plants and manure derived-biochars

Diego Aran[1]; María Balseiro-Romero[1]; Juan Antelo[1]; Sarah Fiol[2]; Felipe Macías[3]
Instituto de Investigaciones Tecnológicas. University of Santiago de Compostela[1]; Department of Physical Chemistry, University of Santiago de Compostela[2]; Department of Soil Science and Agricultural Chemistry, University of Santiago de Compostela[3]

The application of pesticides in agriculture activities, although it has benefits, it can be considered a source of contamination for the environment. The organochlorine pesticides are resistant to biodegradation, they can be easily bioaccumulated in the food chain, and are stable in water for many years (Shukla et al., 2006). The main mechanism for the removal of pesticides in water and soil systems is adsorption on different materials. Among them, biochar is a promising and economical alternative. The different isomeric forms of hexachlorocyclohexane (HCH) (α-HCH, β-HCH, γ-HCH and δ-HCH) were employed to evaluate the adsorption capacity of three biochars. These biochars were obtained from *Miscanthus*, Corn Cob and Chicken manure and showed different physical-chemical properties. Batch adsorption experiments were conducted with biochar suspensions prepared in a solution of $CaCl_2$ and NaN_3 (5mM). The HCH concentrations used varied between 0 and 10 mg L^{-1}. Additionally, the effect of biochar amendments (0-50% in weight) was studied in soil samples collected from a HCH-contaminated area. For each treatment, the contaminated soil was mixed with different

amounts of biochar in a solution with $CaCl_2$ and NaN_3 5mM. The free concentration of HCH isomers present in the solution was determined by gas chromatography coupled to tandem mass spectrometry (GC/MSMS). The experimental results demonstrate that those biochars showing a major carbon content and superficial area have a larger adsorption capacity. These organic contaminants showed a multilayer adsorption behaviour and the experimental data can be described using empirical models. The use of these materials can be considered a good option for remediation of soils and waters contaminated by HCH. Moreover, the results of the biochar amendment experiments showed that manure biochar can reduce in about 50% the amount of HCH in the soil solution, while plant biochar reduced more than 70%.

In order to minimize the problems of applying too much nitrogen, alternatives have been researched, such as the better use of the benefits provided by the association between diazotrophic bacteria which perform the enzymatic conversion of gaseous nitrogen to ammonia. In addition to that, in order to benefit crop performance there are nutrients as well as silicon which, while not considered essential to plants, are responsible for increasing their resistance to pests, diseases, as well as to various types of abiotic stresses. For this purpose, calcium silicate fertilization and inoculation of seeds with diazotrophic bacteria showed a significant increase in a short period of time. In the light of this, the aim of this work was to evaluate the residual effect of different doses of the fertilization with calcium and magnesium silicate and inoculation on the initial performance of seedlings through the evaluation of agronomic characteristics. The experimental design was a randomized block design, in a 5 × 2 factorial scheme, being the first factor the use of five concentrations of calcium silicate and magnesium: 0,0; 1.0; 2.0; 4.0 and 6.0 t ha^{-1} applied before maize cultivation in a previous experiment. The second factor was the absence and presence of seeds inoculated with *Azospirillum brasilense*, with four replications, totaling 40 plots. The soil used was classified as Eutroferric Red Latosol of clay texture, and after the corn cultivation it was carried out the sowing of wheat only with potassium and phosphate fertilization. For the SPAD index, it was observed the highest and lowest mean values of 39.3 and 32.5 in the treatment with residual and absence of inoculation. After 35 days, the height and stem diameter were analyzed, and subsequently the plants were collected to evaluate the dry matter. For the variable plant height, a significant effect was observed for the interaction between calcium silicate dose and inoculation. The residual effect of fertilization with calcium and magnesium silicate was higher at a dose of 6 t ha-1 with inoculant 39.81 cm. Regarding the diameter of the stalk, it was observed a difference in the presence of silicate and in the higher dose, but without the influence of the residual of the inoculation, being 2.47 and 2.34 mm. The same one observed for numbers of tillers, obtaining the highest average of tiller 3.68 per plant.

(5983 - 876) Response of stoichiometry Characteristics and microbial community to agricultural land use change around Taihu Lake Area in Southeast China

Yan Gao[1]; Yuhan Niu[1]; Weiguo Zhang[1]; Jiangye Li[1]

Institute of Agricultural Resources and Environment, Jiangsu Academy of Agricultural Sciences[1]

Agricultural land use is experiencing unprecedented changes around Taihu Lake Area, one of major grain producing areas in China before. More and more paddy field in this area has been converted to orchard due to farmer's pursuit of profit. Such changes and their associative management practices will alter biogeochemical function in ecosystems. Characterizing susceptibility of biogeochemical function to land use change is badly in needs of understanding the response of elemental stoichiometry, functional stoichiometry and microbial community to different land use. In order to achieve these objectives, we investigated the following parameters of soil from peach orchard and paddy filed: 1) bacteria and fungi abundance and their ratio; 2) bacterial and fungal community composition; 3) elementary stoichiometry, e.g. C/N, C/P, N/P; 4) eco-enzymatic stoichiometry. The results showed that paddy soil had obvious higher mean and average values of C/N, C/P and N/P than Orchard soil. The C/N, C/P and N/P ratios of paddy soil in rice-growing season were consistently higher than that in maize-growing season. The similar changing patterns of elemental stoichiometry were also observed in orchard soil between two different seasons. The mean and average values of C-demand/P-demand enzyme and C-demand/P-demand enzyme of paddy and orchard soil in rice-growing season were consistently higher than that in maize-growing season, which was consistent with the changes of soil C/P and N/P. Paddy soil presented much higher mean and average values of 16SrDNA but lower fungal ITS abundance when compared to orchard soil, resulting in obviously lower fungi/bacteria (F/B) ratio in paddy soil. Land use conversion from paddy field to orchard led to gradual reduction of bacterial and fungal community diversity, especially after 20 years of conversion. The class *Nitrospira* that plays a critical role in the nitrogen cycle had much higher abundant in paddy soil than orchard soil, while *Sphingobacteriia* that plays critical role in cellulose degradation showed an opposite pattern. The soil chemical parameters had a stronger contribution to bacterial dissimilarities than physical parameters. The results provide some valuable information about how soil biogeochemical function in agricultural ecosystems will respond to land use conversion.

(8625 - 238) Soil redox processes coupled dechlorination of pentachlorophenol in flooded condition

Yan He[1]; Min Zhu[1]; Yan Xu[1]; Jianming Xu[1]

Zhejiang University[1]

Reductive dechlorination is the main way for transformation of chlorinated organic pollutants (COPs)under anaerobic conditions, which is basically an electron accepting process initiated by anaerobic respiration of dechlorinators. In flooded soils, there are also many co-occurred natural redox processes that consume electrons, such as Fe(III)/SO_4^{2-} reduction, and methanogensis process. These processes can affect dechlorination through competition of the functional microbial groups that drive soil redox processes for the substrates and survive space with dechlorinators. To illustrate the interaction between COPs dechlorination and soil indigenous biogeochemical redox processes, we conducted a flooded soil incubation experiments, with pentachlorophenol (PCP) that has been used worldwide as insecticide, herbicide and wood preservatives selected as the model

COPs. Dynamics in PCP dechlorination and the main redox couples (such as Fe(III)/Fe(II), SO_4^{2-}/HS^-, CO_2/CH_4) during dechlorination were simultaneous analyzed. The results showed that the dechlorination of PCP was synergistically coupled with Fe(III) reduction and methanogenesis, but competitively coupled with SO_4^{2-} reduction. Meanwhile, biochar showed interesting effect on the coupling between PCP dechlorination and soil redox processes. Dechlorination of PCP wasinhibited, while Fe(III)/SO_4^{2-} reduction were significantly enhanced following biochar addition; the production of methane were also accelerated. Q-PCR, Illumina sequencing and DNA-SIP for analysis of soil bacteria and archaea responses revealed that this might be mediated by the functional microbial groups (including dechlorinators, ferric and sulfate reducers, and methanogens) that responded sensitively but contrastingly to the pollution of PCP and the addition of biochar. Specific function of biochar as electron shuttle was also likely the other mechanism involved, through splitting the limited electrons from the inferior electron acceptors (PCP) to the dominant more competitive ones (Fe(III) and SO_4^{2-}) during anaerobic respiration of the functional microbial groups, under an electron limiting condition. The results of this study would lead to a synthetical understanding regarding biochar's function and provide improved strategy for optimizing the remediation of natural flooded soil polluted by reducible COPs.

(2930 - 190) Sorption kinetics, isotherm and mechanisms of PFOS on soils with different physicochemical properties

Changlong Wei[1]; Xin Song[1]; Qing Wang[1]; Zhihao Hu[2]
Institute of Soil Science, Chinese Academy of Sciences[1]; Nanjing University[2]

Perfluorooctane sulfonate (PFOS), an emerging contaminant, is environmentally persistent, bioaccumulative and toxic to human health and ecosystems. It has been widely detected in groundwater, surface water, soil and sediment. So far, very few research has reported on the PFOS sorption behaviors onto soils, one of the primary processes that influence its fate and transport in the subsurface. In this study, the sorption and desorption of PFOS onto six soils with different physicochemical properties were investigated. Kinetic and equilibrium studies of PFOS sorption onto six soils were carried out in batch experiment. The sorption kinetics of PFOS on the six soils demonstrated that PFOS sorption reached equilibrium within 48 h, and the well-fitted pseudo-second-order kinetic model to experimental data suggested that chemisorption was involved in PFOS sorption on soils. The intraparticle diffusion model results indicated that both film diffusion and intraparticle diffusion were the rate-limiting steps for five of the six soil samples, while the intraparticle diffusion was the only limiting step in the PFOS sorption on the sixth soil. PFOS sorption isotherms can be described by the Freundlich model well for all six soils (R^2=0.979-0.999). The correlation analysis between K_F of PFOS and the physicochemical properties of the soils showed that a positive correlation between K_F and Al_2O_3, SOC and Fe_2O_3. The FTIR data demonstrated hydrophobic interaction, ion exchange, surface complexing and hydrogen bonding might all play a role in the PFOS sorption onto soil samples. PFOS sorption onto soil minerals, especially iron oxide minerals, needs to be further explored in future.

Keywords: Perfluorooctane sulfonate; Soil; Sorption behavior; Intraparticle diffusion; LC-MS/MS

(2036 - 1491) The effect of humic substances on the trace elements toxicity

L.V. Perelomov[1]; K.B. Chilachava[1]; A.Y. Shvikin[1]; Y.M. Atroshchenko[1]
Tula State Lev Tolstoy Pedagogical University[1]

The introduction of trace elements in the environment can produce considerable harmful impact on microbial communities and their activities. Numerous studies have shown that humic substances (HS) and their fractions are capable of altering both the chemical and physical speciation of trace elements and affecting their bioavailability and toxicity. In the present study we investigated the effect of humic substances and their fractions - humic acids (HA) and hymatomelanic acids (HMA) on the toxicity of Pb and Zn towards different strains of environmentally important bacteria. Sample of mesotrophic sphagnum peat was collected from the small sphagnum bog situated in Tula region, Russia. HS were isolated using alkaline extraction procedure as described by Stevenson (1994). For the preparation of the HA fraction, concentrated HCl was added to the solution of HS to adjust the pH to pH 1. The HMA fraction of the HS was obtained by ethanol extraction. Gram negative natural rhizobacterium *Pseudomonas chlororaphis* PCL1391, Gram negative bacterium *Pseudomonas fluorescens* 142NF (pNF142) and Gram positive soil bacterium *Rhodococsus* RS67 were used in the experiment. Minimum inhibitory concentrations (levels of bacterial resistance) of Zn and Pb (as their nitrate salts) and minimum inhibitory concentrations in the presence of HS and fractions were determined in a modified mineral Duxbury medium (Duxbury, 1981) by a method described Podolskaya et al. (2002). Our results showed that all the three strains had a low resistance to Zn (0.1 - 0.3 mM) and a slightly higher resistance to Pb (0.3 - 0.5 mM). The highest resistance to Pb was characteristic of *Pseudomonas chlororaphis* PCL1391 and *Rhodococcus* RS67, while *Pseudomonas chlororaphis* PCL1391 showed the greatest resistance to Zn. The combined fraction of HS and HA alone reduced Zn and Pb toxicity at all added concentrations of the organic substances (50 – 200 mg L^{-1}) to all microorganisms. On the other hand, the addition of HMA showed a significant increase in the resistance of *Pseudomonas chlororaphis* PCL1391 to Zn and all the three studied microorganisms to Pb only at the maximum concentration of organic matter (200 mg L^{-1}). Thus, under certain conditions, trace elements ion toxicity might be reduced through complexation with humic substances and their fractions. This is particularly true when the metal-organic complexes hold high stability and low solubility.

(5075 - 2240) Volatilization of n-fertilizer on sandy soil cultivated with sugarcane

Robson Hortêncio de Lima[1]; Ariane Márcia de Sousa Silva[1]; Emídio Cantídio almeida de Oliveira[1]
Universidade Federal Rural de Pernambuco UFRPE[1]

On soil the loss of nitrogen in the form of ammonium by volatilization is dependent on its pH, by the tamping power, and interactions with the environmental temperature, how fertilizer is used, nitrogenous source used, soil texture, humidity and C/N relation. The objective is to quantify and compare the losses of N by volatilization of ammonium in two sources of nitrogenous fertilizers under the management of parcels or complementary fertilization. The

experiment was carried out in an experimental field on the coastal table of Paraíba in Rio Tinto, $6^0$50`35.8"S and $34^0$57`03.2"W, with a variety of RB92579. The experimental parcels were four double lines of ratoon sugarcane with a space of 1.4 m, distributed in causalized blocks, 11 treatments with four repetitions summing 44 experimental parcels. The treatments were nitrogenous fertilization from two sources, nitrate of ammonium (NA) and sulphate of ammonium (SA) and parcels, 100% and 50% of the dose and complement after 60 days of plus 30%, 50% 0r 70%. The treatments were: T1 control zero of N; T2 80 Kg.ha^{-1} of NA; T3 40 Kg.ha^{-1} NA plus 40 Kg.ha^{-1} for complementing; T4 80 Kg.ha^{-1} of NA plus 24 Kg.ha^{-1}; T5 80 Kg.ha^{-1} of NA plus 40 Kg.ha^{-1}; T6 80 Kg.ha^{-1} of NA plus 56 Kg.ha^{-1}; T7 80 Kg.ha^{-1} of SA; T8 with 40 Kg.ha^{-1} of SA plus 40 Kg.ha^{-1}; T9 80 Kg.ha^{-1} of SA plus 24 Kg.ha^{-1}; T10 80 Kg.ha^{-1} of SA plus 40 Kg.ha^{-1}; T11 80 Kg.ha^{-1} of SA plus 56 Kg.ha^{-1}. The ammonium volatilized was caught by 8 cm^2 sponges and volume of 16 cm^3 wet with a solution of phosphoric acid 0,01N wrapped in film PTFE on PVC supports 1cm over the soil surface through the line of fertilization. At laboratory the sponges were washed with deionized water in a Bückner funnel in the vacum, it was taken na alíquota quantitiy of 50 ml and made its distillation (Kjeldahl method) with 15 ml of NaOH 10 mol/L and caught in a solution indicating boric acid at 5% in the output of the distiller. For the determination the output is titrated with HCL 0,02N. Comparing the curve peaks of ammonium volatilization with the pluviosity data it was seen a direct relation in volatilization of both sources NA and SA. After rainy days and drainage of the water excess, the soil was found in reducing conditions and humidity almost the capacity for field, favoring then the microbian activity in the transformations of Nitrogen. The SA was the one which best volitilized N-Fertilizer for getting a reducing means after a heavy rainfall which reduced part of the NA.

(8093 - 2239) Weathering rates in soils originated from I- and S-type granites across a climosequence of Brazil

Rayanna Jacques Agra Bezerra da Silva[1]; Clístenes Williams Araújo do Nascimento[1]; Ygor Jacques Agra Bezerra da Silva[1]; Caroline Miranda Biondi[1]; Peter van Straaten[1]; Valdomiro Severino de Souza Jr.[1]; Tiago Osório Ferreira[1]; Yuri Jacques Agra Bezerra da Silva[1]; Franklone Lima da Silva[1]
UFRPE[1]

I- and S-type granites comprise large areas and play a key role in global soil weathering patterns. I-type granites are originated from melting of igneous source rocks, whereas S-type granites result from melting of sedimentar sources. The objective of this study was to address the effect of petrology and mineralogy of I- and S-type granites on weathering rates across a climosequence. The study area lies in the Borborema Province (Pernambuco State), northeastern Brazil. Three soil profiles and the underlying rocks (from both I- and S-type granites) were sampled under native vegetation in the three climatic zones. The results of the major elements (expressed as oxides) were used to calculate the chemical index of alteration (CIA), according to the equation: CIA = [Al_2O_3 / (Al_2O_3 + Na_2O + CaO + K_2O)] × 100. The degree of weathering of soils originating from I- and S-type granites varied systematically in the different climatic zones. Overall, the weathering intensity decreased in the following order: humid zone > sub-humid zone > dry zone. The CIA values in humid zones were higher than 90%. In the sub-humid zone, the mean CIA values were 75% and 81% for soils derived from I- and S-type granites, respectively. The lowest CIA values were found in the dry zone, with mean values of 73% and 61% for soils derived from I- and S-type granites, respectively. The climate effect was clearly expressed on the soil properties regardless the parent material, i.e., soils from the humid zones were subjected to more intensive weathering (mean CIA values of 95%). The higher clay contents (15–31% and 20–25%, for I- and S-types, respectively), higher chroma colors in subsurface horizons (yellowish in S-type and reddish in I-type), lower BS, lower pH values and higher Al saturation percentages also indicate the more intensive weathering process. Our data highlight the importance of the mineralogy and chemistry of granite types in order to understand the relationship between weathering rates and climate conditions.

C2.5.2 - Advances in techniques to investigate soil interfaces to understand interfacial reactions

(2952 - 939) An assessment of near infrared (NIR) spectroscopy for soil organic matter prediction comparing different pre-processing and multivariate calibration techniques in Southern Brazil

Jacques Krticka Carvalho[1]; Tales Tiecher[1]
Federal University of Rio Grande do Sul[1]

The estimation of soil organic matter (SOM) by near infrared (NIR) spectroscopy is a fast and cost-effective alternative to conventional chemical analysis. However, the accuracy of this method is highly affected by the use of proper pre-processing technics and calibration methods. Moreover, these models are highly site-specific indicating a need to develop specific calibration for each region. This study aimed to evaluate the effect of different pre-processing techniques and calibration methods on SOM prediction by NIR spectroscopy. A total of 2388 soil samples from the north of Rio Grande do Sul and east of Santa Catarina states, Brazil, were analyzed for SOM content by wet-digestion using Walkley-Black procedure and for reflectance using a NIR-spectrometer Unity Spectra Star 2400 (1200-2400 nm). The mean of SOM content of samples was 2.5%, ranging from 0.4% to 12.0%. The data set was randomly split in training (70%) and validation (30%) sets. Six pre-processing techniques were applied to the spectra including: Savitzki-Golay derivative (SGD), continuum removal (CR), detrend (DT), binning (BN), smoothing (SM), and standard normal variate (SNV). Multiple linear regression (MLR) and partial least squares regression (PLSR) were used to generate the models. The different combination of pre-processing and calibration methods were compared by the determination coefficient (R^2), ratio of the interquartile distance (RPIQ) and the root mean square error of prediction (RMSE). Results revealed that the best prediction was obtained by pre-processing data with SM coupled with PLSR (R^2 = 0.71, RMSE = 0.50, RPIQ = 2.03). Using PLSR, the worst prediction was found when combined with CR (R^2 = 0.53, RMSE = 0.53, RPIQ = 1.52). When PLSR model were used, only SNV (R^2 = 0.68), SMO (R^2 = 0.71), BN (R^2 = 0.66) and SGD (R^2 = 0.68) improved the prediction comparing with the use of original spectra (R^2 = 0.63). The PLSR models were more accurate for all pre-processing treatments when compared to MLR. DT pre-processing resulted in the best prediction between MLR models (R^2 = 0.62, RMSE = 0.23, RPIQ = 1.69), and the worst prediction was found when SGD pre-processing was applied (R^2 = 0.45). When compared to original data (R^2 = 0.57), only DT and BN improved the SOM prediction for MLR models. Results indicate that NIR spectroscopy is a good alternative to estimate SOM in subtropical Brazilian soils and could be improved with the use of appropriate pre-processing techniques.

(9767 - 1663) An optical approach to evaluate the effect of various salts on the sedimentation of clay-rich soil material

Andras Sebok[1]; Attila Nemes[2]; Imre Czinkota[1]; Viktoria Labancz[1]
Szent Istvan University, Hungary[1]; Norwegian Institute of Bioeconomy Research, Norway[2]

Eroded soil particles and free or attached nutrients travel distances from the source area, and may eventually end up in our surface waters and cause undesirable changes to the environment. To slow or prevent this, similarly to many other countries, a number of mitigation measures, such as e.g. sedimentation lakes, dams and wetlands were set up around Norway. This work was motivated by the assumption that coagulation of particles can yield larger effective particle-diameters. This may accelerate sedimentation, and help reduce the amount of material that is effectively lost from the vicinity of the source. Our specific aim was to inspect the effectiveness of various ions in enhancing coagulation and accelerating the process of sedimentation. We experimented with the re-sedimentation of a silty-clay-loam subsoil material of marine origin that was only physically disaggregated, retaining its chemical properties. We used several ions as coagulants to accelerate the sedimentation of this colloid-rich material. In a light and reflection controlled environment, we took high-resolution pictures of the sedimentation columns every 10 minutes over a span of 3 hours and analysed them using custom-developed image analysis software. The cations that we examined were Na^+, Ca^{2+}, Mg^{2+}, Fe^{2+}, and Al^{3+}, in 10, 20, 40 and 80 mg/L doses, and the anions were Cl^-, SO_4^{2-} and OH^- in the amount relevant for the cation doses. As our test material, 1 gram of recurrently ground and sieved soil was dissolved in 500 ml of distilled water. We established a number of metrics to compare the efficiency of ion groups and their concentration on sedimentation time, using e.g. the half-time of the background-adjusted colour of the mixed solutions, as a signal of sedimentation. We will introduce the theoretical background, present results and discuss potential practical implications of this process and knowledge towards sustainable landuse.

(8691 - 2318) Application of micronutrients and biostimulants in sugar cane in successive agricultural cycles

Bruno Bernardes de Souza[1]; André Cesar Vitti[2]; Thiago Antônio Basso do Prado[3]; Hélio do Prado[4]; Hélio Basso do Prado[1]
University of São Paulo[1]; Polo Southern Regional Center - APTA[2]; Federal University of São Carlos[3]; Polo Regional Center East[4]

The application of biostimulants and micronutrients on the sugar cane can support the crops. The purpose of this work was evaluated the technological quality and the productivity of stem with addition of different combinations of organo-mineral fertilizers and micronutrients. The chemistry characteristics evaluated in the soils in the depths of 0-20 / 20-40 cm. was: pH - 5,4 / 5,0; P(res) – 19 / 7, S-SO_4^{2} – 8 / 10, B – 0,14 / 0,15, Cu – 0,3 / 0,3; Fe – 27 / 15, Mn – 7,4/7,0, Zn – 3,8 / 1,4 (mg dm^{-3}); M.O. – 11 / 8, (g dm^{-3}); K^+ - 0,9 / 0,6, Ca^{2+} - 34 / 14, Mg^{2+} - 14 / 5, Al^{3+} - 0 / 0, H+Al^{3+} - 13 / 17, SB – 48,9 / 19,6; CTC – 61,5 / 36,7 ($mmol_c$ dm^{-3}); V – 80 / 53 ; m – 0 / 0 (%); total sand – 726 / 712, clay – 178 / 207, silt – 96 / 81 (g Kg^{-1}); textural classification – medium/medium. The experiment was randomized complete blocks design with 10 treatments and 4 replications, size of each parcel was 75 m^2, composed of 5 lines of cane of 10m each one and spaced 1,5m between rows. The basic fertilization was 600 Kg/ha of the formulated 5-25-20, for all the treatments. The application was realized with costal pulverizer at the equivalent dose 150 L^{-1} of volume solution, for the next treatments: T1/T2 – Control, T3/T4 – 1L/ha Biostimulants + 3 Kg/ha Micronutrients; T5/T6 – 2L/ha Biostimulants + 5 Kg/ha Micronutrients; T7/T8 – Standard (Sugar cane Mill); T9/T10 – 1L/ha Biostimulants + 10L/ha Micronutrients. Biostimulants has as characterization 14, 6, 3, 2, 5 % of organic carbon, Alfa-L free aminoacids, molybdenum water soluble and polysaccharides respectively; micronutrients has as characterization 3,5 , 2,5 , 3, 20 , 12,5 % of boron, copper, manganese, zinc and sulphur water soluble respectively. The foliar applications in the odd treatments with the T3/T4 treatment and the harvest were performed on 04/12/2015 and 12/07/2016 in cane-plant, 28/11/2016 and 06/06/2017 in ratoon cane respectively. The variables were subjected to F test and the multiple comparisons between means by Tukey test at 10% of significance. The results conclude that in the cane-plant cycle the foliar responses were not so obvious in relation to ratoon cane, being verified only the difference of the T3 and T4 in relation to the control for stems productivity and the T5 and T6 to the technological quality. In the second successive agricultural cycle the foliar applications of all the treatments were higher in relation to control treatment. Is evident the importance of successive cycles.

(5986 - 201) Assessing the SiO_2, Al_2O_3, Fe_2O_3, P_2O_5 and TiO_2 contents in Brazilian soils via portable X-ray fluorescence equipment

Bruno Teixeira Ribeiro[1]; Nilton Curi[1]; Luiz Roberto Guimarães Guilherme[1]; Bárbara Tenório Simões[1]; Geila Santos Carvalho[1]; Sérgio Henrique Godinho Silva[1]
UFLA[1]

For Brazilian soils classification, mainly for Latosols (Oxisols), the determination of SiO_2, Al_2O_3 and Fe_2O_3 is required. Additionally, the P_2O_5 and TiO_2 are also commonly quantified for soil surveys. The conventional analysis is based on determination by colorimetric, gravimetric, and titration based methods or by using atomic absorption spectrometry (AAS) and inductively coupled plasma emission (ICP) after soil digestion using sulfuric acid. This analysis is completely non-environmentally-friendly, time-consuming and generates a great amount of pollutant residues. The portable X-ray fluorescence equipment (pXRF), still incipient in Brazil, can greatly contribute to soil characterization, in-field or in in-lab conditions. This work used pXRF for determination of SiO_2, Al_2O_3, Fe_2O_3, P_2O_5 and TiO_2 in 156 disturbed air-dried soil samples (< 2 mm). The soil samples were selected from a soil collection of Soil Science Department, Federal University of Lavras, Brazil. In all soil samples the P_2O_5 concentration was below the detection limit. A poor correlation was observed between SiO_2 and Al_2O_3 obtained by pXRF and the conventional analysis. However, an excellent correlation (R^2>0.98) was found for Fe_2O_3 and TiO_2. Others studies indicated that Fe_2O_3 determination by pXRF is not significantly influenced by soil moisture. This is interesting for determination directly in the field any time.

(9447 - 2321) Citrus root system preferably uses the macropore space to explore compacted soil

Thais Nascimento Meneses[1]; Luana Laís de Almeida dos Santos[1]; Mauricio Antônio Coelho Filho[2]

University of Recôncavo of Bahia[1]; Embrapa Cassava and Fruiots[2]

Artificial macropores are low resistance pores channels to plant rooting, allowing access to water and nutrients in compacted soils (Yellow Oxisoil Dystrocohesive). We investigated how artificial macropores (AM) and numbers of vertical distribution in column of compacted soil affect plant growth, root system distribution and gas exchange of citrus plant subjected to a continuous soil water extraction. Five treatments were evaluated in a completely randomized design experiment with five replications. A plant of 'Rangpur' lime (C. limonia Osbeck) per PVC tube with 0.15 m of external diameter and 0.5 m of length was the experimental unit. The entirely soil profile of the control treatment (Ctrl) was filled at density of 1.3 g cm-3. The following treatments the shallow profile (0 – 0.16 m) was filled with weak soil (1.3 g cm-3) and underlying (0.16 m to 0.5 m) filled with compacted soil (1,6 g cm-3): no macropores channels (Comp); one vertical macropore (1 mpc); two vertical macropores (2 mpc); three vertical macropores (3 mpc); and five vertical macropores (5 mpc). The artificial macropores (1 mm) builded with wire of stainless steel crossed the compacted profile. The images of root system revealed the preferential way to the macropores when plants were subjected to compacted soil. The macopores relief the effect of strong soils in relation to gas excange root architecture of young plants of 'Rangpur' lime.

(9159 - 1557) Computer vision technology applied to soil analysis by digital image analysis based on colour

Victor J. Palencia[1]; Manuel S. Palencia[2]; Alvaro A. Arrieta[3]

Mindtech Research Group (Mindtech-RG), Mindtech S.A.S, Cali, 25360, Colombia[1]; GI-CAT, Department of Chemistry, Universidad del Valle, Cali, 25360, Colombia[2]; Department of Biology and Chemistry, University of Sucre, Carrera Barrio Puerta Roja, Sincelejo, Colombia[3]

A digital image can be considered as a discrete representation of data possessing both spatial (layout) and intensity (colour) information. It is viewed as a two-dimensional matrix whose row and column indices identify a small square area of the image called a pixel. A colour space is a three-dimensional model describing the way colour can be represented typically as three numbers (i.e. RGB). In addition, a computer vision-based image analysis system is composed of a camera to acquire digital images, daylight fluorescent lamps to illuminate the object, and a personal computer to process the image data. For a reliable and reproducible analysis, it is important to create fixed conditions during image acquisition. The aim of this work was to develop and evaluate a quantitative parameter that allows the description of the colour intensity for different analytical application in soils. A measuring instrument was built by the Research Group in Science with Technological Applications of Universidad del Valle and Mindtech-RG of Mindtech s.a.s. The main components of the measuring instrument are: (a) An image capture device (Nikon Coolpix P530 digital camera model with a 42x optical zoom), (b) a cell sample holder (glass cell for spectrophotometry 45x12.5 x12.5 mm, 10 mm pitch., (c) a surface to set a background colour (aluminium foil coated SiO2 for different colours to white, the white surface of SiO2 was coated with black paper not bright), (d) a cabin for analysis with an internal lighting system (Lighting devices were placed around the sample holder), (e) a computer for processing information and (f) a reading software of surface colour index from the captured image (Spectrum 2.0, Mindtech s.a.s., Colombia). Digital images analysis was evaluated using different soils in order to analyse the capacity of description of different physical and chemical properties. Results evidenced that digital image analysis is a promissory technique for the description and soil analysis.

(1785 - 1869) Description of colloidal clay particles aggregation in the presence of Hofmeister effects: On the relationship of ion adsorption energy and particle aggregation activation energy

Yaxue Luo[1]; Hang Li[1]

College of Resources and Environment, Southwest University in China[1]

The aggregation of colloidal clay particles is of widespread interest to soil and environmental research, and strongly affects transport, sequestration, and mitigation of ions and contaminant. Particles aggregation is influenced by ion species, concentration, valence and pH, etc. in bulk solution. However, the different ion species especially with the same valence could bring out different colloids stability, usually being referred to as Hofmeister effects, received little attention, and particles aggregation behavior in the presence of Hofmeister effects predicted by the classic DLVO model of Schulz-Hardy rule didn't get satisfying results. Therefore, in our work, a modified description of colloidal clay particles aggregation in the presence of Hofmeister effects based on a theoretical relationship between the ion adsorption energy and aggregation activation energy was established. It indicated that, in the presence of Hofmeister effects, the different additional adsorption energy of cations resulted in the different adsorption affinity with charged surface, which essentially led to the differences in electric field around particles and energy barrier for particle aggregation, and thus the observed ion-specific particle aggregation. Validity of the theory was verified by comparisions of theoretical predicted and experimental critical coagulation concentration (CCC) values in monovalent and divalent electrolyte solutions, and good agreements were achieved. Our findings are helpful for further understanding the interactions of nanoparticles with cations and quantitatively answer how ion-surface interaction affects particle interaction processes.

(9266 - 1764) Description of intermolecular interactions of humic acids and low molecular weight organic compounds

Manuel S. Palencia[1]; Jina M. Martínez[2]; Enrique M. Combatt[3]

GI-CAT, Department of Chemistry, Universidad del Valle, Cali, 25360, Colombia[1]; Mindtech Research Group (Mindtech-RG), Mindtech S.A.S, Cali, 25360, Colombia[2]; Department of Agricultural Engineering and Rural Development, Universidad de Cordoba, Montería, 230002, Colombia[3]

Humified organic matter is the result of different bio-geochemical processes by thousands of years during soil formation (weathering, transport, accumulation, microbial colonization, colonization by plants, etc.); therefore, humified material is considered as a non-renewable resource which cannot be restored by addition of exogenous organic matter. Differentiation of soil organic matter types is very important to understand the processes of soil formation (geo-transformation), as well as, the processes of soil degradation by loss of organic matter. In particular, the interaction of small organic molecules and humic acids, i.e., humic and fulvic acids, is very important to understand the dynamic of exogenous organic matter in the soils, including amino acids, carboxylic acids and different alcohols which are the main constituents of carbohydrates and biomolecules. Therefore, the objective of this work was to describe the interaction

of humic substances, humic and fulvic acids, with low molecular weight organic compounds by different instrumental techniques. For that, different soil samples were selected from different zones and characterized physicochemical. Humic and fulvic acids were extracted by alkaline dissolution, fractionated by acidification and purified by ultrafiltration. Sequential washed were performed in order to remove ions and low molecular weight species. The clay-humin system was removed by filtration. Humic and fulvic acids were put in contact with different molecules (sorbitol, citric acid and aminoacids) and the resulting systems were analysed by attenuated total reflectance spectroscopy, dynamic light scattering and thermogravimetric analysis. Results evidenced different type of interactions in function of pH, ionic strong and the functional groups on organic molecules. It was evidenced that aggregations of humic acids and fulvic acid is controlled main by hydrogen bond interactions.

(5262 - 350) Drivers of species diversity on granitic highlands in the mata atlântica of southeastern Brazil

Prímula Viana Campos[1]; Pedro Manuel Villa[2]; Carlos Ernesto Gonçalves Reynald Schaefer[1]; Jaquelina Alves Nunes[3]; Stefan Porembski[4]; Augusto César Rodrigues Santos[5]; Andreza Viana Neri[1]
Universidade Federal de Viçosa[1]; Fundación para la Conservación de la Biodiversidad[2]; Universidade Estadual de Minas Gerais[3]; Universität Rostock[4]; Universidade Federal de Roraima[5]

Rock outcrops are the typical feature of southeastern Brazil. They occur both at low and high altitudes. This work aimed to investigate the influence of altitude and edaphic features on the vegetation structure of three mountain in high altitude grasslands in the Serra do Brigadeiro State Park, Minas Gerais, Brazil. For that, 100 plots (1x1 m) were randomly distributed across each of the three mountaintops, Totem Deitado (1.625 m), Elephant (1.790 m) and Mamooth (1.857 m). The community structure was evaluated using the Braun-Blanquet approach. One soil sample per plot was collected and submitted to chemical and physical analyses. We constructed a series of multivariate linear models to find the most parsimonious models than explain main effect of potential predictor variables on the response of species richness, abundance, and species composition across an altitudinal gradient. To evaluate the correlation among soil properties and vegetation distribution a Canonical Correlation Analysis (CCA) was performed. A total of 9276 individuals belonging to 39 families and 102 species were analyzed. In the multi-model implemented, we found that our best models indicated that elevation and soil are consistently explained more variation in abundance and species composition (ΔAICc < 2). The different predictors analyzed had no significant main effects on species richness. The abundance was significantly affected by elevation among areas (GLM: $z = 2.29$, $p < 0.001$), and also presented significant change with main effects of physical and chemical soils parameters. The linear mixed-effects models between areas showed that species composition is explained by both elevation and soils drivers through six potential models (ΔAICc < 7). Species composition of both sites was significantly associated with positive effects of elevation ($t = 5.6$, $p < 0.001$) and pH ($t = 4.2$, $p < 0.001$). Additionally, a third model that relates elevation, pH, and CEC showed important main effects on species composition. The CCA revealed the existence of two distinct groups indicating the concentration of species in preferential habitats according to the altitude and soil. Therefore, it could be observed that altitude and soil play an important role for the composition and structure of the studied plant communities in highland grassland.

(2964 - 376) Estimation of clay content in Brazilian agricultural soils based on portable X-ray fluorescence data

Tatiane Melo de Lima[1]; Bruno Teixeira Ribeiro[2]; David C. Weindorf[3]; Regina Maria Quintão Lana[1]; Nilton Curi[2]; Luiz Roberto Guimarães Guilherme[2]
Federal University of Uberlândia[1]; Federal University of Lavras[2]; Texas Tech University[3]

Portable X-ray fluorescence analysis (pXRF) has been used worldwide for rapid and low cost soil chemical characterization. Based on pXRF data, many soil attributes have been satisfactory estimated (e.g., soil texture). The mineralogy of tropical soils (Oxisols) is dominated (mainly) by kaolinite and Fe and Al-oxides (hematite, goethite, and gibbsite). Thus, a good correlation between clay content and oxide concentration can be expected. We hypothesized that rapid soil screening using pXRF to assess the oxide concentration could enable the estimation of soil clay content in Brazilian Oxisols under different land uses. One hundred and twenty six surface soil samples (0-20 cm) collected in different farms in the Triangulo Mineiro and Alto Paranaíba regions, Minas Gerais State, Brazil, were used in this study. The soil samples were air-dried and sieved (< 2 mm), and scanned using a Bruker® S1 Titan LE model (Dual Soil mode) pXRF; samples were each scanned for 60 s. The clay content was determined via Bouyoucos hydrometer method. Samples were randomly partitioned with 70% and 30% of soil samples used for modelling and validation, respectively. Based on simple linear regression, the clay content was well correlated to oxide concentration, mainly with ($Al_2O_3 + Fe_2O_3$) and ($Al_2O_3 + Fe_2O_3 + TiO_2$). Using multiple linear regression, the clay content was well estimated ($p<0.01$) by the equation (clay = -67.25 + $1.95Al_2O_3 - 1.76Fe_2O_3$) with R^2 and R values of 0.83 and 0.91, respectively. The data validation resulted a correlation close to a 1:1 line ($R^2 = 0.83$; $R = 0.91$ and RMSE = 79 g kg^{-1}). Thus, we concluded that the Al_2O_3 and Fe_2O_3 concentrations obtained by pXRF were useful estimators of clay content for soils in a representative agricultural area in Brazil.

(3178 - 1711) Estimation of the specific surface area in subtropical soils of Brazil

Alberto Vasconcellos Inda[1]; Jessica Souza de Oliveira[1]; Tatiele Fruett dos Santos[1]; Jessé Rodrigo Fink[2]
UFRGS[1]; IFPR[2]

Specific surface area (SSA) is an important property for the physical and chemical behavior of soils. However, although the various methods of SSA determination, this soil property is not commonly reported in the literature due to time-consuming analysis or equipment constraints in most soil laboratories. The aim of this work was to estimate the soil SSA, determined by means of water adsorption method (SSA_{water}), using the following soil atributes: total organic carbon (TOC) determined by dry combustion in a carbon analyser; Fe in pedogenic iron oxides (Fed) obtained by extraction with dithionite–citrate–bicarbonate; Fe in poorly crystalline iron oxides (Feo) extracted with acid ammonium oxalate; and clay content obtained using the pipette method. The determinations were performed using fine earth samples (Æ<2mm) from 76 subtropical soils of contrasting parent materials collected at surface horizons in Rio Grande do Sul, Brazil. The description of SSA_{water} was performed by single and multiple linear regressions using software SigmaPlot-14. Soil SSA_{water} varied from 1.3 to 69.1 $m^2 g^{-1}$. The evaluated attributes

showed expressive amplitudes: TOC varied from 2.0 to 102.8 g kg^{-1}; Fed ranged from 1.2 to 108.2 g kg^{-1}; Feo ranged from 0.2 to 9.9 g kg^{-1}; and clay content varied from 20 to 802 g kg^{-1}. All attributes were positively related to SSA_{water} (P<0.001; n=76), with TOC being the attribute most strongly related (SSA_{water} = 8,175 + (0,738 * COT); R=0.718). The best multiple regression obtained was SSA_{water} = -4,043 + (5,505 * Feo) + (0,0556 * Argila) (P<0.001). This equation explained well the observed values (R=0.861). When TOC and Fed atributes were included as inputs in multiple regressions, the prediction power not increased. The use of equations proposed here to estimate SSA_{water} to soils in the south of Brazil should be validated for other regions due to variations in soil attributes.

(5642 - 2991) FDR sensor calibration for moisture determination in a dystrophic Yellow Latosol from the Savana of Roraima.

Matheus Gonçalves Paulichi[1]; João Vitor Garcia de Lima[1]; Carlos Abanto Rodriguez[2]; Wellington Farias Araújo[1]; Raimundo Lima Soares[3]; Raphael Henrique da Silva Siqueira[3]; Augusto César Rodrigues Santos[1]; Marcus Vinicius Cardoso Trento[4]; João Luiz Lopes Monteiro Neto[1]; Victor Braz Cabral[1]
Universidade Federal de Roraima[1]; Instituto de Investigaciones de la Amazonía peruana-IIAP-Perú[2]; Instituto Federal de Educação, Ciência e Tecnologia do Amazonas[3]; Universidade Federal de Lavras[4]

The determination of soil moisture by humidity sensors helps decision making in irrigation of agricultural systems. However, they are not always accurate since their accuracy is measured by the characteristic of each soil class in addition to the factory calibration itself. Therefore, the objective of this work was to calibrate a commercial FDR sensor for moisture determination in a dystrophic Yellow Latosol from the Savana of Roraima. For the calibration of the data provided by the sensors, undisturbed samples were collected in PVC pipe of 20 cm (height) x 15 cm (internal diameter), calculating three replicates for each treatment and depth of insertion of the sensors. In laboratory, after toilet, the initial weight (Pi) of the samples was fixed. Soon after, the saturation point was reached (water slide up to 2/3 of the volume of the container placed in a tray with distilled water), then the samples were weighed again and their humidity measured with the FDR sensor, obtaining the output reading. After, they were placed in an oven at 60ºC until reaching 35% humidity and then the sensor was inserted again, obtaining by weight difference the water content. The process repeated until reaching 10% humidity of the samples. Then, the samples were dried in an oven at 105ºC to determine the dry weight and generating the values of sensor output and humidity. To estimate dry weight and soil density with reference humidity between 35 and 10%, an extra repetition was collected in the field, which allowed estimating the desired wet weight for the other samples, as described by Silva et al., 2012. The accuracy of the raw data obtained by the sensor readings was verified using the 1: 1 line and the root mean square error calculation. For the adjustment of the data, mathematical models were generated. First all the series of data were used and then they were separated by treatment. The one that best fit was selected due to the lower RMSE (after calibration) associated to the linear model. The accuracy was verified using the model generated by the calibration, where reduced overestimation of the error has a greater proximity of the data to the 1:1 line. The linear model was obtained for each treatment by the transformation of the data of the real humidity sensor that presented, in general, greater accuracy. The mean squared error was reduced to near zero, which provided better accuracy of the moisture data for calibration of the sensors in the dystrophic Yellow Latosol.

(4763 - 1037) Geochronology for evaluation of stream piracy processes: application in sediments of dry valleys of Guaratuba(SP).

Natalia Nunes Patucci[1]; Deborah de Oliveira[1]; Carlos Batista Silva[1]; Marina Souza[1]
USP[1]

River captures are related to drainages rearrangements processes and occur when part of a course of a river channel moves to join another channel, causing a "Pirated drainage". The phenomenon affects the regional and local morphogenesis, as well as leave observable features in the landscape that allow evaluate the evolution of the process, such as: elbows of capture , dry valleys , beheading, ruptures in the longitudinal profiles, laps, gravel and mineralogical and morphoscopy gravels correlations. The research aims to investigate the different materials of soil formation of the dry valleys of the Guaratuba River (region between the rivers drainages of Guaratuba and Claro through absolute dating using Optically Stimulated Luminescence method (OSL) and radioactive isotopes (14C) in order to assign specific periods of landscape evolution, the origin of these features. Macromorphological, granulometric, morphoscopic and mineralogical aspects of the Dry Valleys coverage material will be searched, as well as the ages of the same shall be verified through absolute dating through (OSL) and (14C). Finally, additional statistical analyses, specifically multivariate and trends, will be applied in the results to analyze the main components (PCA) results. The systemic environmental assessment in conjunction with the use of the proposed methods will develop a pedological/ sedimentological study approaches, that relate the genesis of surface coverage of dry valleys, its chronology and spatial distribution to the process of river piracy. The granulometric analysis indicated the predominance of the sandy fraction in all horizons described; the mineralogical analysis indicated the predominance of the fine sand, quartz and mica fraction. The morphoscopic analysis indicated the smooth surface texture and tendency to sub-rounding and rounding of the grains of quartz observed, which may suggest that these grains past mechanical erosion by current flow, for example. Gleissolos, Espodossolos and Organosols found in the basin divider between the high Guaratuba and Rio Claro present gravel, which means that they can represent the old bed of Guaratuba .Geochronological results demonstrate that the capture occurred in the late Pleistocene, indicating the correlation of the process with the climatic oscillations occurred in the Quaternary.

Keywords: River Captures, Dry Valleys, Sediments,Radioactive Isotope (14C),Optically Stimulated Luminescence(OSL).

(8400 - 3163) Mineral composition of cowpea (*Vigna unguiculata*) plants fertilized with bulk and nanoparticulated zinc oxides

Franklone Lima da Silva[1]; Adriana Alves Batista de Souza[1]; Luiz Henrique Vieira Lima[1]; Clístenes Williams Araújo do Nascimento[1]; Djennyfer Karolaine de Melo Ferreira[1]
UFRPE[1]

The interest in the using of nanoparticles (NP) in agriculture has increased in the last years, especially as micronutrient fertilizers. in this context, the present study aimed to evaluate the effect of doses of zinc oxidein bulk (ZnO) and NP (ZnO-NP) forms onthe nutritional status of cowpea plants(*Vignaunguiculata*).The treatments included the two sources of ZnO applied atfiverates (0, 100, 300, 500 and 800 mg dm^{-3}) in pots containing 5 dm^3 of soil. Soil was fertilized with a solution containing macro and micronutrients as follows: 250 mg kg^{-}

^{1}of N, 240 mg kg^{-1}of P, 150 mg kg^{-1}of K, and 100 mg kg^{-1}of S, in the forms of NH_4SO_2, $NH_4H_2PO_4$ and KNO_3; the micronutrients Fe ($FeSO_4$.7 H_2O), Mn ($MnCl_2$.4H_2O), B (H_3BO_3), and Mo (Na_2MoO_4.2H_2O) were applied in the concentrations of 2, 4, 1, and 0,2 mg kg^{-1}, respectively. Each pot was cultivated for 110 days with two cowpea plants. In order to evaluate the nutritional status of plants, the concentrationsof N, P, K, Zn, Fe, Cu and Mn, besides Zn, were determined. The collected data were submitted to analysis of variance and to the regression analysis using the statistical program Sisvar.Results showed that the Fe concentration in shoots was significantly reduced with the doses increasing of both the NPand the bulk sources ofZnO. This is probably due tothehighamount of Zn available in soil that decreased Fe uptake, since both elements are divalent cations. The K concentration in shoots increased about 45% and 70% for the NP and bulk ZnO, respectively. On average, the bulk source promoted higher K concentration in shoots than the NP source. For the roots, the concentrations of P and Cu were negatively altered by the increase of the oxides doses, regardless the source. The reduction of the P content should be related to the decrease of the available P content in the soil by the precipitation with the soluble Zn. For Cu, similarly to reported for Fe, there was a decrease in concentration owing to antagonistic effects. In general, both ZnO sources caused alteration in the plant's mineral composition.

(8710 - 806) On-Farm Assessment of Soil Health in Kumamoto Japan

Toru Nakajima[1]; Takahiko Nakamura[1]; Machito Mihara[1]
Tokyo University of Agriculture[1]

Globally, climate change has major implications for agricultural production. In response, farmers and soil scientists need ways to ensure the resiliency of soybean (*Glycine max* (L.) Merr.) productivity while minimizing the environmental impacts of their management decisions in response to those changes. The resiliency of crop production is a key perspective for increasing agricultural production to meet the pressure of an increasing population. Soil health is the capacity of the soil to function as a living agro-ecosystems that sustains plants, animal, and humans. Soil health index (SHI) assessment is a tool for assessing the impacts of land use and soil management practices in agroecosystems. SHI requires an evaluation of soil physical, chemical, and biological attributes to know how well the resource is functioning. Therefore, in this study, the objectives were 1) to demonstrate SHI for assessing agronomic productivity and 2) identifying soil properties that can serve as key indicators for SHI assessment on-farm-site in Kumamoto Japan. Results showed that hydraulic conductivity and soil organic carbon were identified as key indicators for SHI assessment. SHI values showed a significantly positive correlation with soybean yield suggesting that SHI assessment can be an effective guideline tool for assessing on-farm agronomic productivity in Kumamoto Japan.

(6328 - 653) Presence of straw in the soil sample increases soil P and MO concentrations

Pâmela Cristina Cassanelli[1]; Jaqueline Pereira Machado de Oliveira[1]; Fabiano Mariani[1]; Luís Carlos Iuñes de Oliveira Filho[2]; Volmir Frandoloso[1]
UNOESC XANXERÊ[1]; UDESC CAV[2]

The aim of this study was to evaluate the concentration of phosphorus, potassium, organic matter and pH in water of a Oxisol, taking in account two types of sampling: sampling with vegetal residue in cover and sampling without vegetal residue (previously the collection was carried out the removal of the cover of the soil). The study area has been conducted under no-tillage system for 4 years. In the area, grazing is used in winter (*Avena sativa*) and corn planting in the summer, and the straw present on the day of collection was from corn planting. Samples were taken with a cutting blade, in the 0 to 10 cm layer. Five samples with straw presence and five samples without straw were collected. Sampling occurred at random, because the work has exploratory. However, it was sampled on the same plot, taking into account the same soil type and even place for the minimum chemical variations to occur, being considered as treatments: T1 - Sampling without presence of straw; and T2 - Sampling with presence of straw. Concentrations of phosphorus (P), potassium (K), soil organic matter (SOM) and pH in water were evaluated. The results obtained were statistically evaluated by *t* test ($P<0.05$). The pH and K variables did not present statistical differences. On the other hand, the P and SOM variables presented differences. The presence of straw provided an increase of 28.8 and 24.4% in the concentrations of P and SOM, respectively, compared to the sampling without straw. In the present study, the values obtained did not influence the recommendation of fertilization of phosphorus and nitrogen. This is because, although the results of both variables showed a difference between the treatments, they are at the same level of recommendation foreseen in the Manual of SC and RS, and the concentrations of SOM considered average and of P considered very high, in soil with clay higher than 60% (typical of the Oxisols). Therefore, the straw interfere in the analytical concentrations of P and organic matter of the soil, not altering pH and K. Considering the need for fertility correction, this study points to the great importance of a well-made and organic-free soil sampling. This could interfere with the amounts and formulas of fertilizers used for correction, depending on the need of each soil, as well as directly affect the costs of the crop.

(6494 - 1246) Reasons for the slow emergence of soil meta-proteomics

Siobhan Staunton[1]; Herve Quiquampoix[1]
INRA[1]

The term meta-proteomics was coined about a decade ago and since then the number of studies in this field has increased exponentially for many media, but not for soils. A literature search on Web of Science shows that the vast majority of papers identified with the words soil and proteom* do not in fact involve soils. In contrast to plants, bacteria and the human gut, soils and similarly complex media such as sediments and sludge are not the focus of increasing numbers of papers, indeed the number of papers appears to have peaked and to be declining. A significant proportion of papers concentrate on the potential of proteomics for the understanding of important soil functions, others highlight the experimental difficulties, none present robust techniques or exciting findings that announce a new era of Soil Science. The purpose of this presentation is to present some of the reasons for the slow progress of proteomics in soil. There are two classes of hurdles to the development of soil proteomics: The efficient and un-biased extraction of proteins from soil and the purification of the extracts so that proteins may be separated and characterised, usually by gel electrophoresis then mass spectrometry The identification of sequences of amino acids from libraries of known proteins from soil biota All soil scientists know that soil is a complex heterogeneous material. However, not all soil scientists know that proteins vary in size, conformation and charge characteristics and that the nature and extent of interactions between proteins and other soil constituents are various and complex. Intracellular proteins fulfil specific functions. With reasonable precautions, soil microbes may be removed from the soil matrix and the intracellular proteins solubilised

by cell lysis to obtain a fairly simple medium that can be subjected to protein analysis like other simple biological and environmental matrices. Proteomic study of extracellular proteins released into soil is more difficult. These may have been secreted or released by cell leakage or lysis. Proteomic analysis of extracellular proteins, or the proteins contained in biota that are not easily removed from the soil organo-mineral complex, is fraught with difficulties due to the strong, quasi-irreversible adsorption of proteins on mineral surfaces and the co-extraction of humic material.

(4956 - 2862) Root Volume by 2D images in soil with different levels of compaction with inoculation of Arbuscular Mycorrhizal Fungi

Raphael Henrique da Silva Siqueira[1]; Matheus Gonçalves Paulichi[2]; João Vitor Garcia de Lima[2]; Luciane Reis Sales[3]; Geanderson Nascimento da Silva[3]; Augusto César Rodrigues Santos[2]; Marcus Vinícius Cardoso Trento[3]; Diogo Francisco Rossoni[4]
Instituto Federal de Educação, Ciência e Tecnologia do Amazonas, Campus Manaus Zona Leste[1]; Universidade Federal de Roraima[2]; Universidade Federal de Lavras[3]; Universidade Estadual de Maringá[4]

Soil compaction causes a decrease in the development of the plant root system when the physical impediment reaches critical levels, making it difficult to absorb water and nutrients. In addition, the destructive analysis of the root system of the plants does not provide data on their behavior and distribution in different soils and management, but also it prevents the continuity of field experiments when the number of plants does not allow a reliable analysis of the variables. Therefore, the objective of this work was to evaluate the development in the volume of Brachiaria roots in soils with different compaction levels inoculated or not with arbuscular mycorrhizal fungi (AMF). The experimental design was a randomized complete block design in a 4x2 factorial scheme with four replications and the treatments being composed of four levels of soil compaction (Ds) represented by the densities 1.08; 1.2; 1.4 e 1.6 mg m^{-3}, and with (CM) or without (SM) AMF inoculation. At the end of the experiment, the root system was analyzed using the trench method to study the crop profile (Brasil et al., 2007). The vessels were cut in half with a circular saw. One of the parts of the vessel under the projection of the brachiaria was used to evaluate the roots. The soil alongside the vessel was scarified, which means that a thin layer of soil (≅ 3 cm) was removed to expose the roots. The acquisition of the digital images was done with a semiprofessional digital camera with a spatial resolution of 32 megapixels. After the acquisition, the images were corrected and aligned with the use of the Adobe Photoshop software CS5 12.0.4; then they were submitted to quantification of the volume (mm^3) of the roots, identified by the Sapphira app (Jorge & Silva, 2010). In vessels inoculated and not inoculated with AMF the root volume is higher in densities 1.2, 1.4 and 1.6 mg m^{-3}, whereas in the density of 1.08 mg m^{-3} there is no variation. The best root distribution in the vessel is observed at densities of 1.2 and 1.6 Mg m-3 with soil inoculated with FMA The best root distribution in the vessel is observed at densities of 1.2 and 1.6 mg m^{-3} in the soil inoculated with AMF. The analysis of roots by 2D images constitutes a promising technique since it allows to evaluate the development of the plants during the cycle without the loss of experimental plots.

(4592 - 904) Soil amendment with ashes generated in wood processing plants - Effect on soil chemical properties

Viviana Falcón[1]; Leticia Rogel[1]; Jorge Hernández[1]; Amabelia del Pino[1]
Facultad de Agronomia, Garzón 780, Montevideo, Uruguay[1]

The forestry sector in Uruguay has recently increased to areas that are appropriate for tree growth, but with important limitations for agricultural use. Soils of the northern region are sandy textured, acid, with low cation and organic matter contents. Moreover, previous studies show soil acidification after some years of afforestation, with pH reduction and increase of exchangeable acidity. As an alternative to maintain the site productivity in the long term, and the nutrient stocks, the use of residues of the forestry industry as soil amendments has been proposed. Our aim was the evaluation of wood ashes as soil amendments, quantifying their effects in chemical properties (pH, exchangeable acidity, exchangeable cations and available P) in a reforestation of *Eucalyptus* (*grandis* x *camaldulensis)*. The field experiment consisted in two fresh ash rates (4 and 8 Mg ha^{-1}) and a control without amendment, which were combined with two fertilizer application levels: 0 and 100 g of diammonium phosphate per plant. From the site preparation the soil was sampled five times (at 0, 2, 6, 12 and 24 months) at 0-20 and 20-40 cm depth. The trees were measured 12 and 24 months after planting (height and diameter at breast height, DBH). No effects of ash application were observed in Eucalyptus height, DBH, or nutrient content of leaves, although there was a positive response of fertilizer application in all of these parameters. Regarding the effect of ash on soil properties one year after application a significant pH increase was observed in the superficial soil layer that reached 0,23 pH units with the highest ash rate, and in the second year a further increase was registered (0,37 pH units). In agreement with these results, a decrease in exchangeable acidity was observed, from the initial 1,85 $cmol_c$ kg^{-1}, to 1,66 $cmol_c$ kg^{-1} (average values of the two ash rates) in the first year, and 1,43 $cmol_c$ kg^{-1} in the second year. Considering exchangeable cations only K showed significant increases after two months of ash application. It was concluded that although ash application was effective to promote positive changes in soil chemical properties, those changes could have been more marked with higher ash rates. It should be remarked the importance of ash characterization before soil application, because its composition is highly variable as a function of the burned material, and particle size, which in turn determines the velocity of the reaction with the soil.

(6591 - 2974) Soil biogeochemical reactions in controlled slash and burn in the western Amazon

Elizio Ferreira Frade Junior[1]; Sarah Vieira Novais[2]; Renato Paiva de Lima[3]; Marcos Siqueira Neto[2]; Mauricio Roberto Cherubin[2]; Izaias Pereira Lisboa[2]; João Andrade Carvalho Junior[4]; José Carlos Santos[5]; Pedro Avelino Maia de Andrade[2]; Fernanda Martins[2]; Stella Cristiani Golçalvez Matoso[6]; Fernando Dini Andreote[2]; Carlos Eduardo Pellegrino Cerri[2]
Federal University of Acre[1]; University of São Paulo[2]; Federal Rural University of Pernambuco[3]; São Paulo State University[4]; National Institute of Space Research[5]; Rondônia Federal Institute[6]

The Amazon rainforest is the largest tropical biome in the world and develops strategic environmental services on the planet. However, for more than two decades, deforestation in Amazon has driven global GHG emissions, reducing soil carbon storage with changes in microbial populations dynamics and in biogeochemical cycles due to land use change. The objective of this study was to evaluate the temporal alterations of soil chemical attributes, quantify CO_2, CH_4 and N_2O emissions and verify changes in soil bacterial structure, due to the slash and burn of the native vegetation in Amazon. The study was developed in an area of native vegetation in the north of Rondônia

state, southern region of Amazon in Brazil. The study area consisted of 4 hectares, where it was cut and burned in 2.25 hectares. Samples were collected to evaluate soil fertility and carbon (C) and nitrogen (N) stocks until 100 cm. These samples were collected in native vegetation until 365 days after cutting and burning. The attributes pH, Al, H + Al, Ca, Mg, K, P, C, N were determined and the values of base sum, CEC, base saturation and aluminum saturation were calculated. The samples to quantify GHG emissions were carried out simultaneously in the native vegetation area and in the central hectare of the cutting and burning area until 350 days after burning. The microbiological attributes of the soil were evaluated by T-RFLP technique with simultaneous samplings in the two areas until 360 days after plant biomass burning. A rapid increase in soil fertility and a decrease in acidity and Al^{+3} contents after burning were verified, however this effect was not persistent, returning to the initial soil status after one year. There was a 30 % reduction in soil C and N stocks at the end of the study, evidencing the deleterious effects of land use change on soil chemical attributes. Also, a 50 % reduction in CO_2 emissions after cutting, compared to native vegetation and, a 35 % reduction in GHG emissions after one year of study, were observed. We verified in the surface layer, significant alterations in the soil bacteria structure due to the fire impact and the changes in the chemical attributes, such as surface deposition of ashes. However, we did not verified significant changes in the layers lower than 5 cm. Our study provided important information for understanding the impacts and changes of the tropical forest conversion process by slash and burning native vegetation in Amazon

(5089 - 652) Spatial distribution of roots in "patched" sodic soil

Bonadeo Elena[1]; Milán Cecilia[2]; Bauk Lucrecia[3]; Salvatierra Paola[2]
Universidad Nacional de Río Cuarto, Ruta Nac. 36 - Km. 601 - Río Cuarto, Córdoba. Argentina. Universidad Nacional de Villa María. Arturo Jauretche 1555, Villa María, Córdoba. Argentina.[1]; Universidad Nacional de Villa María. Arturo Jauretche 1555, Villa María, Córdoba. Argentina[2]; Universidad Nacional de Río Cuarto, Ruta Nac. 36 - Km. 601 - Río Cuarto, Córdoba. Argentina.[3]

The sodic soils occupy 2,800,000 ha in the province of Córdoba, Argentina. In these soils the crops show uneven growth, a phenomenon known as "patched". It is hypothesized that in the lower growth sectors of the crop, the soil presents morphological alterations and unfavorable physico-chemical properties that alter the normal pattern of root distribution. The objective of the work is to compare the morphological and physical chemical properties of the soil where the crop has less development (LD) than the soil where the crop has the highest development (HD), as well as to compare spatial distribution of alfalfa (*Medicago sativa L.)* roots of both situations. In a paddock with alfalfa located near San Basilio town, province of Córdoba, (33 ° 29'13 "S, 64 ° 21'21" W) on a typical Natrustol, situations LD and HD were selected. The morphology of the soils was described, physico-chemical properties were evaluated and spatial distribution patterns of root length density (RLD) were determined considering 4 replications for each situations. To study the spatial distribution of the roots, mixed linear models were adjusted and the structure of spatial correlation was determined. The results show that the prisms of the Btn horizon of LD have greater cohesion and the clay skins are darker in color with respect to the same horizon in HD. The carbonate concretion in LD were found closer to the surface of the soil. The pH (1:2,5 soil: water suspension) in both situations increased with depth but was always higher in LD. On the Btn horizon it was 7.47 and 9.27 for HD and LD respectively. The sodium adsorption ratio of the saturation extract (SARe) of the Btn horizon was 27 and 50 for HD and LD respectively. The spatial distribution of RLD was adjusted to a spherical model in all the replicates of HD although variations between the values of the parameters were observed. Regarding the condition of LD, spatial distributions were different in each repetition, indicating the high variability of RLD in this situation. In all the analyzes carried out, a better estimation of RLD was always shown when considering its spatial dependence. It is concluded that the spatial distribution of roots of HD with respect to LD are different, related to differences between morphological and physical-chemical properties.

(5811 - 1380) Surface energy characterization of an Andisol from souther Chile treated with biosolid.

Itilier Salazar[1]; Karin González[1]; Alejandra A. Jara[1]
Universidad de La Frontera[1]

A common practice in many countries is to apply biosolids from sewage treatment plants on soils to improve physical properties - increasing the level of organic matter- and improve their fertility. The biosolids contain a high level of organic matter and macronutrients, be these, N, P, K and microelements at trace level. The surface properties of soil particles are dependent on their composition, and this can change when adding other materials, such as contaminants, biocides, biosolids or others. In this work, we study the effect of the biosolid application on the surface properties of a volcanic soil of southern Chile through its chemical characterization, contact angle, adhesion work to determine the magnitude of the surface interactions with the biosolid. The biosolid and the soil were characterized, the contact angle was determined as the average of five measurements using a probe water by sessile drop method, to a reference soil (TA), chemical fertilizer soil (TF) and soil plus the equivalent to 30, 60 and 90 tons/ha of biosolid (T30, T60 and T90). The value of the contact angle, Θ, was determined for each system, and calculated the solid-liquid adhesion work, Wadh. Adhesion work is the result of two types of intermolecular forces, van der Waals dispersive and non-dispersive or polar forces. The experimental results showed that the contact angle values followed the sequence, TF <TA <T30 <T60 <T90 and the Wadh, T90 <T60 <T30 <TT <TF indicating that there is a strong effect of the treatment on the surface properties of the soil particles, so the soil to be fertilized acquires greater polarity and therefore a greater interfacial interaction solid-water, ie. wettability. From TA to T90 the contact angle increased indicating that the polarity decreases due to the addition of biosolids, doing the surface more hydrophobic. This phenomenon is confirmed with the Wadh values that follow the sequence, T90 <T60 <T30 <TT <TF. The magnitude of dispersive forces exponentially increase as TF<TA<T30<T60<T90, y=7.9994e0.4202x, r2= 0.9298. This growth is attributable to the fact that the non-dispersive forces decrease as consequence of the organic matter increased contributed by the biosolids. The total surface free energy of the system exponentially decreased from TF to T90, y= 132.7e-0.649x, r2= 0.9101. In addition, the total surface free energy decreased yielding a surface on soil particles with higher hydrophobic character.

(3948 - 1778) The role of iron nanominerals in the preservation of soil organic matter under long-term fertilization

Ping Wang[1]; Jidong Wang[1]; Hui Zhang[1]; Yongchun Zhang[1]; Yuchun Ai[1]
Agricultural Resources and Environment Institute, Jiangsu Academy of Agricultural Sciences/Scientific Observation and Experimental Station of Farmland Conversation and Cultivation in Jiangsu[1]

The organo-mineral associations play a significant role in soil organic carbon accumulation. However, little attention has been paid to the role of highly reactive Fe minerals in soil organic carbon (SOC) preservation in soil aggregates. In this study, the effects of four long-term (37-year) fertilization regimes (NPK, chemical fertilization; NPKM, chemical fertilization + cattle manure; M, cattle manure; CK, non-fertilization control) on OC stability, soil iron fractions in bulk soil and soil aggregates were studied to characterize the capacity and mechanism of Fe minerals to preserve SOM in soil. The results showed that long-term fertilization significantly (p <0.05) altered the Fe fractions in soil and soil aggregates. The two applications with manure (NPKM and M) increased the non-crystalline Fe content, while the chemical fertilizer (NPK) increased the crystalline Fe content. The non-crystalline Fe was positively correlated to the SOC content in both soil and soil aggregates. Meanwhile, the long-term fertilization treatments greatly changed the mass distribution and OC content of soil aggregates. Silt and clay were found to be the dominant particles in soil aggregates among all treatments. In conclusion, long-term manure fertilization promoted the formation of non-crystalline Fe fractions, which bounds to SOC to form soil macro-aggregates. Thus, the formation of SOC-Fe association in soil and soil aggregates plays a crucial role in SOC preservation.

(8944 - 991) The role of organic amendment and cropping system on improving physical and biological properties of a soil poor in quality for sustainable agro-ecosystem

Ardeshir Adeli[1]; John Brooks[1]; Gary Feng[1]

USDA-ARS[1]

Erosion changes soil properties, especially physical properties, mainly because it removes surface soil rich in organic materials and exposes lower soil layers. This study was conducted on an eroded Loring silt loam soil with 1-3% slope to determine the effects of broiler litter and cropping systems on improving soil quality and crop production under both conventional tillage and no-till systems. A randomized complete block design with three replications and split-plot arrangement of treatments was used. The main plots were tillage and no-till and the sub-plots were broiler litter at 9 Mg ha^{-1} , inorganic fertilizer at 220 kg N ha^{-1} as urea ammonium nitrate (UAN solution) applied in split, 75 kg ha^{-1} at planting and 145 kg ha^{-1} as side-dress at knee high and unfertilized control. The cropping system was corn-wheat rotation. Broiler litter was applied only to corn before planting. Winter wheat was planted after corn in the fall and harvested for grain in June. Corn grain yield, grain N and P uptake were significantly increased as compared to inorganic fertilizer at approximately equivalent rate. Corn grain yield and N uptake were greater with conventional tillage (4014 and 63 kg ha^{-1}) than no-till corn (2608 and 42kg ha-^{1}), respectively. Residual effect of broiler litter significantly increased wheat grain yield and grain N uptake (1778 and 26 kg ha^{-1}) as compared to the control (901 and 14 kg ha^{-1}), respectively. Broiler litter application improved soil chemical, physical and biological properties. Averaged across years, Soil P, total N, and total C increased from the base line of 0.033, 0.45, and 10.1 g kg-1 to 0.120, 0.74, and 13.4 g kg-1, respectively, at the 0-15 cm depth. Dehydrogenase levels were greatest in broiler litter treated soils. At 0-15 cm depth, broiler litter application significantly reduced bulk density and soil penetration resistance by 6 and 26%, respectively, while soil water stable aggregate increased by 22% . No differences in soil physical indicators was obtained between inorganic fertilizer and unfertilized control. Results of this study indicated that long-term use of organic amendments along with soil and crop management systems soil restore soil quality and improve crop productivity of an eroded soil

(4754 - 1739) Tolerance to and Accumulation of Cadmium, Copper, and Zinc by *Cupriavidus necator*

Rayssa Pereira Vicentin[1]; Jessé Valentim dos Santos[1]; Cláudia Regina Gontijo Labory[1]; Amanda Monique da Costa[1]; Fatima Maria de Souza Moreira[1]; Eduardo Alves[1]

UFLA[1]

Preliminary results of *in vitro* experiments with multicontaminated soils and solid media indicated that nodulating diazotrophic bacteria of the genus *Cupriavidus* are promising for the remediation of contaminated environments due to their symbiosis with legumes and metal tolerance. Thus, strains of *Cupriavidus* spp. (LMG 19424T, UFLA 01-659, UFLA 01-663, and UFLA 02-71) were tested for their ability to tolerate and bioaccumulate cadmium (Cd), copper (Cu), and zinc (Zn) in Luria-Bertani broth. Changes in the growth pattern of *Cupriavidus* strains in the presence or absence of heavy metals were analyzed by scanning electron microscopy and metal allocation by transmission electron microscopy, to clarify the mechanisms of bioremediation. Highest tolerance was detected for strain UFLA 01-659 (minimum inhibitory concentration of 5, 4.95, and 14.66 mmol L-1 of Cd, Cu, and Zn, respectively). Among the removal rates of the metals tested (9.0, 4.6, and 3.2 mg L-1 of Cd, Cu, and Zn, respectively), the bacterial activity was clearly highest for Cd. The efficiency of strain UFLA 01-659 in removing the heavy metals is associated with its high biomass production and/or higher contents of heavy metals adsorbed and absorbed in the biomass. In response to the presence of heavy metals in the liquid culture medium, the bacteria produced exopolysaccharides and small and aggregated cells. However, these responses varied according to the strains and heavy metals. Regarding allocation, all heavy metals were adsorbed on the cell wall and membrane, whereas complexation was observed intracellularly and only for Cu and Zn. These results indicate the possibility of using *C. necator* UFLA 01-659 for remediation in areas with very high Cd, Cu, and Zn contents.

Keywords: heavy metals; electron microscopy; diazotrophic bacteria; bioremediation; tolerance mechanisms.

(8589 - 2020) Transmission X-ray Microscopy (TXM) Reveals the Nonionic Surfactant Adsorption on Bentonite

Ya-Ting Chan[1]; Yu-Min Tzou[1]

National Chung Hsing University[1]

Macroscopic properties of bentonite are controlled by the structural arrangement of the clay and by the morphology of its finest fraction. The structural properties of clays or foreign ions-modified clays are commonly examined in a dried condition that may interfere the direct observations of the structural changes upon interactions with ions in solutions. For instance, the intercalations of organics, such as surfactants, would lead to clay swelling based on the changes in the interlayer space using a powder X-ray diffraction (PXRD) technique. However, the de-watering process prior to PXRD analyses can lead to an unreal scenario of the reactions in the interlayer spaces of clay minerals where is full of water molecules. A new technique, transmission X-ray microscopy (TXM), makes it possible to investigate the internal structures of the clay aggregates in an aqueous environment. In the study, adsorption/desorption of nonionic surfactants of Brij 30 and Igepal CO890, followed by spectroscopic

analyses was conducted to observe the tomographic reconstruction of bentonite upon its interaction with nonionic surfactants. The adsorptions of Brij 30 (entitled as BB) and Igepal CO890 (entitled as BI) on bentonite were up to 260.5 and 122.1 mg C g^{-1}, respectively, depending on the initial concentrations of surfactants. Based on the results of desorption experiments associated with the changed in the PXRD patterns, both intercalations and physical adsorption of surfactants on the clays occurred. The thermogravimetric analysis (TGA) and PXRD results showed that the surfactants were layered in the interlayers of the bentonite. The TXM micrographs indicated that morphology of the pristine bentonite looked like a cell, and the central of internal space of bentonite could be expanded to 965 nm in an aqueous environment. Upon the addition of surfactants, the interlayer space of bentonite would be narrowed down to ca. 439-455 nm. In addition, the interlayers of bentonite would be further shrunk to 314-316 nm when more surfactants were intercalated. Compared with PXRD results, TXM results might reveal to how the swelling phenomenon of surfactant adsorption/ desorption in bentonite caused by a combination of hydration and electrostatic forces.

Keywords: bentonite, nonionic surfactant, transmission X-ray microscopy (TXM)

(5003 - 813) Using DRIFTs to investigate the dynamic effect of organic matter input on soil carbon functional groups

Zhaolong Zhu[1]; Budiman Minasny[2]; Damien J. Field[2]; Mario Fajardo Pedraza[2]
State Key Laboratory of Soil Erosion and Dryland Farming on the Loess Plateau, Northwest A&F University[1]; Faculty of Agriculture and Environment, the University of Sydney[2]

Soil organic matter (SOM) is an important indicator of soil quality, and diffuse reflectance Fourier transform mid-infrared spectroscopy (DRIFTs) has been widely used to investigate the composition of soil organic matter. While certain organic functional groups can be found in the MIR spectra, its quantification is still unclear. The choice of peak and valley areas at certain wavelength was arbitrary, and thus the effect of different soil organic matter inputs to the carbon functional groups is still ambiguous. A study was undertaken to investigate this problem by incubating a clay soil dominated by kaolinite amended with two different sources of organic matter (alfalfa, C: N=16.7 and barley straw, C: N=95.6) at different levels (0, 10, 20, 30 g kg^{-1} soil). The incubation was conducted for a period of 3 months under a control condition of constant room temperature (20±1 ℃) and soil moisture (70% of field capacity). Specific DRIFTs wavelengths (3010-2800, 2060-1930, 1930-1840, 1735-1650, 1660-1580, 1546-1520 cm^{-1}) and their peak/valley areas were quantified using continuum removal to represent different soil carbon functional groups (aliphatic and aromatic). The results showed that: (1) Direct abiotic effects of organic matter are immediate following inputs; (2) The specific DRIFTs valley/peak areas changed according to the quality and quantity of OM applied, e.g., for 1650-1580 cm^{-1} (aromatic functional group), the peak area increased with C levels applied, and decreased for soils with barley straw amendment; (3) The valley/peak area generally changed with incubation time, i.e. decrease with time; (4) Functional groups at 3010-2800 cm^{-1} and 1930-1840 cm^{-1} have a significant relationship with aggregate stability as measured using wet sieving techniques (R^2 = 0.93). It is concluded that specific functional groups as measured by DRIFTS can be used to quantify organic matter functional groups which are related to soil aggregation function.

(3192 - 2590) Lithological influence on K, Al concentrations and guano density of Streptoprocane species in quartzitic karst landscape

André Luiz Miranda Reis[1]; Nicoló Clemente[2]; André Luiz Lopes de Faria[1]; Liovando Marciano da Costa[1]
Federal University of Viçosa[1]; Federal University Rural of Rio de Janeiro[2]

The Natural Heritage Private Reserve (RPPN) of the Serra do Caraça is located in the municipalities of Catas Altas and Santa Bárbara in the state of Minas Gerais, Brazil. The RPPN is located in the geological province of the Quadrilátero Ferrífero and is lithologically defined by quartzites of the Super Group Minas. In this region there was an intense process of metamorphism and rocks weathering. The weathering action in the fractures allowed the formation of caves, which house swifts of the species Streptoprocne zonaris and biscutata. These birds are responsible for the accumulation of guano on the floor of the cave, phosphate and nitrogen-rich substances that constitute the largest energy source available in the cave environment. Therefore, the objective of this work is to analyze and discuss the dynamics of K, Al and their relationship with density, in different deposits of guanos located in the caves of the RPPN. A transect was collected from the entrance of the cave to the deepest part, with the objective of identifying and collecting the guano deposits. The layers were identified by evaluating the degree of decomposition and humification from the most superficial to the deepest, and thus collected, with a metal shovel in 21 layers of guanos organized in seven deposits. The samples were conditioned in plastic bags and analyzed in the laboratory with soil methods, in the determination of K, Al and density. The results showed a significant increase in the contents of K, Al and density in the deeper layers of the deposits. This is explained considering that the quartzite, submitted to the physical, chemical and biological processes, alters and disintegrates the structure itself and the minerals present, such as feldspar-K and sericite, that rich in K and Al, released these elements to the deeper layers of guano. Therefore, the guano in direct contact with the rock, accelerates the process of weathering, due to the organic acids produced, a fact that contributes in the increase of these elements and density of the guano. It can be considered that the guano, in the layers below 30 cm is influenced by the lithology, being the rock a factor of formation of this material in depth.

(9707 - 372) Advance in automatic measuring tool of soil losses using water environment research equipment ISCO 6712 Model

Tae-young Kim[1]; Yeong-Gyu Lee[1]; Gye-Ryeong Bak[1]; Sam-Nyeo Ji[1]; Dong-Shig Oh[1]; Gye-Jun Lee[1]

Rural development administration[1]

In soil loss research work in-situ timely correct measurement for loss quantities is a hard task. The rain is suddenly coming on and its intensity is changeable every moment. On-time automatic measurement of soil losses accordingly with such a raining occurrence is really laborious and complicated. In environment-friendly agriculture research laboratory of Korea Highland Agriculture Research Institute, the automatic measuring technology of soil losses was developed using compositive water environment research equipment ISCO 6712 Model(made in USA) over the year of 2015 and 2017. Soil losses are automatically measured as follows; Site Area; 1 × 5 ㎡, Planting Crop; Maize(planted density, 60×25 ㎠), Site Soil; Saprolite(Loamy Sand), Rainfall and Run-off Water Level Measurement; Rain Gauge and Bubbler Hose attached to Model No. 6712 Equipment, Automatical Suspended Water Sampling; Automatic Catching of Suspended Water by a Sampling Bottle connected to each horizon of Water Reservoir. The expectable accuracy for soil losses quantification measures up to the goodness of 75% and 95% in the ratio of estimate to occurrence quantity in a storm of rain 201.3㎜ and 82.6㎜, respectively.

(1038 - 603) African soil partnership implementation plan for addressing the challenges of sustainable soil management in the sub saharan africa

Victor Okechukwu Chude[1]

Chairman, African Soil Partnership Steering Committee National Program for Food Security Federal Ministry of Agriculture and Rural Development. Abuja, Nigeria[1]

Land is the main resource base for many people in Sub-Saharan Africa. Even with an estimated 65% of arable lands, 30% of grazing land and 20% of forests already degraded in Africa, the region still has the potential to position itself as champion in food production. Sustainable soil management is vital to achieving this goal and, for this reason, is one of the cornerstones of the Global Soil Partnership (GSP). The African Soil Partnership has identified six main areas of action as priority in sub-Saharan Africa which include: a)Addressing soil degradation as a major factor in food insecurity and making country and region-wide efforts to rehabilitate degraded lands and change them to productive assets through community participation; b) Guiding and enabling the implementation of sound and sustainable soil management practices and the restoration of soil health at all levels towards food security; c) Developing, updating and disseminating updated and harmonized national and regional soil resource information addressing all user needs including soil fertility information and making the best use of science available to increase soil productivity; d) Addressing climate change and developing resilience towards climate change adaptation; e) Developing and implementing training and capacity building programmes in all soil applications for existing and new generations of experts in soil science and land management, taking into account the gender balance; f) Establishing linkages and networks with other national, regional and global initiatives that impact soil health. This paper discusses all the identified challenges associated with Sustainable Soil Management in Africa and Regional implementation plans for addressing the challenges. The Implementation Plan sets out the road map for the next 5 years to achieve SSM over the longer term and includes a large number of outputs and activities which are considered priority in this first phase of establishing the AFSP. It is envisaged that funding for these activities will be secured by capitalizing on existing in-country initiatives and activities, as well as by actively sourcing additional external funding. Since the GSP is a voluntary initiative, it calls for the strong support of national governments, as well as national and regional entities involved in natural resource management to contribute to achieving the common goal of improved and sustainable soil management.

(8699 - 2558) Agricultural potential for Crop-Livestock-Forestry integration system in the Matopiba region, Brazil

José Francisco Lumbreras[1]; Amaury de Carvalho Filho[1]; Paulo Emilio Ferreira da Motta[1]; Pedro Luiz de Freitas[1]; Alexandre Hugo Cezar Barros[1]; Mario Luiz Diamante Aglio[1]; Ricardo de Oliveira Dart[1]; Hilton Luis Ferraz da Silveira[1]; Carlos Fernando Quartaroli[2]; Rodrigo Estevam Munhoz Almeida[3]

Embrapa Solos[1]; Embrapa Territorial[2]; Embrapa Pesca e Aquicultura[3]

In this paper, it is presented the agricultural potential for integrated production systems for the Matopiba region, which covers approximately 73 million hectares and represents an important frontier for the expansion of agricultural production in Brazil. In soil and climate studies, the main limitations to agricultural land use have been identified, complemented by field campaigns to validate interpretations. The agricultural potential of the land for the adoption of Crop-Livestock-Forest integration systems (CLFi) considered the high technological level for crops, and medium and high for silviculture and planted pasture. The evaluation is presented in map compatible with the 1:500,000 scale. Mixed systems of agricultural production, based on the spatial and temporal integration of agricultural components (annual and perennial crops), forestry (silviculture) and livestock (pasture) were considered. The systems used for sustainable intensification of land include: crop-livestock-forest system or CLntegrating agricultural, livestock and forestry components in rotation, consortium or succession in the same area. They include the forest-agriculture systems or crop-forest integration with emphasis on crop-forestry systems; crop-livestock systems or Crop-Livestock integration (CLi): integrating agricultural components (annual crops) and livestock in rotation, consortium or succession, in the same area and in the same agricultural year or for multiple years. They include inadequate areas for the implantation of forest species; forest-livestock systems or Livestock-Forest integration (LFi): integrating livestock (pasture and animal) and forestry components into a consortium. They include areas that are unsuitable for planting; and, pastoral systems - exclusively for livestock component in areas not suitable for crops or forestry. They include the recovery of degraded pastures and management techniques that guarantee high productivity and pasture support capacity. A wide range of soils occur under varying climatic conditions, reflecting distinct qualities and vulnerabilities for agricultural land use. Soils with great potential for agriculture, such as Argissolos and Latossolos, are noticed. On the other hand, soils with a high vulnerability to degradation, with high sand content (Neossolos Quartzarênicos), gravel (Plintossolos Pétricos) and strong drainage restrictions (Plintossolos Argilúvicos and Háplicos, Gleissolos and Planossolos) are frequent.

(3555 - 2167) Arbuscular mycorrhizal fungi and phosphate

fertilization in production of araucaria seedlings

Carlos Vilcatoma Medina[1]; Marcos Antonio Dolinski[1]; Glaciela Kaschuk[1]; Flávio Zanette[1]

Universidade Federal do Paraná[1]

Araucaria or Paraná-pine [*Araucaria angustifolia*] is a slow-grower endangered tree species of the Mixed Ombrophylous Forest in South America that makes symbiotic association with arbuscular mycorrhizal fungi (AMF). This work was performed with the objective of verifying the effects of AMF and single superphosphate (P) fertilization on the production of araucaria seedlings. An experiment was settled with five treatments [(1) inoculation with *Rizophagus intraradices* (AMF1), (2) with *Acaulospora colombiana* (AMF2) and (3) with forest soil, (4) fertilization with simple superphosphate (SP) and (5) control (C)], under entirely random design, and five replicates. Seedlings were produced with local seeds sown in the Mecplant® substrate mixtured with washed sand in the proportion 1:1. AMF inoculation was done with 100 g of a soil-root AMF inoculant containing either, spores of *Rizophagus intraradices*, or *Acaulospora colombina*, or litter from a 50 years-old araucaria forest. Fertilization was achieved with application of 100 mg of SP. The control was the treatment in which seedlings grew without any amendment. Seedlings were let to grow for 75 days and, then, AMF root colonization, seedling height, stem diameter, fresh and dry shoot and root matter were measured. All measured variables were not affected by treatments at the 75th day of seedling growth. On average, inoculation with any strain of AMF resulted in a colonization rate of 48% while soil forest, SP and control had 44, 42 e 35 %, respectively. Seedlings measured on average 23.7 cm of height, 4.0 mm of stem diameter, 15.4 g of fresh shoot matter, 4.6 g of fresh root matter, 3.8 g dry shoot matter and 1.0 g of fresh root matter. This experiment is being continued and a new harvest happen at 180 days.

Keywords: Seedlings; symbiosis; substrate; nursery.

(7537 - 2597) Background and Reference Values of Heavy Metals in soils of the Brazilian Amazon

Luiz Henrique Vieira Lima[1]; Franklone Lima da Silva[1]; Clístenes Williams Araújo do Nascimento[1]; Fernando Bruno Vieira da Silva[1]

Universidade Federal Rural de Pernambuco[1]

The Amazon is considered the biome with greatest biodiversity in the world and of great socio-environmental and economic importance for Brazil. The sustainability of this environment is threatened by increasing soil contamination by heavy metals which are added by anthropogenic activities. Quality Reference Values (QRVs) reflect the natural concentrations of heavy metals in soils without anthropic interference and the initial step for environmental management of contaminated areas. In this sense, the study aimed determine the background and quality reference values for Ba, Cd, Cr, Cu, Fe, Mn, Ni, Pb, Sb e Zn in soils of a sedimentary basin located in southwest of the Brazilian Amazon. 114 soil samples were collected at a depth 0.0 – 0.2 m at sites with minimal anthropogenic interference. The samples were air-dried, ground in agate mortar and passed through a stainless steel 0.15 mm mesh sieve. 1 g of the samples were digested in a microwave at 175ºC with HNO_3 + HCl according to methodology 3051A of US Environmental Protection Agency. As quality control for the analyzes were used blank samples and the reference material SRM 2709a (*San Joaquin Soil*), with the contents of metals certified by National Institute of Standards and Technology. All analyses were performed in duplicate. The heavy metals contents were determined in ICP-OES (Perkin Elmer 7000 DV). From the data set, were calculated the mean, median, minimum, maximum and standard deviation; the QVRs for metals were defined based on the 75th percentile of the data set, eliminating the anomalous values as recommended in the Brazilian legislation. The recoveries of the metals in reference sample ranged from 90 – 114%. The average natural contents were 15462.0; 19.3; 15.1; 8.7; 6.3; 4.5; 3.3; 2.5; 1.0 e 0.1 mg kg^{-1} for Fe, Ba, Mn, Cr, Zn, Pb, Cu, Ni, Sb e Cd, respectively. When comparing the results obtained with other records in the country, it was observed that the contents of the metals in the present study were inferior due to the sedimentary origin predominant in the region. Based on the natural contents the QVRs were defined and the following decreasing order was observed (in mg kg^{-1}) Fe (15462.0) > Ba (16.5) > Mn (13.4) > Cr (6.9) > Zn (5.7) > P (4.4) > Cu (2.8) > Ni (1.7) > Sb (0.9) > Cd (0.1). The results of the present study will serve as a basis for the definition of public policies in order to investigate the environment impacts resulting from the change of land use in legal Amazon territory.

(6433 - 211) Chemical attributes variability of a quartzipisamment cultivated with eucalyptus in response to limestone application

Elizeu de Souza Lima[1]; Lenon Henrique Lovera[1]; Diego Alexander Aguilera Esteban1[1]; Zigomar Menezes de Souza[1]; Rafael Montanari[2]; Ingrid Nehmi Oliveira[1]; Henrique Barbosa Sandoval[1]; Angela Nunes Wendt Lima[3]

State University of Campinas (Unicamp), Agricultural Engineering (Feagri)[1]; State University Paulista (UNESP)[2]; [3]

Eucalyptus has been cultivated in Cerrado regions predominantly for highly weathered soils, possibly causing lower productivity, whose prevention involves soil correcting and fertilization as well as the use of monitoring and assessment methods to determine the variables mostly affecting eucalyptus growth. We aimed at analyzing the spatial variability of Eucalyptus urograndis as function of the chemical attributes of a Typic Quartzipisamment. We collected plant samples at Bom Retiro Farm, county of Três Lagoas-MS, in 2014, regarding the following attributes: height (HEI) and soil at layers 0.00-0.20 m and 0.20-0.40 m, for determination (hydrogenic potential) pH, organic matter (OM), calcium (Ca), magnesium (Mg), and aluminum (Al). Data were analyzed through descriptive statistics with SAS while the semivariogram spatial dependence was verified using GS+ software. By analyzing average contents of OM (11.14 and 9.98 g dm^{-3}), pH (4.53 and 4.31), Ca (11.74 and 6.06 mmol$_c$ dm^{-3}), Mg (9, 46 and 4.94 mmol$_c$ dm^{-3}), and Al (6.26 and 8.52 mmolc dm^{-3}) at the layers assessed and comparing with contents from before the limestone application, we found an increase in Ca in Mg. These are ideal contents to clonal eucalyptus crop because of their low nutrient values; however, it is necessary to constantly correct soil fertility upon critical levels of nutrients below the adequate content to the species. The semivariograms presented spatial dependence for ALT and OM at layer 0.00-0.20 m, Al and pH layer of 0.20-0,40 m. In relation to kriging maps, it was possible to identify homogeneous and soil specific zones for most of the attributes studied. High spatial similarity for practical soil management effect occurred for the maps of HEI, OM and Al at layer 0.00-0.20 m. Heterogeneously similar spatial distribution occurred in the northwest and southeast regions of the kriging maps, concentrating the highest eucalyptus heights (3.6-4.0 m), highest OM contents (11.3-12.5 mg dm^{-3}) and consequently the lowest Al content (3.5-5.5 mmol$_c$ dm^{-3}). We concluded that plant height, organic matter content, and pH were the attributes which presented spatial dependence between 55.8 and 89.9% as well as reaching from 11.7 to 20.6 m, thus determining specific management areas.

(6341 - 645) Comparation between diagnostic metodology cda versus methodology cda innovated aiming to transform degraded areas into conservation agriculture areas

Oswaldo Julio Vischi Filho[1]; Oscar Yoshikatsu Kanno[1]; Raul Barros Penteado[1]; Roberto Mikio Arabori[1]; João Flávio Bernardoni Caldas[1]; Fabrício Sales Massafera Tristão[1]; Roberto Ciciliato[1]; Jorge Aparecido Quiessi[1]; Antonio Celso Alves Vilella[1]; Edna A. Menegucci Scachetti[1]
Coordenadoria de Defesa Agropecuária[1]

Coordenadoria de Defesa Agropecuária has developed the inspection activity of agricultural soil use and conservation in the state of São Paulo for 18 years. The area of the state occupied with agriculture, has 18 million ha, with 330 thousands farms. For applying the conservation law of agricultural soil a diagnostic is done which consists on watershed delimitation, as well visit to all properties belonged to this watershed. The inspection consist on preliminary survey stage, on the visits on the properties, on conservationist projects presentation and finishes at the agri-environment rehabilitation. The inspection methodology CDA was developed from 1999, was improved in 2017, named Diagnosis Methodology CDA Innovated. The pilot project of methodologies Innovated was done in watershed of Rio do Peixe, on the of 59000ha, located in Marília region. The beginning of activities, using the old methodology, was in 2007, and finished in 2011 where it was evaluated 14076ha and, from 2011 to 2015, evaluated 8175ha totalizing 22251ha, 216ha per month, being done by a team of four Agronomist Engineer, during 103 months. Many technological innovation options were tested, the using of model airplane, helicopter and drone, however the results were only favorable when it was developed a new work method. With the new methodology it was diagnosed from 01/2017 to 09/2017, 27586ha, that is, 3065ha per month. The methodology using data base of Rural Environment Registration, of Animal and Vegetal Defense System and Aerial Images of Google Earth Pro, doing the diagnose and the inspection by remote sensing. After this stage the obtained date base work done on GE, were checked on the field and the inspection and agri-environment rehabilitation consequent are completed. This methodology allows the evaluating, with details, an area that by the old methodology would take 103 months to be done, in only 9 months, a save in time and cost, that is, a performance of 1418% favorable to the methodology CDA Innovated.

(9783 - 2136) Definition of soil management specific units at farm level

Juan Carlos Rey[1]; Gustavo Martínez[2]; Jorge Marquina[2]
1Instituto Nacional de Investigaciones Agrícolas, Av. Universidad, Maracay 2105, Venezuela. (jcrey67@gmail.com)[1]; Instituto Nacional de Investigaciones Agrícolas[2]

Soil management at the farm level is commonly uniform, at least for each land use type, without considering the soil variability. The elimination of subsidies and shortages of fertilizers, promotes a more efficient use of inputs every day. In this sense, the definition of soil management specific units (SMSU) is proposed from the description of soil augers, soil laboratory analysis and statistical analysis involving the data exploratory analysis, principal components analysis and a conglomerate analysis. The variables considered in the description of the augers were the horizons thickness (HT), soil color (SC) and depth of mottles (DM); as well as the drainage classification (D) and tha land capability use (LCU). The variables considered from the laboratory analyzes were the contents of sand, silt and clay, nutrient content (phosphorus - P, potassium - K, calcium - Ca, magnesium - Mg and microelements - Mic), pH, organic matter contents (MO) and electrical conductivity (CE). In Los Catires farm (15 hectares), located in the south of the Zulia State, four SMSU were determined, where important differences were found in the depth to mottles, pH, MO, soil granulometry and P, K and Mg contents. At El Diamante farm (54 hectares), located in Trujillo State, six SMSU were determined; these six SMSU showed important differences in the depth of mottles, MO, granulometry and contents of P, K, Ca and Mg. For both banana producing farms, the aptitude of each SMSU was determined, and fertilization management programs were designed by lot, according to the localization of SSMU, demonstrating the utility of these methodology for the farmers planning.
Keywords: soil management, farm, soil variability

(9425 - 952) Delineating homogeneous zones in a watershed with respect of the susceptibility of lands to degradation by agricultural use

Michender Werison Motta Pereira[1]; Mara de Andrade Marinho[1]; Antonio Paz-González[2]
UNICAMP[1]; University of Corunna[2]

Land degradation has been a recurrent aspect concerning soil conservation and management. The association between intensive agricultural use and soil degradation, mainly due to the compaction and soil erosion, is widely known and studied. The history of soil degradation in the Ceveiro watershed (SP, Brazil) has motivated the present work, once the current main use is still with sugarcane, considered an overuse according to the agricultural land suitability. The goal of this work was to delineate homogeneous zones according the susceptibility of lands to degradation by agricultural use as a tool to guide the sustainable use and management. To reach our purpose we made use of concepts from Pedometrics and approaches concerning the continuous in-depth modelling of soil attributes (by using the *spline equal area function*) and digital soil mapping. To define and map the homogeneous zones according to their susceptibility to degradation we elected the following conditioning factors: the *solum* depth (A+B); particularly for *Alfisols (Argissolos)* and *Ultisols (Luvissolos)*, the depth of the top of the argillic horizon (B textural); the content of soil organic carbon; the (global) soil density; the soil macroporosity; the soil texture; and, the inclination of the terrain (slope angle). Maps representing the spatial variability at different depths (up to 1.0 m) were generated for each conditioning factor. Then, these maps were reclassified according to five levels of limitation grade to degradation, null, slight, moderate, severe, extreme, by assigning a weight for each level as suggested by Lal (1999). These maps were combined (by addition) by pairs in a GIS. At the end of this step, according to the final summation of each identified polygon, the image was reclassified to generate the map of homogeneous zones, by distinguishing the zones of very low, low, medium, high, and very high susceptibility to degradation. The more restrictive conditioning factors of land degradation in Ceveiro were identified as being the depth of the top of the argillic horizon, the content or soil organic carbon, the soil macroporosity and the terrain inclination. The percentages of distribution of the homogeneous zones in Ceveiro according to their susceptibility to degradation are as follow: very high (56%), high (28%), medium (12%), and low (4%). We conclude that is mandatory the conversion for less intensive and more conservative uses in keeping with the agricultural land suitability.

(4835 - 2274) Distribution of the radical system of capim mombaça mixed with legumes with nitrogen fertilization management

Flavia Alessandra Mignacca[1]; Tassiane Sanchez Calles[1]; Marcelo

Augusto Statello[1]; Carlos Henrique dos Santos[1]
UNOESTE[1]

Sandy soils are sensitive to intensive management, with essential use of the no-tillage system, with improvements in the chemical, physical and biological properties of the soil. Objective of this work was to evaluate root development in an Argisol under no - tillage system cultivated with mombaça grass mixed with legumes. The experiment was carried out at the experimental farm of University of Western São Paulo. The experimental design was a randomized complete block design with four treatments and four replications: single unmanned mombaça grass;Single mombaça grass with nitrogen fertilization (250 kg ha^{-1} of N); Mombaça grass mixed with horse gram without nitrogen; mombaça grass mixed with pigeonpea without nitrogen. The roots were collected with 10 x 10 x 10 cm iron monoliths at the following depths: 0-10, 10-20, 20-30, 30-40, 40-50, 50-60, 60-70, 70-80, 80-90 and 90-100 cm, in the center of the face of each trench. After being collected, the roots were washed with tap water and stored in vials containing 70% deionized water and 30% absolute alcohol, under refrigeration (± 10 ° C).To obtain the biometric parameters as volume (mm^3 cm^{-3}), surface area (mm^2 cm^{-3}) and length (mm cm^{-3}) the roots were submitted to SAFIRA.After the readings, they were oven dried at 65ºC for quantification of dry biomass (g cm^{-3}).The soil resistance to penetration with the IAAPLANALSUCAR / STOLF penetrometer was evaluated and four points were randomly sampled in each experimental plot and the resistance was measured at depths of 10, 20 and 40 cm. There was no statistical difference between the evaluated parameters of the roots, and all the managements presented higher volume and area of roots in surface with gradual decrease in depth. However, the volume, surface area and biomass values of the roots of the mombaça grass intercropped with the horse gram tended to show numerical superiority in the majority of the evaluated depths, whereas the single mombaça grass with nitrogen showed inferior in all the depths. In relation to the lenght parameter of the roots, the mombaça grass mixed with horse gram and the mixed with pigeonpea tended to larger values, and the single mombaça grass without nitrogen obtained a smaller root lenght, mainly in the superficial layers. There was no statistical difference in soil resistance to penetration, but they followed the same tendency of the roots, that is, they decreased in depth (3.1, 2.7, 2.2 MPa respectively from 0-10, 10-20, 20-40 cm)

Keywords: horse gram, pigeonpea, forage, compaction

(5760 - 2886) Effects of sugarcane removal straw on carbon and nitrogen from soil microbial biomass

Paul Lineker Amaral de Melo[1]
Centro de Energia Nuclear na Agricultura/Universidade de São Paulo[1]

Recently the search for energy sources capable of replacing non-renewable sources has become a global effort to reduce greenhouse gas emissions. The straw from the sugarcane harvest is considered to be an important raw material in energy generation and in reducing the impact on the environment. It is believed that the maintenance of these residues on the soil will promote the occurrence of microbial communities, often associated with variations in the physical or chemical properties of the soil. The non-removal of these residues on the soil for the industry would promote soil pH increase, reduction of aluminum content in the soil and a higher soil moisture, it is believed that this management will favor the biological activity of the soil. The experiment was developed in 2016 an Oxisoil with clay texture, an area belonging to the Usina Bom Retiro in the city of Capivari. The xperimental design was a randomized block with 4 treatments and 4 replicates. The treatments consisted of the maintenance of 0, 25, 50 and 100% of the straw on the soil, which resulted in 0, 4,2; 8.7; and 18.9 Mg ha-1 of straw on the soil, respectively. The soil samples were drawn 0.90 m inter-row with 0.10 m depth, stored in plastic bags with breathing apparatus and taken to the laboratory for immediate extraction. The microbial biomass of the soil was estimated using the Fumigation-Extraction method of Vance et al. (1987). The concentration of microbial C in extract of 0.5 mol L-1 of potassium sulfate (K2SO4), as well as the C-labile extract was determined in Shimadzu® TOC-VCPN® equipment (Tokyo, Japan). No significant difference was observed between treatments for C and N-microbial values and CBM / NBM ratio (p> 0.05). In spite of this, the highest values of CBM were found when 18.9 Mg ha-1 of straw was kept on the soil (without removal), which may be justified due to the greater amount of residue available to the microbiota. For this treatment, an average value of 376 mg C / g Dry Soil (C-BM) was observed. Lower C-BM levels were observed for treatments with 8.7 and 0 Mg ha-1 with 256 and 264 mg C / g dry soil, respectively. For N-BM, the highest observed values were for treatments with 0 and 18.9 Mg ha-1, with a mean of 25 and 24 mg N / g dry soil (N-BM), respectively. In fact, the straw deposition did not reflect on the analyzed variables, a fact that may have been provided by adequate water sufficiency beyond the short straw deposition period (1 year) for evaluation.

(9125 - 2421) Energy balance in corn culture, cultivated in different soil conservational preparation systems

Gabrielle Passos[1]; Michael Mazurana[1]
UFRGS[1]

The need to produce food on a large scale, to meet the growing demand of the population, is becoming a bigger problem every day. That is why the search for new sources of energy and the reformulation of production systems dependent on fossil fuels are vital. In this sense, one of the most appropriate ways to evaluate the level of production /consumption of agriculture in a stable region is the analysis of its energy flows associated with the various activities carried out in the systems. The determination of the best management strategy for an ideal agricultural system will depend not only on the analysis of the endemic environmental conditions and the economic data of the activity, but also on the definition of the energy balance, a basic instrument capable of maximizing energy gains through better knowledge of the energy input/output relationships in agricultural production. Therefore, the objective of this research was to analyze and evaluate the energy efficiency of corn (Zea mays) production for grain, cultivated in different conservational tillage, in order to establish the energy flows through the identification of total demand and efficiency, reflected by the net gain and the output-input ratio, quantifying all the inputs used (fertilizers, pesticides, machines and equipment) and produced products that are transformed into energy units for final accounting. This experiment was installed at the Experimental Agronomic Station of UFRGS, located in the municipality of Eldorado do Sul, on a typical Argissolo Vermelho Distrófico under Cfa climate, according to Köppen. Four methods of soil preparation (treatments) with two replications, in a completely randomized design, were tested: no – tillage (NT), no - tillage with chiseling every 9 years (NT+Ch 9), chiseling using an equipment with a clod-breaking roller (ChR), and chiseling followed by disking (ChD). Due to meteorological adversities in the corn crop harvest period, the results cannot be fully compiled, analyzed and discussed to date. With the data, we can understand the cause-effect relationship of soil conservation treatments in the energy balance and search, each time more, the balance between sustainability and agricultural productivity.

(4696 - 3153) Eucalyptus harvest residues decomposition as affected by nitrogen fertilization and residue incorporation

Thaís Corrêa Sales[1]; Gustavo Conforti Ventura Mayrink[1]; Helen Carla Santana Amorim[1]

Universidade Federal de Viçosa[1]

Eucalypt plantations have been established in areas with predominantly low- fertility soils, in which nutrient cycling is critical for forest sustainability. However, despite continuous research on harvest residues management, the extent by which its decomposition rate is affected by management practices, such as N fertilization and residue incorporation still need to be better understood. Thus, the main goal of this study was to assess the decomposition dynamics of combined residue (leaf + twig + plant litter) of eucalyptus as affected by N fertilization and residue incorporation. The experiment was conducted in Três Lagoas, MS, Brazil, and consisted on four treatments mounted in a complete 2x2 factorial scheme. The treatments were: N fertilization + residue incorporation, N fertilization + without residue incorporation, without N fertilization + residue incorporation, and without N fertilization + without residue incorporation. The amount of N applied in the fertilized treatments was 200 kg ha^{-1}. The residue decomposition was evaluated in each experimental unit at the beginning of the experiment (0), and after 3, 6, 12 and 36 months of the experiment installation. The experimental units consisted on PVC pipes of 15 cm in length and 15 cm in diameter, installed up to 10 cm deep in the soil. The highest decomposition rate was verified upon residue incorporation in soil, despite of the N fertilization. This might be justified by the increased contact of the residues with soil, which favors the action of microorganisms. On the other hand, the lowest decomposition rate occurred in the surface residue when N was applied. This may be due to N immobilization in the surface residue. Therefore, the incorporation of residues in soil provides rapid residue decomposition. N fertilization is not determinative to residue decomposition when the residue is incorporated in soil; however, it affects positively the decomposition of the surface residue.

(4383 - 446) Evaluating Heavy Metal Distributions in Agricultural lands near Industrial complexes in Jeon-Buk Regions in Korea

K.I. Kim[1]; K. K. Lee[1]; J.H. Han[1]; S.W. You[1]; S. Sorakon[1]

Mokpo National University[1]

Evaluating hevy metal distributions in agricultural lands near industrial complexes are very important issues in Korea. Especially, in southwestern part of Korea, heavy metal distributions such as cadmium (Cd), chromium (Cr), nickel (Ni), lead (Pb), mercury (Hg), and zinc (Zn) have not evaluated yet precisely. The obejctives of this study were to investiage heavy metal contaminations and to provide heavy metal concentrations in agricultural lands near industrial complexes in Jeon-Buk Province in Korea. Fifteen industral complexes in Jeon-Buk province in Korea were chosen. 300 Soils with a depth of 0-15 and 15-30 cm within 0.5 and 1 km radius at each industrial comples were sampled at 10 agricultural fields randomly with four directions (east, west, south, and North) in 2017. Soils were analyzed for As, Cd, Cr, Cu, Ni, Pb, Zn, and Cr^{+6}. Research results showed that soil samples did not exceed the levels of Soil Contamination Warning Standard (SCWS) for cultivated lands (Region 1), which is regulated by Soil Environment Conservation La (SECL), Ministry of Environment (MOE) in Korea. All of heavy metal concentrations were lower than their warning levels. The warning levels are 25, 4, 100, 200, and 200 mg/kg for As, Cd, Ni, Pb, and Zn, respectively.

(2644 - 1967) Evaluation of the accuracy of maps of apparent soil electrical conductivity (ECa) in different sample densities

Kaynara Fabíola Lima Kavasaki[1]; Valdeir Moraes Soares[1]; Ricardo Santos Silva Amorim[1]; Oscarlina Lúcia dos Santos Weber[1]; Eduardo Guimarães Couto[1]; Gilmar Nunes Torres[1]

University of Mato Grosso[1]

The measurement of apparent soil electrical conductivity (ECa) is among the most common tools used in research in precision agriculture, due to the spatio-temporal characterization of soil properties that influence crop yield, thus presenting potential for determination of soil management zones. This study was conducted to evaluate the accuracy of ECa maps in different spacing schemes. Four areas of about 30 ha were cultivated with sugar cane and subjected to different times of applications of vinasse. The treatments comprised: A1 - Latosol of clay texture fertigated with vinasse for more than 10 years; A2 - Latosol of medium texture fertigated with vinasse more than 10 years; A3 - sandy texture neosol without fertigation with vinasse; A4 - Latosol of clayey texture without fertigation with vinasse. For each area the following ECa read spacing schemes were created: 12.5 m; 25 m; 37.5; 50 m; 75 m and 100 m. To evaluate the accuracy of the ECa maps obtained for the different spacing schemes was performed using the correlation coefficient, Willmott concordance index and confidence index. Results showed that the increase in the distance between lines of reading of the apparent electrical conductivity of the soil reduced the confidence index. However, spacing of 25 and 37.5m gave rise to maps that maintained the same patterns of variability of the map produced from the spacing of 12.5m.

(9410 - 965) Geological and magnetic susceptibility of land use support capability managment in watersheds.

Renata Cristina Araújo Costa[1]; Gener Tadeu Pereira[1]; Teresa Cristina Tarlé Pissarra[1]; Diego Silva Siqueira[1]; Fernando António Leal Pacheco[2]

São Paulo State University, School of Agricultural and Veterinary Studies (FCAV), Campus Jaboticabal, São Paulo State, Brazil.[1]; Trás-os-Montes and Alto Douro University, Ap 1013, Vila Real, Portugal[2]

Evolution is a standard indicator of spatial variability of soil attributes, including the magnetic susceptibility, and it can be used as a criterion for planning land use and occupation. This study intended to improve knowledge about the physical and gemorphological behavior of soil associated with pedogenesis, confirming the representative of the Tiete River Basin with the Occidental Plateau of São Paulo State (*Plantalto Ocidental Paulista* - POP), inserted on the sedimentary basin of Paraná, to define the analyzes of land use capability maps using Tietê watershed subbasin. The comparative analysis at this moment has been made on the geological map of 1: 700.000, dissection map and kriging map of magnetic susceptibility. As result of the comparative analysis of the geologies, two main formations were identified Serra Geral (POP - 18.9% of area) and (Tietê River - 11.7% of area), formation of the Vale do Rio do Peixe (POP - 53.4% of area) and (Tietê River 58.0 area). The dissection map analysis also found similarity of occupation high dissection (POP - 16%) and (Tiete River 21%), intermediate (POP - 69%) and (Tiete - 68%) and less intense (POP - 15%) and (Tietê River - 11%). For the analysis of magnetic susceptibility with mean ± sd (standard deviation), POP 9.79 ± 2.02% and Tietê River 8.60 ± 1.77%. We can conclude that Tietê River Basin

can be used as a representative study basin to detail the problematic and for a better understanding of the geological conformation of the terrain as for the development of land use support capacity indicators aiming to minimize the impact of agricultural production.

(4440 - 3130) Influence of the crop-livestock farming integration system on the accumulation of organic matter in the Cerrado of Mato Grosso.

Bianca Nathiele Favetti Chagas[1]; Michael Ortigara Goulart[1]; Roberto Antonio Savelli Martinez[1]
Universidade do Estado de Mato Grosso[1]

One of the main difficulties for the agriculture in the Brazilian Cerrado is the increase of organic matter, being this a determinant factor for arise of productivity of the agricultural crops. As an alternative of improving the scenario the process of establishment of technologies such as the non-tillage system, the use of cover crops and a crop-livestock integration began. The use of forage plants in cropping areas guarantees an improvement on the chemical, physical and biological properties of the soil, due to the presence of soil straws and improvement of the soil conditions as aeration, as well as the water infiltration capacity. In this context, the aim of this work was to evaluate the influence of the crop-livestock farming integration system on the increase of organic matter content of the soil, on the Cerrado of Mato Grosso – Brazil, during four consecutive crops. Thus, the organic matter content in two different cropping systems in a rural property in Campo Novo do Parecis– Mt were evaluated.The areas consisted of a succession of soybean-corn and another with crop-livestock farming integration system. The cropping periods analyzedwere: 2014/2015, 2015/2016, 2016/2017 and 2017/2018. In all the cropping periods, the forage used in the integration area was the *Urochloa ruziziensis* with the cattle placed on the area between the months of June and September and average-stocking rate of 12 animals per hectare. The area with soybean-corn succession and the area with crop-livestock integration had250 and 242.9 ha respectively.Several soil samples were taken being one sample every 20 ha and a composite unit was made in order to perform a soil chemical analysis. According those analyzes carried out, the organic matter content in the with succession area soybean-corn were 3.68%, 3.21%, 3.07% and 3.47% in the cropping years 14/15, 15/16, 16/17 and 17/18, respectively, while in the area of crop-livestock integration system, the levels were 3.30%, 3.30%, 3.21% and 3.99%. As a result, there was a trend of organic matter increase in areas with crop-livestock integration. Thus, the crop-livestock integration system, which is a sustainable practice, tends to improve the organic matter content on soils and improve the exploitation of agriculture areas, thus being an important option to obtain high productivity in the edaphic-climatic conditions of Mato Grosso.

(6818 - 2225) Magnetic soil susceptibility in the "Cerrado" of Piauí, Brazil

Sammy Sidney Rocha Matias[1]; Gasparino Batista de Sousa[1]; Maria Iolanda Leal Lustosa[1]; Cinthya Herley Kochhann Ribeiro[1]; Ronny Sobreira Barbos[2]; Rafael Felippe Ratke[2]; Júlio César Azevedo Nóbrega[3]; Tarcisa Fé da Silva[1]; Maysa Danielly de Sousa Ferreira[1]; Inária Vogado Borges[1]
Universidade Estadual do Piauí[1]; Universidade Federal do Piauí[2]; Universidade Federal do Recôncavo da Bahia[3]

Magnetic susceptibility (MS) is a non-destructive attribute that can serve as a parameter forassessment of soil management. The present work had as objective to verify the variation of the magnetic susceptibility of the soil in an area of tropical savannah (Cerrado) of Pauí, Brazil. The work was conducted in the municipality of Barreiras - Piauí, whose geographic coordinates are 10º03 'south latitude and 45º68' longitude west, with an average elevation of 400 m. The climate of the region is type AW', average temperature of 27 ° C. The average annual precipitation is around 1200 mm, with concentrated rainfall from November to April. The soil was classified as ENTISOLS. The area under study was delimited and georeferenced, being selected an area of 1 (one) hectare with dimensions of 100 x 100 m. In this area a regular mesh of 10 x 10 m was assembled, totaling 121 sample points, being collected soil samples in the depth of 0,0-0,20 and 0,20-0,40 m. The parameter evaluated in the work was the magnetic susceptibility of the soil (MS), being analyzed by means of an analytical balance. Soil characterization was performed by means of a soil profile. Data were evaluated through semivariograms using the GS + program, and the models were adjusted in spherical, exponential and gaussian. By means of these models, we predicted each attribute in areas not sampled by kriging, represented in contour maps, using the surfer program. The choice of the theoretical models was performed, taking into account the sum of the square of the residuals, the coefficient of determination and, later, the correlation coefficient obtained by the cross-validation technique. The classification of the degree of spatial dependence was performed based on the ratio between the nugget effect and the level ($C_0/C_0 + C_1$), being considered strong, higher than 75%, moderate between 25% and 75%, and lower of 25%. The magnetic susceptibility was adjusted at both depths to the exponential model. The degree of spatial dependence was classified as weak (less than 25%). The range reached for both depth (0.0-0.10 and 0.20-0.40 m) distances of 18 and 32 m, respectively. The spatial determination coefficients (R2) for both depths were above 0.60. The cross-validation regression correlation confirmed the result of R2, by obtaining values close to 1 (b) and 0 (a). Magnetic susceptibility identified spatial variability in soil. The depth of 0.20-0.40 m was better for identification of the magnetic susceptibility.
Keywords: Soil management, magnetization, spatial variability.

(8878 - 719) Morphological characterization and yield of bean and corn crops in different soil classes of a toposequence from Unaí, Minas Gerais

Alceu Linares Pádua Junior[1]; Iago de Oliveira Bastos[1]; Laura de Lima Rodrigues[1]; Rannery Camargos dos Santos[1]
Universidade Federal dos Vales do Jequitinhonha e Mucuri[1]

The classification of soils is essential so that the knowledge acquired by research and agricultural practice can be scientifically organized. A plant develops vigorously in one location, while in another, it produces less (considering the same climate and management conditions), so it is important to know the soils of both locations. Soil chemical and morphological conditions associated with climate can influence the development of crops in different production environments. The objective of this work was to evaluate the morphological characteristics and chemical attributes of soils of a topossequence from Unaí, state of Minas Gerais, cultivated with the crop of bean in the year of 2015/2016 and of corn in the year of 2016/2017. The following parameters were evaluated in the bean crop: yield (Mg ha^{-1}), sieving, color, and *fusarium* infestation. In the corn crop, the evaluated parameters were: yield (Mg ha^{-1}), length cob, and number of grains per cob. All the variables were compared by the 5% t-test. In the landscape, the soils were distributed as follows: in the upper

position was the Petroferric Eutrustox (FFe) phase, in the middle position was the Petroferric Haplustox (LVAd-petroferric) phase, and in the lower position was the Plinthaquic Haplustox (LVA-plinthaquic) phase, being all the phases with clayey texture. In the bean crop, the highest values of yield, sieving and color, and the lowest *fusarium* infestation were recorded for the FFe, probably due to the lower accumulation of water in this phase when compared to the LVAd-petroferric and LVAd-plinthaquic phases in function of the soil position in the landscape and the presence of impediment in the subsurface. In the corn crop, the parameters evaluated were higher for the LVAd-plinthaquic phase, followed by the LVAd-petroferric phase and less expressive in the FFe phase, probably due to the greater effective depth and accumulation of water during the cycle of the crop imposed by the presence of petroplintite at 70 cm depth in the LVAd-petroferric phase, to the presence of mottled and plintite at 120 cm in the LVAd-plinthaquic phase and to the lowest effective depth in the FFe phase. Therefore, the presence of the evaluated morphological attributes had a distinct influence on the development of the bean and corn crops, regardless of the chemical condition of the soils.

(7977 - 1744) Physical structure of an obstacle quartzarenic neosol in different systems of use in the brazilian pantanal region

Jeferson da Silva Muniz[1]; Victor Barros damacena[1]; Giovana Fornaciari Moreira[1]; thalia Inês Aleixo barbosa[1]
Instituto Federal do mato grosso - campus Caceres/ professor Olegário baldo[1]

The sustainable use of the wetland soils should follow the principles of agroecology, where the interrelations between the different elements of the agroecosystem are considered. Soil management is an art that requires a lot of care and common sense, since its use in the wrong way leads to inexpressible losses in its biodiversity, maintenance and recovery. In view of the above, this study aimed to investigate the physical structures of a quartzenetic orthotic neosol in different systems of use in the Pantanal. The study was conducted in the Pantanal area located at Bom Sucesso site, Cáceres - MT (Brazil). The experimental area is at latitude 15º47'41.3 "S, longitude 57º53'54" W and latitude 110 m. Three treatments with different uses were considered: T1- preserved area, T2- area under pasture and T3- cultivated area. For each treatment, six replicates were collected for the analysis of soil physical attributes. Samples were taken at depths of 0 to 15 cm and sent to the laboratory. In the laboratory the samples were weighed and placed in an oven at 105ºC and after 24 and 48 hours, and after cooling were weighed again. Subsequently, 20 g of soil, weighed in an aluminum container of known weight, were weighed, left for 6 to 12 hours, and then weighed again to obtain the weight of the dried sample at 105ºC. The samples were removed to a volumetric flask of 50 mL, filled with ethyl alcohol and stirred until all the air bubbles had been eliminated and the volume of the flask was complete. The following calculation was performed: Particle density (g cm3) = a / 50 - b where a = weight of sample dried at 105 ° C and b = volume of alcohol spent. Finally, the Total Poros Volume was calculated by the formula: Total porosity = 100 (a - b) / a where a = actual density and b = apparent density. The analysis of variance of the data and the comparison of the averages (Tukey to 5%) was performed using software R. According to the results, it was verified that T3 presented higher density and lower porosity value. In T1, there was lower value of soil density and higher value of porosity.

(3648 - 450) Predicting and evaluating spatial soil information's using soil profile data and soil maps - Examples prediction soil carbon stock in Germany and potential benefits from biochar application in Ethiopia

Andreas Möller[1]; Tegbaru Belete[2]; Selamyihun Kidanu[2]; Konen Lars[1]; Andreas Richter[1]; Tobias Seitz[3]; Steffen Schulz[4]
Federal Institute for Geosciences and Natural Resources (BGR), Hannover, Germany[1]; Agricultural Transformation Agency (ATA), Addis Ababa, Ethiopia[2]; Biochar Europe UG, Halle, Germany[3]; Gesellschaft für Internationale Zusammenarbeit (GIZ), Eschborn, Germany[4]

Predicting spatial soil information is still a challenge, although worldwide many open questions in geosciences, like carbon sequestration in soil, can only be answered with precise soil information. Therefore, enormous efforts are done globally to overcome these knowledge gaps. Two examples are given here for different approaches. The first example is the evaluation of back ground values of soil carbon stocks in German soils, by combining available soil profile information's within the soil information system (FisBO BGR) and the soil map of Germany the BÜK 200 (scale of 1:200 000). The BÜK 200 includes not only spatial soil data, but also involves standardized soil profiles with estimated soil data for every soil polygon. Otherwise huge amounts of soil point data are available within the FisBO BGR and from the federal states of Germany. Coupling the two datasets with a soil carbon model based on the differentiation criteria, soil type, horizon, sample depth and land use revealed very precise soil carbon stocks in German soils. The results confirm that pedogenesis and land use are the main factors determining soil organic carbon stocks in Germany. The second example is the predictions of potential benefits from the application of biochar substrates to agricultural soils in Ethiopia. The evaluation was done in cooperation with the Ethiopian Soil Information System (EthioSIS) project. It is based on their enormous dataset of soil samples collected and analyzed from current crop lands and potential agricultural lands. Using this dataset and predictive satellite imageries in the ensemble modelling of three machine learning algorithms (MLA) Ethiopian wide spatial distributions of soil parameters were determined. Based on an evaluation matrix including these soil parameters (pH, SOM available phosphorous and CEC) benefits from biochar application were calculated. The results indicate that there is a significant area of soils which would benefit greatly from the application of biochar substrates.

(5944 - 2640) Productivity and quality of Tempranillo grapes cultivated on three different soils in the Sao Francisco Valley, Brazil

Mayame de Brito Santana[1]; Mateus Rosas Ribeiro Filho[1]; Brivaldo Gomes de Almeida[1]; Giuliano Elias Pereira[2]; Tony Jarbas Ferreira Cunha[3]; Antonio Mendes de Souza Nascimento[3]; Kaline Gomes da Costa[3]; Joyce Fagundes de Souza[3]; Jamilla Fiama Maia Silva[3]
Federal Rural University of Pernambuco, Recife-PE, Brazil[1]; Embrapa Grape & Wine/Tropical Semiarid, Petrolina-PE, Brazil[2]; Embrapa Semiarid, Petrolina-PE, Brazil.[3]

Brazilian viticulture ocupies an area of 81 thousand hectares, with vineyards planted from extreme south until regions nearby equator line. At northeast of Brazil, especially at the San Francisco Valley, occured an expansion of grapevine culture, due to ideal conditions of soil and climate, obtaining more than one harvest per year. Studies aiming the grapevine zoning of the region indicates the potential of several cultivars adapted to local conditions and suitable to contribute for the typicality of the wines, as for example, using grapes from Tempranillo cultivar. The objective of this work was to evaluate the

productivity of Tempranillo cultivar grapevines on three different soil types and how these soils interfere on fruit quality. The study took place at Santa Maria farm, with Tempranillo cultivar, producing 2 harvests in 2017 (May and November) in an eight year stablished vineyard, growed in spalier, at the county of Lagoa Grande-Pernambuco State, Brazil. Three soil profiles were described and sampled, identified as: Argissolo Vermelho-Amarelo Eutrófico abrúptico plintossólico (Ultisol), Argissolo Amarelo Eutrófico abrúptico (Ultisol), with medium texture and Argissolo Amarelo Eutrófico abrúptico (Ultisol), with coarse texture, abunding with gravel and pebbles. The area of each soil was delimited, and in these areas were harvested grapes, counted, weighed, and measured the pH, total soluble solids (ºBrix), total titratable acidity (TTA) of the must and the mass and volume of 100 berries. The Yellow Argisol with medium texture presented average yield aproximately 20% higher than the Red-Yellow Argisol on both harvest, while the Red-Yellow Argisol presented lower productivity in comparison to the two other types of soil on both harvest. However, this lower productivity can promote concentration levels of phenolic and aromatic compounds, wich have great importance in enology, since they are related directly or indirectly to wine quality, being responsable for its color, body and astringency. The number and weight of bunches per plant also presented higher values on the area of the Yellow Argisol with medium texture, differing statistically from the other areas on the winter harvest. The pH, ºBrix, TTA, mass and volume of bunches did not differ statistically on both harvests. Also, differences can be noticed between the values that can lead to wine production with different quality, so that can aggregate value to the product.

(8274 - 399) Soil Permeability for Geotechnical Mapping Purposes Applied to Planning

Alan Silveira[1]; Cenira Maria Lupinacci[2]; Patrícia Borges Silveira[3]
Federal University of Uberlândia (UFU), Geography Institute (IG), Campus Monte Carmelo, MG, Brazil[1]; Territorial Planning and Geoprocessing Departament (Deplan) of São Paulo State University (UNESP), Campus Rio Claro, SP, Brazil[2]; Geographer and PhD Student in the Graduate Program in Geography (PPGG) of São Paulo State University (UNESP), Campus Rio Claro, SP, Brazil[3]

The surface permeability is an important data for the characterization of the unconsolidated materials, as it directly interferes with the infiltration and flow of rainwater. The identification of the areas of greater and lower permeability also contributes to an evaluation of the materials that are more resistant and more susceptible to the erosive processes. Therefore, this work aims to present the results of the permeability of surface horizons acquired for the organization of the chart of Unconsolidated Materials of the Córrego das Ondas Basin, located in the urban expansion area of Piracicaba (state of São Paulo, Brazil), established between latitudes 22º38'30''and 22º41''30'' S and longitudes 47º41'15'' and 47º43'30'' W. The document was adapted to the proposals of Zuquette et al. (1994) and Pejon and Zuquette (1997). In the field, with the use of cups to collect undisturbed samples, were collected 21 samples distributed in toposequences in the basin under study. Afterwards, these samples were sent to the Surface Formation Analysis Laboratory (SFAL) of Deplan/IGCE/UNESP *Campus* of Rio Claro for the experiments procedures of calculation of permeability coefficients (cm/s, factor K), through the Permeameter of Variable Load, using method B of NBR 14545. We found the following results: (1) Homogeneous material of intermediate thickness derived from the Serra Geral Formation with low to medium permeability (3,2 x 10^{-4} a 1,6 x 10^{-3} cm/s; (2) Thick homogeneous material derived from the Corumbataí Formation (reddish facie) with medium permeability (1,4 x 10^{-3} a 5,0 x 10^{-3} cm/s); (3) Thick heterogeneous material derived from the Corumbataí Formation (reddish facie) with low to medium permeability (5,2 x 10^{-4} a 1,4 x 10^{-3} cm/s); (4) Thick homogeneous material derived from the Corumbataí Formation (reddish facie) with low permeability (1,4 x 10^{-4} a 7,0 x 10^{-4} cm/s); (5) Homogeneous material of low thickness derived from Corumbataí Formation (reddish facie) with very low to medium permeability (3,7 x 10^{-5} a 1,0 x 10^{-3} cm/s); (6) Homogeneous material of low thickness derived from Corumbataí Formation (grayish facie) with medium to high permeability (4,2 x 10^{-3} a 1,1 x 10^{-2} cm/s); (7) Unconsolidated material derived from river dynamics.

(8690 - 724) Spatial and temporal analysis of synergy and trade-offs between Agroecosystem services in the Dry farming areas of northeast China in nearly a decade

Huang Yuanfang[1]; Zhuo Zhiqing[1]; Xin An[1]; Sun Zhongxiang[1]; Zhang Shiwen[2]; Cao Meng[1]; li Zhen[1]
China Agricultural University[1]; Anhui University of Science and Technology[2]

In the process of transition from traditional agriculture to modern agriculture, the role of agriculture is changing from a single production function to a multi-functional one. Comprehensive evaluation on the synergetic degree of agroecosystem has guidance for the area sustainable development. In this research, taking 85 counties located in the Dry farming areas as a case study, the synergy and trade-offs between Agroecosystem services from 2005 to 2015 were analyzed based on the synergetic model and root mean square error (RMSE). This research aims at revealing the temporal and spatial evolution characteristics of three agroecosystem services. The results showed that (1) the synergy degree of agroecosystem service was at low level in the dry-farming areas of northeast China, it has decreased 0.12 in the last decade. The synergy degree of production function and ecological function decreased 0.03 and 0.45, respectively, but the synergy degree of living function increased slightly. Except for the Drying farming areas in Liaoning province, the synergy degree of agroecosystem services decreased seriously in Jilin province and Heilongjiang province. (2) There were spatial-temporal trade-off relationships among the various functions of agroecosystem. From 2005 to 2010, the trade-offs between production-ecological function and living-ecological function benefited from ecological function. However, from 2010 to 2015, the trade-offs benefited from the production function and living function. Moreover, the root mean square error among the functions were declining with the changing of benefit direction. (3) The main reasons causing the fluctuation of synergy degree were the trade-off relationships among three functions and the changes of their benefit direction. Furthermore, the changes of RMSE can be taken as an effective indicator to evaluate the synergy degree of agroecosystem services in Dry farming areas of northeast China.

(2080 - 953) Water infiltration in soils subjected to direct and conventional planting systems.

Maria Caroline Garcia Paschoal[1]; Camila Pereira Cagna[1]; Bruna Camila Lameira[1]; Maycon Diego Ribeiro[1]
Universidade Federal do Paraná[1]

The water infiltration in soil is a process in which occurs water penetration in the soil profile, depends on its texture and varies

according to the use and management that it is subjected to. The objective of this work was to determine the Basics Infiltration Velocity (BIV), the estimation equations of Accumulated Infiltration (AI) and the Infiltration Velocity (IV) throughout the Kotiaskov's potential model in a clay-textured latosol subjected to different management systems. The experiment was conducted in a property located in the city of Borrazópolis, state of Paraná. The infiltration tests were performed with a ring infiltrometer, composed by a 25 cm and a 50 cm diameter rings, both 25 cm height, from which 15 cm were buried and installed concentrically. During the experiment realization, water was simultaneously added in both rings and, every 2 cm of water blade height decrease, the infiltration time was measured with a chronometer, repeating this process until three sequences of equal measurements in time and height could be observed. The experimental design was made in two distinct areas, one with conventional planting system implanted 3 years ago and another with a direct planting system implanted 20 years ago. The calculated BIV for the soil with direct planting system was 2,25 cm h^{-1}, classified as high BIV, whereas the calculated BIV for the soil with conventional planting system was 4,56 cm h^{-1}, classified as very high BIV. The accumulated infiltration equation for the soil subjected to direct planting system was AI = $0,429T^{0,620}$ and for the soil subjected to conventional planting system was AI = $0,405T^{0,752}$. The conventionally prepared soil presented higher infiltration velocity concerning to the direct prepared soil, fact that can be explained due to the conventional system, during the soil preparation, promote great movements on it, causing its collapse and favoring the process of water infiltration. On the other hand, in the direct planting system, where there's a reduction or elimination of soil preparation, the haulm decreases the superficial rain water flow and increases the infiltration capacity of this soil. Therefore, the conventional planting system exhibited BIV and AI values higher than the direct planting system due to the vast soil movements during its preparation for planting.

(9008 - 538) Zoning Edaphic for grapevines in the Municipality of Santa Maria of Boa Vista-PE.

Tony Jarbas Ferreira Cunha[1]; Mateus Rosas Ribeiro Filho[2]; Iedo Bezerra de Sá[3]; Mayame Brito[2]; Vanderlise Giongo[3]; Tatiana Yaco Taura[3]

Embrapa Semiário[1]; UFRPE[2]; Embrapa Semiárido[3]

Variety, grapevines composition and vines development are directly related to the soil, which, together with the climatic conditions, determine grape sensorial qualities as well as the quality of the wines. The soil, in turn, through its attributes, is of great importance due to its influence on the wines qualities. The goal of this edaphic zoning was to identify the areas with the greatest potential for grapevine growing, in the municipality of Santa Maria da Boa Vista, PE, and thus contribute with the geographical indication of origin for the wines produced in the mentioned municipality. In this zoning, an semi-detailed survey in the 1: 25,000 scale was used as the basic material. The edaphic requirements of the vine were systematized, each of the variables being classified into four categories. Four classes of suitability for grapevine growing (1-Preferential, 2-Recommended, 3-little Recommended and 4-Not Recommended) were defined. In the municipality of Santa Maria da Boa Vista it is verified that there is no Preferential class. Most of the area falls into class 4 (not recommended), making a total of 20,857.61 ha and corresponding to 40.4% of the mapped area. The first and only limiting factor for this class was character. The second largest area was the Recommended Class, which represents a total of 20,151.87 ha corresponding to 38.3% of the mapped area and having as a first limiting factor the texture of the B-horizon. The class little recommended has as first limiting factor the soil class, corresponding to an area of 11,650.78 ha or 22.1% of the mapped area. In the little recommended or Non-Recommendable area, it is suggested a greater mapping detail in the soil studies, since in the legend appear only components with better potential than the one evaluated for the first component of the legend. The municipality of Santa Maria da Boa Vista presents a large area with potential for grapevine growing. In the areas little recommendable or not recommendable, it is suggested a greater detail in the studies of soil survey because, in the legend appear only components with better potential than the evaluated one for the first component of the legend.

C3.1.2 - Multi-scale and multi-domain approaches to develop smart farming

(3493 - 1948) Arbuscular mycorrhizae in agroforestry systems with oil palm in the Amazon

Rodrigo da Silva Maia[1]; Steel Silva Vasconcelos[2]; Danielle do Socorro Silva Batista Melo[3]

UFPA[1]; Embrapa[2]; UFRA[3]

In tropical agroecosystems Arbuscular Mycorrhizae (AM) has the role of increasing the soil volume explored by host plants in the water and nutrient uptake. The oil palms (Elaeis guineensis) produce few root hairs and possibly need the mycorrhizal symbiosis in the field. In the Amazon region, conventional palm oil cultivation (monoculture) has been widely used, however an alternative and sustainable model inserting the oil palm in Agroforestry Systems (AS) was proposed for the municipality of Tomé-Açú, state of Pará. This study evaluated the AM in oil palms of approximately 10 years grown in two AS types, one composed by species with the function of producing biomass for the soil (ASfertilizer) and the other composed by diverse species (ASbiodiverse) and also in oil palms conventionally grown (monoculture) in the municipality of Tomé-Açú. In September 2017, six simple samples composed of five subsamples of soils (0-10 cm) and fine roots of oil palm (diameter ≤ 2 mm) were collected in four plots (30m x 30 m) in these treatments. Spores were extracted by the wet sieving method and the roots were cleared in 10% KOH solution and stained with 0.05% Trypan blue. Analysis of variance of repeated measures was used to test the differences between treatments and the results compared by the Turkey test at the 5% probability level. The results showed a significant difference in the spore density, ASfertilizer and ASbiodiverse presented a mean of 1.67 and 1.05 spores/g, respectively, while the mean monoculture of 2.61 spores/g. The mean of mycorrhizal colonization in the ASfertilizer and ASbiodiverse were respectively 40.81% and 45.12%, while in the monoculture the average was 14.5%, with a significant difference. The higher density of spores in monoculture compared to AS can be explained by processes related to the history of the area and random patterns of mycorrhizal dispersion. On the other hand, the higher mycorrhizal colonization in AS indicate that soil management through a system of low inputs and addition of organic matter may increase colonization. Therefore, oil palm cultivation in AS may favor mycorrhizal colonization, improve root capacity and provide a more sustainable palm oil management for the Amazon region.

(8904 - 1493) Characterization of soil properties effects on apple production in South Uruguay

Alliaume, Florencia[1]; Severino, Vivian[1]; Alvares, José Luis[1]; García, Marcia[1]; De Iacovo, Matías[1]; Tachini, Ramiro[1]; Arias, Mercedes[1]

Facultad de Agronomía, UDELAR[1]

Soil properties that may influence on apple production are being evaluated on 24 fields cropped with the two varieties most exported of Uruguay: Gala Baigent and Cripps Pink, on farms located in the south of the country. The yield of apple in Uruguay in relation to the neighbor countries are: 30% of the Chile and 45% of the Argentina and Brazil, according to FAOSTAT database for 2016. The causes of such a low productivity, in spite of using technologies as plant density higher than 2000 pl/ha, dwarf- inducing rootstocks, changes on conduction system and irrigation, needs to be depicted. Soil properties and their current management are hypothesized to be an important limiting factor that explain the low yields of export quality apples. The aim of this study is to assess soil characteristics of apple orchards to identify their main limitations for achieving larger yields of two highly productive varieties and discuss best management practices to increase the yields. Accordingly, potentials and limitations of topography and soils are being assessed using field survey to support the evaluation, together with climatic and management variables. The topographic characteristics to be assessed include slope and surface drainage class. A soil profile pit was opened and described in each field, and soil samples from each horizon were obtained. Soil properties to be analyzed are: soil texture, soil pH, soil organic carbon, $CaCO_3$, electroconductivity, cation exchange capacity, available phosphorous, drainage class, water retention properties, soil root depth, soil morphology, depth to a water table, and soil resistance with a penetrometer at field capacity. All these variables will be analyzed together with apple yields of three years using clustering analysis. The soil properties that explain most of the yield variation will be used to build a capability index and limits will be proposed for each of the soil characteristics. It is expected that resulted soil capability index will provide a reasonable prediction of potential apple yield for mature apple orchards of var Gala Baigent and Cripps Pink. Results will be discussed taking into account-predefined optimal growth requirements. Soil management strategies to lift soil constraints will be discussed with local stakeholder, and results will be taken into account in future research.

(6835 - 1694) Conventional and ecological crop management systems affect bacterial diversity on the phyllosphere

Carolinne Rosa de Carvalho[1]; Elke Jurandy Bran Nogueira Cardoso[1]
ESALQ/USP[1]

Crop management affects physical, chemical and biological properties of the agroecosystem, and may have a significant impact on soil fertility, crop quality and ecosystem diversity. Conventional agriculture has been well established over the years and uses efficient but environmentally aggressive methods to optimize food production and to yield high profit. Controversely, agroecological alternatives apply long-term approaches that stimulate and explore ecological services provided by the environment and the organisms interacting in the field. Microbial communities can provide relevant benefits to plant health and fitness, which can therefore reflect on crop quality and productivity. In this study, we proposed to evaluate the effect of conventional and ecological management on the bacterial diversity of *Citrus* phyllosphere, identifying possible divergences in microbial structure and composition. Leaves were sampled in January/2017 in Mogi Guaçu, SP, sampling about 40 leaves of 20 trees from each treatment area. The bacterial community of the phyllosphere was analysed by Illumina sequencing of the 16S gene, allowing to determine the bacterial diversity and to compare them between treatments. The obtained amplicons were clustered and analysed using the software QIIME 1.9.1, and identified according to the database Silva. We found the phyla Proteobacteria, Bacteroidetes, Actinobacteria and Firmicutes to be the dominant groups in both treatments, thus suggesting them as phyllospheric residents, which means that they compose this microenvironment independently of the management. However, the treatments applied to the plant may affect the abundance and distribution of those bacterial phyla. A rarefaction curve of the data allowed us to compare the alpha diversity in order to overlook the influence of management on the bacteria. We obtained a higher bacterial diversity in the ecological management, which can benefit the plant by decreasing its susceptibility to colonization by pathogens. Higher and more complex bacterial communities on the phyllosphere normally implies in better crop quality and productivity. The structure of the bacterial community also presented some divergence between the managements, demonstrating a significant dissimilarity when evaluated by a PCoA. This dissimilarity can indicate the modulation of the bacterial community structure by the kind of agricultural management, inferring that it is an important microbial driver of the phyllosphere.

(4428 - 3202) Evaluation of Soil Nutrients in Drip Irrigation Based on PCA and BP Neural Network

Shuqing Yang[1]
China Inner Mongolia Agricultural University[1]

This reserch is aimed at achieving the comprehensive evaluation of soil nutrient under drip irrigation.By using descriptive statistical analysis, Principal Component Analysis (PCA) and BP neural network, the soil nutrient with drip irrigation under mulch was evaluated in Kezuo Zhongqi,Tongliao which were combined with single factor evaluation and compared with the most widely used fuzzy mathematics comprehensive evaluation results in traditional methods.According to the second national soil nutrient grading standard and verified by measured data,the results show that the comprehensive evaluation level of soil nutrient with drip irrigation under mulch in Kezuo Zhongqi in 2015 and 2016 is grade 3,and we can get more objective results which are more suitable for the actual situation by connecting PCA and BP neural network in the aspect of evaluating level of soil nutrient.It's feasible and reliable to solve the soil science problem by connecting PCA and BP neural network according to the comprehensive study of many experts' achievements.The evaluation method of combining PCA with BP artificial neural network model is suitable for the samples with many factors and high complexity and high precision.Combining PCA with BP neural network can not only solve the problem of too much information and difficulty in analyzing but also reduce the fuzziness and the precision declining.It link the respective advantages effectively. Compared with the traditional method it can be more scientific and reasonable, accurate and effective to comprehensive evaluate the soil nutrients,and the results are more reliable.

(4159 - 559) Goana

Rokhaya Daba Fall[1]; Ibrahima Deme[2]; Abdoulaya Dia[3]
Governing African Development[1]; Post Doctorate[2]; Green Wall[3]

GOANA was the Senegalese initiative to respond to face food crisis and rise in basic food prices. The impact on hungry population leading to riots in several part of the world, in particular in Africa, was the light that led to this initiative. GOANA is a well-known acronym in Senegal and all over the region, as some introduced vegetables and fruits are

so called since 2008. GOANA is the French acronym of « Grande Offensive Agricole pour la Nourriture et l'Abondance », that can be translate in English « Global Agricultural Offensive for Food and Abundance ». This study was an answer of a query: do Senegal have enough agricultural land to sustainably produce more, in order to allow people to feed themself. The study conclusions led to a Global Return to Food Production and to a never reached investment on soil for food production and water management. Two methods and way of calculation led to the same results: than 64% of the territory has been identified as potentially good for agricultural activities. Tools for each method are the Soil and Terrain database (SOTER) and the existing morphopedological maps as well as rainfall and geographical maps and Google earth images. Few terrain verifications were needed. With consideration of regional specificities and adequate definition of "Land aptitude for Agricultural activities", methods used design best farm agrotechnologies and farming systems for each land aptitude category. Critical need for sufficient Food and Fuel have led us to identify and analyze key limiting soil pedoclimatic functions that determine agricultural type and biological crop, trees or animal yield as well as level of investment profitability. Regarding Land Capability there is Will and trust than investment beyond food and fuel.

(9073 - 343) Impact of landuse planning and management on land degradation in Kadawa Irrigation scheme, Kano, Nigeria

Bashiru A. Raji[1]

University of Ilorin, Ilorin, Nigeria[1]

Soil is the basic natural resources that support life on earth hence maintenance of this valuable resource in a state of high productivity, through appropriate sustainable land use planning is a primary necessity. Data from NigeriaSat-1 and ILWIS; a geographic information system (GIS) were used to assess the current and potential landuse on degradation in the Kadawa sub-sector of the Kano River Irrigation Project. Existing soil map of Kadawa at 1:25,000 and topographic map at 1:50,000 were digitized and used to obtain the land suitability/potential landuse map. Supervised algorithm was employed in the classification of the December 2003 NigeriaSat-1 image of Kadawa area. Overall, rainfed agriculture remained the predominant landuse, accounting for close to 50 percent of the total land area. The different land utilization types within the irrigated areas could not be discriminated at the scale of the study. As a whole, irrigated agriculture accounted for only 5 percent of the total land area. Some problems encountered included the misclassification of rivers as settlement and also some irrigated fields were placed as forest/woodland. The most comparative advantage of the NigeriaSat-1 is the provision of the most recent source of image for the country at affordable cost in local currency (Naira). Assessment of the adequacy of current landuse management shows that only 36 percent of the total land area is properly managed while 41 percent of the land area is categorized as over-utilized. About 23 percent of the land area is under-utilized. These are areas of high suitability being utilized for moderate and extensive intensity-use, and also areas of moderate suitability being allocated to extensive-use. Within this land, most severe environmental problems are envisaged to be caused by intensive-use established on soils of moderate and marginal suitability. In all, irrigated cropping and rainfed agriculture are located on about 35,000 ha of land with either severe or moderate soil limitations of depth and poor drainage. In the study area, this has caused rising groundwater table thereby limiting the effective soil depth and increasing salinity. Salinization is evident by the occurrence of black salt patches observable on irrigated fields. Conservation measures must urgently be taken to stem increasing soil erosion and avoid permanent land degradation.

Keywords: Landuse, management, degradation, irrigation

(5446 - 2534) Land use changes in Poland in the years 2004-2014

Piotr Skłodowski[1]; Anna Bielska[1]

Warsaw University of Technology, Faculty of Geodesy and Cartography[1]

The purpose of the research was the analysis of land use changes in Poland, taking into account the exclusion of arable and forest lands from production. The research was based on statistical data on quantity and quality of lands excluded from agricultural and forest production, as well as on changes in land use. The data were analysed for the whole territory of Poland, taking into consideration the administrative division into voivodships, and for two time periods - i.e. 2004-2008 and 2009-2014, in order to identify the changes that may result from the amendments to the Act on the Protection of Arable and Forest Lands that were enacted in 2009 and which repealed the legal protection of arable and forest lands located within the administrative boundaries of cities and towns. The most important problem is the decrease in the total area of arable lands that has been accelerating over the last 25 years. At present there is 0.49 ha of arable lands per one citizen of Poland, while 30 years ago there was 0.53 ha. This problem is aggravated by the constant decrease in the total area of best quality soils, which are protected under the Act on the Protection of Arable and Forest Lands. In the years 2004-2014 lands of the total area of 44,609 ha were excluded from agricultural and forest production in Poland. In order to demonstrate the scale of this problem it should be noted that the total area of lands excluded from production during 10 years equals the area of approximately 3-4 Polish communes. From the perspective of the amendments to the Act on the Protection of Arable and Forest Lands that were enacted in 2009 (repeal of the legal protection of arable and forest lands located within the administrative boundaries of cities and towns) it can be noted that the total area of lands formally excluded from production in the years 2009-2014 (19,201 ha) was smaller than in the years 2004-2008 (25,408 ha). However, this did not follow from any decrease in the area of lands designated for development. On the contrary, in the years 2009-2014 the total area of lands subject to development increased by 55% compared to the years 2004-2008. The decrease in the total area of lands formally excluded from production results solely from the fact that lands located within the administrative boundaries of cities and towns can now be developed without any administrative proceedings on their exclusion from agricultural or forest production.

(9528 - 886) Origin and Properties of Deep Sands of South-Eastern Cambodia

Richard W Bell[1]; Sarith Hin[2]; Veng Seng[2]

Murdoch University[1]; CARDI[2]

Deep sand profiles are a feature of many landscapes in Southeast Asia but explanations for their origin are contested. Deep sand and sand on clay profiles cover a large proportion of the landscape of Cambodia. Our aim was to determine the likely origin of these sands in relation to sand profiles elsewhere in Southeast Asia. The sands in Cambodia are commonly used for rainfed rice production but increasingly attention is turning to their potential for crop diversification in uplands of Cambodia. The current study examined the origin and properties of 19 sand profiles along four toposequences (Kampot, Tramkak, Ponhea Krek, and Rolea Bíer/Tuek Phos districts) in south-eastern Cambodia particularly to recognize those properties that will pose constraints for management of upland crops. From particle size analysis of 19 profiles, sand fractions ranging from 63 to 200 µm and 200 to 600 µm were predominant in most profiles, except for Kampot 4, where the fraction was dominated by sand grains from 200 to 600 µm and five profiles from Kampong Chhnang province, where the three sand fractions (63-200, 200-600 and 600-2000 µm) were equally

prevalent. Clay content was generally < 100 g/kg within 0-80 cm depth but generally increased from 80 to 100 cm depth. Sub-angular and sub-rounded grains were the major shapes of sand grains in most profiles (20-80%). Sub-angular shapes of sand grains in Tramkak and Kampong Chhnang generally decreased from the site at the base of mountain to the lower part of the toposequence. In contrast, percentages of sub-rounded grains were higher in the profile in the lower part of the toposequence. Moderately spherical sand grains were the major class in all profiles, ranging from 40-75% of grains. Based on the above analysis and their proximity to the mountains, the sand profiles sampled along the four toposequences in south-east Cambodia showed the major influence of in situ weathering of siliceous parent materials and to a lesser extent colluvial transport of sands. There was no evidence of long range transport of the sand grains or of any aeolian processes in re-working of the sands.

Keywords: colluvial, granite, particle size analysis, sand grain analysis, sandstone

(3878 - 2979) Predicting potassium availability for eucalyptus in tropical soils

Filipe Bruno de Oliveira[1]; Sergio Henrique Carneiro[1]; Naiara Fernanda de Souza[1]; Cecília Fatima Carlos Ferreira[1]; Ivo Ribeiro da Silva[1]; Samuel Vasconcelos Valadares[1]

Universidade Federal de Viçosa[1]

Mehlich 1 (M1) is the official extractant for P, K and some micronutrients in several states of Brazil. Problems with M1 are frequently reported for P. Another issue is the use of M1 as a K index for plants able to use higher quantities of nonexchangeable K (NE-K) forms (e.g.: eucalypt). We assessed the extractants M1, Mehlich 3 (M3) and Hot Nitric Acid - 2 mol L^{-1} (HNA) as available K indexes for eucalypt. The HNA was included in this work because of the better correlations of this extractant with plant K in previous studies with eucalypt. The experiment was carried out in a greenhouse between 3/12/2017 and 07/04/2017. The treatments were five soils of different textures and mineralogy. The randomized blocks design was used, with four replicates. The experimental units were pots with 2 dm^3 of soil. One seedling of eucalypt (*Eucalyptus urophylla x Eucalyptus grandis* – clone AEC I44) was planted in each experimental unit. Soil samples were collected 2 days before planting. The other nutrients than K were applied equally in all experimental units. The plants were grown for 114 days when they were cut at the soil level. The K accumulation in the plant shoots (plant-K) was measured. A two-way ANOVA and the Tukey test were used to assess if differences in soils had effect on the soil K indexes (M1-K, M3-K, and HNA-K). The Pearson correlation test was used to assess the relationships of the soil tests with plant-K. The soil tests were sensitive to differences among soils. The HNA-K provided a lower discrimination of soils compared to M1-K and M3-K. The extractants M1 and M3 had high correlations with plant K ($r = 0.90$ with $P < 0.05$ and $r = 0.92$ with $P < 0.05$, respectively). We did not find significant correlations of HNA and plant K. The higher importance of exchangeable K pools for short-term K supply to plants explain why M1 and M3 correlated better with plant K. The HNA had a good performance in previous long-term studies for which a higher contribution of NE-K pools is expected. The main practical applications of our work are: M3 is good extractant to predict short-term K availability for eucalypt; considering previous studies that report HNC as a better long-term K index for eucalypt, the combination of M3 or M1 with HNC may be better to indicate both immediate (i.e. K availability during the initial development of the stand) and long-term K supply for eucalypt plantations.

Keywords: Mehlich 3, Mehlich 1, hot nitric acid, K-supply

(2576 - 664) Root growth of cover crops cultivated under compacted pasture in Rolim de Moura Rondônia

Fábio Lucas de Mattia[1]; Marcelo Henrique Gomes[1]; Emerson Oliveira Souza[1]; Diogo Arthur Valiati Dantas[1]; Anderson Cristian Bergamin[1]; Wesley Santana Ferreira[1]; Renan Marré Bizatti[1]; Fábio Régis de Souza[1]

Fundação Universidade Federal de Rondônia[1]

The physical limitation caused by compaction can infer in the productive potential of the agricultural crops, then becomes necessary search effective solutions for this problem. The principal methods of decompaction are realized by mechanical operation and has higher costs and low efficiency, with this, be necessary the search for alternative methods for this problem, like biological decompaction. On this way the work has as objective evaluate the root development of cover crops in a compacted soil. The experiment was installed in an Oxisol soil (Typic Haplustox) dystrophic in the experimental farm of UNIR at Rolim de Moura (RO). The experiment delineation was in randomized blocks with three repetitions, assessing the root development of four treatments: *Brachiaria brizantha, Crotalaria grahamiana, Crotalaria spectabilis* and mechanical scarification (soil cover with *B. brizantha*), in five induced states o compaction: 0, 1, 2, 4 and 8 passes of an agricultural tractor. When the cultures were find in flourishing was open trenches cross-cutting in the cultivation lines, exposing the roots of the plants, the profile was divided in layers with the aid of a mesh put on the soil, next, photographs was taken and the picture was segmented with the threshold technical. The determination of the root system was taken by a computer program SAFIRA v1.1. For the root length in the 0,0-0,05 m, 0,05-0,10 m layers, the brachiaria with or without mechanical scarification in all tractor passes presented higher values for root length highlighting a good performance of this specie explored even with physical limitation. With eight passes of an agricultural tractor reduced 42,9%, 66,3%, 54,6% e 30,9% the root length of the brachiaria *C. grahamiana, C. spectabilis* and mechanical scarification, respectively, in compare where not was compacted. The root surface was reduced too with the compaction rise of the soil, where the brachiaria presents higher values in compare with species of crotalaria. The soil compaction promote a reduced of the root system of the crops, and the brachiaria can be an alternative to explore better the soil and create greater amount of biopores left by you root system more vigorous.

Keywords: Decompaction of soil, root system, *Brachiaria brizantha*.

(4540 - 1518) Soybean (Glycine max) development in three tropical soil classes: the principle to determining production environments

Rannery Camargos dos Santos[1]; Thyara Ferreira da Silva[1]; Ingrid Horák-Terra[1]; Igor Alexandre Souza[1]; Alceu Linares Pádua Junior[1]

Federal University of the Jequitinhonha and Mucuri Valleys[1]

Nowadays agriculture has increasingly demanded ways of increasing crop productivity, not just the choice of area and cropping system, but also knowledge of all factors that condition the environment. Although there are large crops areas in Brazil, the more apropriete cultivar cultivation environment, or the adequate plant material, has not always been sought, in particular over the Cerrado biome, considering the Brazilian savanna, where soils profile are predominant deeps, well-drained, low fertility, and acidic. This research investigated how soil properties effect on soybean yield, grain weight, and plant morphology, as well as the number of pods per plant and the number of grains per pod were analyzed in Rhodic Haplustox, Rhodic Kandiustox and Rhodic Kanhaplustalf with mollic epipedon in a central Brazilian Cerrado during the 2014/2015 harvest season. The higher yields were obtained in Rhodic Kandiustox and Rhodic Kanhaplustalf, which can be explained by the morphology and

chemical condition of these soils, due to the greater exchangeable bases content and the presence of block and prism structure can increase the available water, unlike Rhodic Haplustox, with a granular structure and a lower content of exchangeable bases and probably less water availability. The chemical attributes had a great influence on productivity and grain weight, especially Rhodic Kanhaplustalf, due to the higher organic matter content, due to the soil location in a small basin of the landscape, associated to the presence of calcareous rock 150 cm depth, contributing to increase pH and calcium and magnesium content and low levels of toxic aluminum in the soil profile. Even though the three classes are considered highly weathered soils, this characteristic mainly affected the Rhodic Haplustox, in which the lower yields of grain weight can be explained by the low capacity of nutrient retention and increase in the content of toxic aluminum. In the test of comparison of means there were no statistical differences in the number of pods and number of grains per pod in the soybean crop at the three types of soil. Thus, soil descriptions at more detailed levels allow verifying the morphological and chemical differences of the soil at the landscape and can be used as alternatives tools for the planning of land use for agricultural purposes.

(4129 - 3078) Soybean crop expansion versus slope and soil in the Brazilian Pampa Biome through a GIS

Gabriel da Silva Lemos[1]; Aline Warnke Hipólito[1]; Rodrigo Rizzi[1]

Universidade Federal de Pelotas – UFPel[1]

In recently years, soybean cropped area has rapidly increased over the Brazilian Pampa Biome, located in the South portion of Rio Grande do Sul State, Brazil (RS). This region has been traditionally used to extensive livestock and cropped with irrigated rice over plain areas and hydromorphic soils. Soybean fields are been planted mainly in native grassland but also over low drainage lands in rotation with irrigated rice. This new scenario can greatly impact crop grain yield, soil conservation as well as the environment and its services. Thus, the objective of this work was to assess the occurrence of soybean fields regarding to slope and soil classes in the municipality of Hulha Negra-RS by using a Geographic Information System. Study area is mainly characterized by hydromorphic soils and increased the soybean area around 570% from 2012 to 2016, according to the Brazilian official data. In order to assess soybean fields along with to their slope and soil classes we used a soybean map previously performed by a meticulous and time-consuming visual interpretation over a set of five Landsat images (30-m spatial resolution) throughout the 20013/14 crop season. A slope map from the TOPODATA project which derives from the Shuttle Radar Topographic Mission with a 30-m spatial resolution and a Brazilian soil map at scale of 1: 750 000 were use as slope and soil data. Results showed that the majority of soybean area (84.6%) was above 5% slope and 14.6% between >3 and 5% slope. We also observed that soybean areas were mainly cropped over VERTISSOLO EBÂNICO (49.5%), ARGISSOLO VERMELHO (22.2%), LUVISSOLO ÁPLICO (12.9%) and CHERNOSSOLO ARGILÚVICO (10.2%), that is, soybean fields were mainly cropped above 5% slope and over low drainage soils. Since the soil erosion increases as the slope increases, especially over hydromorphic soils and conventional tillage system, soybean plantation over the Pampa Biome in Hulha Negra-RS requires carefully management techniques in order to achieve the best environment and soil conservation. Is it important to point out that since both soybean and slope maps are at 30-m spatial resolution, more detailed results can be retrieved by using a finer scaled soil map.

Keywords: Landsat Mapping; soil conservation; geotechnology.

(2611 - 2198) Spatial dependence of the soil mechanical resistance to penetration in areas of sugarcane under mechanized harvesting with controlled traffic at mata paraibana mesorregion of Paraiba State, Brazil

Josévaldo Ribeiro Silva[1]; Flávio Pereira de Oliveira[1]; Carlos Henrique de Azevedo Farias[2]; Maíra Cunha de Souza[1]; Danillo Dutra Tavares[1]; Raphael Moreira Beirigo[1]

UFPB[1]; ProjetAgro[2]

The controlled traffic is established as a method to mitigate risks such as compaction. Spatial variability emerges as an evaluating tool for applied methods in the field. This study was to evaluate the spatial dependence of an area of sugarcane under harvesting with controlled mechanized traffic. The study was carried out in an area that belongs to Santa Emília II farm, municipality of Rio Tinto, state Paraíba - Brazil. Two areas were selected in a Alfisol, from a first (PC) and third (TC) mechanized cuts. The resistance penetration (RP) was determined using the IAA / Planausucar-Stolf impact penetrometer. It was established a sampling grid contemplating wheel tracks (EL) and planting row (LI), all georeferenced. The variability was initially analyzed with the classic statistic, generating mean, median, variance, coefficient of variation, asymmetry, kurtosis and the Shapiro-Wilk test. The spatial dependence was evaluated throug had justed semivariograms generated by the GS + program, making possible the production of isolines maps by the software surfer 14. The mean and median values were very similar, indicating normality of the data, fact end orsed by the Shapiro-Wilktest, as well as asymmetry close to zero, these data imply that the data are suitable for geostatistic alanalysis. The RP presented effect only in PC, in the depths of 0.0-0.10 and 0.20-0.30 m in the interlines, and 0.30-0.40 m in the line, in the others conditions and positions the nugget effect observed was null. A Gaussian model was observed only in TC, specifically at 0.0-0.10 and 0.30-0.40 m of the EL, and 0.0-0.40 m of the LI, the spherical model was presented in 0.10-0.20 m of the EL and 0.0-0.10 and 0.40-0.50 m in the PC LI, the same at 0.10-0.20 and 0.50-0.60 m of the EL and 0.50-0.60 m of the TCLI, the presence of the exponential model occurred in 0.30-0.60 m of the EL and 0.10-0.20 m, and 0.50-0.60 m of the PC LI, as well as between 0.20-0.30 and 0.40-0.50 m of the EL and 0.40-0.50 m of the TCLI. The ADE, in the evaluated conditions with nugget null effect, was classified as very high, with an average range of 27 m for PC and 49 m for TC, a condition that can be explained by the fact that the trafficability can generate homogenization of some soil attributes. The controlled traffic was efficient, present inglower resistance in the plantingrow in both area sand the spatial dependence was classified as verys trongand with large aches in the third leaf area.

(7396 - 706) Spatial variability of organic matter content in a Red Nitosol under an *Eucalyptus benthamii* plantation

Laura Camila de Godoy Goergen[1]; David José Miquelutti[1]; Scott X. Chang[2]

Universidade do Estado de Santa Catarina[1]; University of Alberta[2]

Organic matter is an important indicator of soil quality, since it plays a fundamental role in maintaining nutrient supply, providing cation exchange capacity, and the formation of soil structure. The objective of this work was to analyze the spatial variability of organic matter content in a clonal plantation of *Eucalyptus benthamii* Maiden et Cambage, located in the municipality of Ponte Alta do Norte, SC, Brazil, in a Dystrophic Red Nitosol. Soil samples were collected from

the 0-20 cm layer from an 8 ha area. The sampling points were distributed in a 70 x 70 m grid, totaling 16 samples. The organic matter content was quantified by the wet digestion method and later, the data were submitted to the exploratory analysis and to the spatial dependence analysis through a semivariogram. After verifying spatial dependence, the kriging map was developed to interpolate values in non-sampled areas. A strong spatial dependence for the organic matter content was found and the best semivariogram adjustment was obtained with an exponential model, with a range of 122,80 m. The map generated from kriging allowed us to identify regions with different levels of organic matter content. The results showed that the geostatistical techniques are useful to understand the spatial variation of organic matter, evidencing the need to manage the soil in a site-specific way.

Keywords: precision forestry, kriging, geostatistic.

(4221 - 2005) The influence of biological preparations and humus content on soil biological activity

Zita Kriauciuniene[1]; Rita Mockeviciene[1]; Ausra Marcinkeviciene[1]; Rimantas Velicka[1]; Robertas Kosteckas[1]; Lina Marija Butkeviciene[1]; Sigitas Cekanauskas[1]

Aleksandras Stulginskis University[1]

Soil biological activity has been shown to be closely related to agricultural activities, various soil factors and climate. Scientists and farmers are looking for the methods to sustain and increase soil fertility for high and good quality agricultural production. The application of sustainable technologies and bio-preparations in agriculture could increase biological activity of the soil, which has been proved to be powerful indicator of soil quality. Field experiments were carried out in 2014–2016 at the Experimental Station of Aleksandras Stulginskis University (54°53' N, 23°50' E), Kaunas District, Lithuania. The aim of the research was to estimate the effects of bio-preparations and humus content on the soil biological activity using non-chemical weed control methods (thermal, mechanical and self-regulation) in organic spring rapeseed crop (*Brassica napus* L. spp. *oleifera annua* Metzg.) cultivated in soil with regular and thickened humus layers. Experiments showed, that the activity of soil enzymes urease and saccharase, number and mass of earthworms, CO_2 emission from the soil depended on the meteorological conditions. In the soil of both humus layer types, the highest average number and mass of earthworms and the strongest activity of saccharase and urease were identified in the plots of self-regulation, compared with thermal and mechanical weed control. Positive effect of the bio-preparations on the abundance of earthworms and the activity of soil enzymes was established in the droughty year of 2015. The application of mechanical and thermal weed control methods without bio-preparations decreased CO_2 emission from the soil, while their combination with bio-preparations increased it. In 2014 and 2015 experimental years, in the soil with a regular humus layer there were established strong correlations between the number of earthworms and oilseed rape root length (in 2014 – r = 0.94, P<0.05; in 2015 – r=0.85, P<0.05), between the number of earthworms and root area (in 2014 – r=0.86, P<0.05; in 2015 – r=0.85, P<0.05). In 2014–2016, strong and very strong correlations were established between the number and mass of earthworms (in 2014– r=0.94, P<0.01; in 2015 – r=0.91, P<0.05, in 2016 – r=0.89, P<0.05). In the soil with a thickened humus layer, there were established strong and very strong correlations between saccharase activity and organic carbon content in the soil (in 2015 –r=0.97, P<0.01; in 2016 – r=0.87, P<0.05).

Keywords: bio-preparations; humus; soil enzymes; CO_2 emission; earthworms

(8729 - 3095) Variation in soil properties, moisture, and botanical composition across catenas in northwest Arkansas, USA

Jenny Richter[1]; Christine Nieman[1]; Kabindra Adhikari[2]; Phillip Owens[3]

ORISE[1]; University of Arkansas[2]; USDA-ARS[3]

Differences in soil properties result in functional variations that affect botanical growth and composition, hydrology, and nutrient distribution across the landscape. This spatial variation makes it difficult for producers to manage fields for uniform productivity. The landscape of northwest Arkansas, USA presents pasture management challenges for livestock producers, where the natural topography creates environments favorable to certain forage species. This is generally characterized by bermudagrass [Cynodon dactylon (L.) Pers.] dominating upper hillslopes and tall fescue (Festuca arundinacea Schreb.) thriving in swales. We hypothesize that botanical distribution is driven by differences in soil properties and plant available moisture across catenas. Three catenas within continuously grazed pastures were examined to determine the variation in soil properties across the hillslopes as well as corresponding botanical composition at the summit, backslope, and footslope positions. Soil pits were mechanically excavated at each of the three hillslope positions, whereupon a soil profile description was completed and soil samples were taken from each horizon in the upper 60 cm of the profile. The soil samples were then analyzed for P, K, and organic C, as well as plant available water holding capacity, particle size, and pH. Areas at each hillslope position were fenced off to exclude grazing cattle during the study. Within the enclosures, tensiometers were placed at 30 and 60 cm depths in the three hillslope locations at each catena to monitor matric potential in the soil. Tensiometer readings were taken each month, coinciding with herbage sampling. Herbage mass was taken every month from two 1-m^2 areas within the enclosures. Herbage samples were separated by species to determine botanical composition at each site. Samples were dried and weighed to determine biomass production and biomass contribution from botanical constituents. Subsamples of all botanical contributors were analyzed for NDF, ADF, CP, P, and K. Understanding the soil distribution driving botanical composition across catenas is important for management, particularly for producers deciding whether or not to invest in cultivation and management of improved and more expensive varieties of tall fescue and bermudagrass. Knowledge of soil properties across catenas can aid producers in precision management decisions and help determine whether or not it is feasible to strive for a monoculture.

(3325 - 879) Baseline concentration of vanadium in different types of soils from TaiwanBaseline concentration of vanadium in different types of soils from Taiwan

Cho-Yin Wu[1]; Zeng-Yei Hseu[1]

Department of Agricultural Chemistry, National Taiwan University[1]

Baseline concentration of vanadium in different types of soils from Taiwan Cho-Yin Wu and Zeng-Yei Hseu* Department of Agricultural Chemistry, National Taiwan University No. 1, Sec. 4, Roosevelt Rd., Taipei 10617, Taiwan *E-mail: zyhseu@ntu.edu.tw The global vanadium (V) demand in industry increased 8% from 2006 to 2014, which will become 3.45% higher in next decade. This increase of V requirment may lead to more potential risk to the environment quality and human health than before. However, only 5 countries

currently regulate the guideline of soil vanadium (42-180 mg/kg) excluding Taiwan. Geochemical fractionation is crucial to the solubility of V in soils, this study attempted to explore the fractions of soil V for the baseline of vanadium based on 17 pedons with 94 horizon samples throughout Taiwan. These pedons were selected from different soil parent materials comprising slate, sandstone and shale, andesite, serpentine, and basalt. The potential mobility of V was assessed by using the BCR sequential extraction technique to divide total V into 4 fractions: acid-exchangeable (F1), Fe-Mn oxide bounded (F2), oxidation (F3) and residual (F4). The total V concentration was analyzed by using portable x-ray fluorescence (PXRF) in situ and ICP-AES followed with HF-digestion in the lab. The total V concentration by ICP in the soils from Taiwan ranged from 35.4 to 475 mg/kg and the average level was 182 mg/kg. Moreover, the total V concentration in the basalt-derived soils was much higher than sandstone-derived soils. Nevertheless, the weathering degree of soil did not clearly affect the V level between pedons. Furthermore, V concentration obtained by PXRF was significantly and positively correlated with that by ICP, demonstrating PXRF was feasible alternative to determine V in the field for rapid screening of V. The results of BCR sequential extraction indicated the residual V accounted 94.01% of total V indicating a low mobility of V in the soils. Keywords: mobility; sequential extraction; PXRF; soil contamination; vanadium

Keywords: mobility; sequential extraction; PXRF; soil contamination; vanadium

(6863 - 220) Can earthworms' activity affect water transport and storage in soils?

Jamal Hallam[1]; Mark E. Hodson[2]; David Robinson[3]; Joseph Holden[4]
University of York, Environment Department, York, United Kingdom (jh2066@york.ac.uk), National Institute of Agricultural Research of Morocco (jamal.hallam@gmail.com)[1]; University of York, Environment Department, York, United Kingdom (mark.hodson@york.ac.uk)[2]; Environment Centre Wales, Centre for Ecology and Hydrology, Bangor, United Kingdom (davi2@ceh.ac.uk)[3]; University of Leeds, School of Geography, Leeds, United Kingdom (J.Holden@leeds.ac.uk)[4]

We studied the combined effect of earthworms and plant roots on soil physical and hydraulic properties. Two different groups of earthworms, *L terrestris* and *A chlorotica* which produce vertical and lateral burrows respectively, were studied for 16 weeks in columns under three different soil types. We used a factorial design with presence and absence of both winter wheat and either *L terrestris* or *A chlorotica*. Overall, in the *L terrestris* experiment water flow under field saturated and unsaturated conditions was mainly controlled by plant roots in all the soil types. The addition of *L terrestris* to the planted and bare columns led to an increase of the hydraulic conductivities in all soils. However, the increase was only significant in the sandy loam soil. The soil water release curves showed the same behaviour between treatments at high matric potential (up to 10kPa). At lower matric potential (10–500kPa) the wheat+*L terrestris* treatment held water less tightly than the other treatments. The presence of *L terrestris* also resulted in a slight, but not significant, increase in water holding capacity. The percentage of water stable aggregates increased and were significantly influenced by plant roots rather than earthworms. Earthworm-present caused a significant increase of shoot dry matter biomass in silt loam soils. *A chlorotica* had a significantly greater influence on soil hydraulic and physical properties compared to *L terrestris*, particularly for the plant+earthworm treatments. Compared to the other treatments, the field saturated hydraulic conductivity increased more rapidly across time in wheat+*A chlorotica* treatment. After 16 weeks the field saturated hydraulic conductivity was 12, 34 and 39-fold more than the control in loam, silt loam and sandy loam soils respectively. In all the soil types, wheat+*A chlorotica* treatment resulted in a significant increase of water holding capacity, % stable aggregates and dry shoot biomass compared to other treatments. These results suggest that the combined effect of earthworms and plant roots can significantly increase both soil water flow and retention. However, there are species effects due to the different ecological niches occupied by earthworms. In conditions where earthworm burrows are disconnected from drainage system, lateral burrowing earthworms have more of an impact on soil water flow than vertical burrowing species. The results are of special interest for wet areas of high flooding and waterlogging risks.

(7377 - 456) Comparison of soil quality using comparative diagrams in riparian areas, Brazil

Piero Iori[1]; Reginaldo Barboza da Silva[2]; Moacir de Souza Dias Junior[3]; Ricardo Nakamura[2]; Luis Carlos Ferreira de Almeida[2]
Universidade Federal de Goiás[1]; Universidade Estadual Paulista "Júlio de Mesquita Filho"[2]; Federal University of Lavras[3]

Land areas adjoining watercourses and water bodies are considered conservation areas and are extremely important for a variety of environmental services, including sediment filtration, bank stabilization and aquifer recharging. Cultivating these areas can cause serious changes in the physical, mechanical and chemical properties of soil, promoting negative environmental processes such as siltation of water sources, which is caused by erosion. The consequences of these changing conditions are felt directly by populations living in riparian areas. Consequently, soil quality assessments can be used to evaluate and monitor sustainable land management practices in agroecosystems. The aim of this study was to compare soil quality using comparative diagrams in response to land use in riparian areas in the Sub-basin of the Ribeira Iguape River, Brazil. The physical, mechanical and chemical properties of soil were determined in land used for banana cultivation, degraded pastures, silvopastoral land and native forest, as a reference area, along the Ribeira River in Brazil. The impacts of different agricultural land uses different showed a close and inverse relationship between soil quality and land use intensity. Based on the obtained data, comparative diagrams (radar graph type) were drawn and analyzed to compare the soil quality and the area in the graph for each type of land use. Agricultural land use alongside rivers (riparian areas) has caused negative changes to the main physical, mechanical and chemical properties of soil. The polygons formed in the radar graphs, which were used to compare the reference areas to the areas for the three different agricultural land uses, differed in shape and area compared to reference values, proving that these comparative diagrams are a useful tool in the assessment of soil quality in riparian areas. Comparing diagram areas, land under banana cultivation, degraded pastures and silvopastoral land had values that were 40%, 36% and 29%, respectively, of diagram areas for native forest. The adoption of comparative diagrams for soil assessment helped to elucidate the relationships between agricultural land uses and the physical, mechanical and chemical aspects of soil quality in riparian areas.

(6434 - 2776) Effect of former topography on insufficient growth caused by excess soil water in upland crops cultivated on paddy field

Yuta Shimizu[1]; Kenji Matsumori[1]; Hidetoshi Mochizuki[1]; Shinsuke Mori[1]
Western Region Agricultural Research Center, National Agriculture and Food Research Organization[1]

Existence of excess soil water at root depth is one of the largest potential threat to plant growth. In hilly and mountainous area in western Japan, farmers face to the above-mentioned problem when they conduct farming with the crop rotation mixed with rice paddy, soybean, and winter wheat on terraced paddy field which is recently introduced as a farming program. The source of the excess soil water is possibly due to high groundwater level based on several monitoring experiences. Current terraced paddy fields were re-developed by farmland consolidation which enlarged through gathering each small field. The farmland consolidation significantly changed the topography because it has buried and leveled most of hills and small valleys in a village-scaled area to obtain large flattened paddy fields. We thought the higher groundwater level relates to former topography before the farmland consolidation based on the assumptions that groundwater flows alongside with former river channels which is buried under the current field. The objective of this study was to confirm the spatial relationship between excess soil water and topographic changing. Former river channels and amount of soil volumes disturbed by farmland consolidation were estimated based on comparison of elevation maps between before and after the construction using GIS technique. Spatial distribution of insufficient growth of the crops were confirmed using aerial photos taken by an unmanned aerial vehicle. Water potential at root depth, and groundwater level were monitored during cultivation period. Results show that there is a clear relationship between land reclamation and plant growth; inefficient growth of crop was found on the land filled small valley while well-grown crop was found on the land leveled hills. The reason of insufficient growth is considered that the crop was damaged by excess soil water based on observed water potential trend. Moreover, the groundwater level monitored in the land filled small valley was always higher than the land leveled hills throughout the monitoring period. Consequently, former topography could be a crucial factor to predict the field influenced by excess soil water. To identify the zone is important for the farmers because the zoning is eventually related to judgement that crop can growth or not.

(9955 - 1470) Effects of anthropization in veredas from Central Brazil

Adrieny Kerollen Alves Lopes[1]; Maria Emanuelly Ramires[2]; Rafaella Loryane Alves Cardoso[3]; Fabrício da Silva Terra[4]; Leonardo Barros Dobbss[3]; Igor Alexandre de Souza[3]; Alceu Linares Pádua Junior[3]; Alexandre Christófaro Silva[1]; Ingrid Horák-Terra[1]

Federal University of Jequitinhonha and Mucuri Valleys (UFVJM), Unaí, Brazil.[1]; Federal University of Jequitinhonha and Mucuri Valleys (UFVJM), Unaí, Brazil (emanuellyinter@hotmail.com).[2]; Federal University of Jequitinhonha and Mucuri Valleys (UFVJM), Unaí, Brazil .[3]; Federal University of Pelotas (UFPel), Pelotas, Brazil.[4]

Veredas are ecosystems that occur in the Cerrado biome characterized by the presence of Buritis-palm trees in poorly drained environments. In general, their soils have high organic matter content and allow to function as water reservoirs taking part in the hydrological cycle by regulating water discharge. In Minas Gerais state, veredas are protected by law, and the most of them hold heads of the São Francisco river's main tributaries. However, with increasing of agricultural activities in central Brazil, veredas have been often used without any specific management because there is scarce information about the characteristics of these environments. Here, we presented a characterization based on morphological and physical properties of two soil profiles, each one representing one part of the same vereda (northwestern MG state) under different conditions: anthropized (AP) in downstream and preserved (PP) in upstream of the catchment (2.5 km apart from each other). The anthropization was due to a construction of an artificial drainage channel. The AP (81 cm depth) was sampled by horizons (9 samples) in an exposed profile in this channel, and the PP (160 cm depth) was sampled each 20 cm in a borehole (8 samples). The analyzed properties were: organic carbon (C_{org}), unrubbed (URF) and rubbed fibres (RF), bulk density (BD), bulk density of the organic matter (BDO), gravimetric moisture (GM), minimum residue (MR), and mineral material content (MM). The AP was classified as Terric Haplosaprists with maximum C_{org} (25%) in the first horizon and decreasing up to the base (~ 7%) with almost absence of fibers and very decomposed. Its GM also decreased from 34 to 21%, while MM and BD increased in depth up to 89% and 1.4 Mg m^{-3}, respectively. The PP was classified as Hydric Haplofibrists with C_{org} higher than AP, from 34% to 59% in depth, and higher URF, RF, and GM increasing in depth up to 76, 68 and 90%, respectively. Its MM and BD were decreasing up to 4% and 0.09 Mg m^{-3}, respectively. Values of BDO and MR for AP ranged between 0.14-0.20 Mg m^{-3} and 0.18-0.90 m m^{-1}, respectively, and for PP between 0.08-0.18 Mg m^{-3} and 0.003-0.09 m m^{-1}. Variations among these properties reflect the conservation states of these both profiles. AP is more degraded with high stage of material subsidence losing thickness and reducing soil porosity and, consequently, its water storage capacity. PP is more preserved with more organic matter and able to storage more water.

(2244 - 2783) Soil carbon pools in temperate saltmarsh and mangrove environments

Cecelia Chan[1]; Vanessa Wong[1]

Monash University[1]

Intertidal sediments sequester significant amounts of C globally. C sources can be categorised into organic C inputs from within the estuary (autochthonous) and inputs trapped within the estuary derived from external sources (allochthonous). SOC can be divided into three C pools, particulate organic carbon (POC), humus carbon (HC) and recalcitrant carbon (RC). Belowground organic carbon stocks in mangrove and saltmarsh environments have been quantified in a number of environments globally, identifying the potential to store substantial amounts of C. In this study, we quantified the SOC stocks in temperate saltmarsh and floodplain environments and identified the contribution from the three C pools. We found that saltmarsh sites had a higher potential to accumulate SOC compared to mangrove areas, which was related to increasing distance from the creek network and higher elevations. The mangrove sites had a higher proportion which have be related to deposition of both allochthonous and autochthonous materials. The saltmarsh sites had higher potential for C sequestration due to higher proportions of HC. These results highlight the importance of protecting these environments, not only as they provide a transitional environment between the coastal and terrestrial zone, but also as important stores of more stable organic carbon

Keywords: soil carbon, wetlands, mangrove, saltmarsh

C3.2.2 - Soil management in organic production and agroecology

(2435 - 1176) Comparison between the effects of sun-coral (*Tubastraea spp.*) and limestone as soil amendments in cultivated corn (*Zea mays*)

Julia Barra Netto Ferreira[1]; Thuany da Costa Janête[1]; Marlon Henrique deOliveira[1]; Rafael Thales da Silva Magalhães[1]; Ricardo de

Castro Dias[1]; Joel Christopher Creed[2]; Everaldo Zonta[1]
Universidade Federal Rural do Rio de Janeiro[1]; Universidade Estadual do Rio de Janeiro[2]

In the 1980s the accidental introduction of an exotic marine invasive species called sun-coral (Tubastraea spp.) caused an environmental and social imbalance through the coastal region of Brazil. This work is aimed to investigate whether the sun-coral can be employed as a source of soil corrective either for family or organic agriculture. The experiment was conducted with corn(Zea mays) plants grown in pots with soil from a *Planossolo háplico* (Typic fragiaquult), at initial pH of 5.1. An addition of 50 g of AlCl3 was made to raise the aluminum content to 1.0 cmol dm^{-3} in order to analyze the potential of sun-coral in neutralizing the soil acidity. The doses used were 0; 2.0; 4.0 and 8.0 ton ha-1 for both the sun-coral and commercial limestone. The plants were collected at 60 DAS, when the height, diameter and shoot dry matter were evaluated. The contents of P, K, Ca, Mg and Na on the aerial part of the plants were also determined by sulfuric digestion (Tedesco et al., 1995). The treatments were compared by analysis of variance and means were compared by the Tukey's test within the confidence limit of 95% of probability. Diameter and total content of K were the parameters which presented statistical difference. The average of plant diameter was 19.30 mm for the control; 17.98, 17.69 and 17.70 mm for doses of 2.0; 4.0 and 8.0 ton ha-1 limestone, respectively; and 18.52, 19.48 and 18.86 mm for doses of 2.0; 4.0 and 8.0 sun-coral, respectively. The average of total K content was 6.9 g.kg-1 for control; 9.2, 10.5 and 9.3 g.kg-1 for doses of 2.0; 4.0 and 8.0 ton ha-1 limestone, respectively; and 9.3, 11.1 and 11.3 g.kg-1 for doses of 2.0; 4.0 and 8.0 ton ha-1 sun-coral, respectively. The final plant diameter was lower than control in almost all treatments. The pH analysis at the end of the experiment showed an average value of 6.3, different from the initial pH, causing the precipitation of the Al added at the beginning of the experiment. This may have been due to the fact that the soil collected for the experiment was corrected without any record keeping. Therefore, comparing the averages of diameter in limestone treatments with those of sun-coral, those with coral were higher, which may be related to the total nutrients content in the composition of sun-coral structure, which increased the availability of nutrients. For the K content, only the 8 ton.ha-1 dose was significantly higher in the sun-coral than in the limestone (Tukey's test, 5% probability).

(7763 - 3183) Content of organic matter and calcium in soil cohesive treated with gypsum and leguminous residues

Jéssica de Freitas Nunes[1]; Thales Pereira Pires[2]; Virley Gardeny Lima Sena[3]; Vinícius Ribamar Macedo[2]; Lorena Silva Campos[2]; Emanoel Gomes de Moura[2]
Universidade Estadual do Maranhão[1]; UEMA[2]; USP[3]

The use of gypsum ($CaSO_4 .2H_2O$) in addition to the availability of Ca^{2+} can increase the stability of the aggregates and improve root performance in deeper layers and as a result, increase the efficiency of water and nutrient use. The use of limy ($CaCO_3$) is also an alternative to provide calcium to the soil and raise the pH which are correlated with the decomposition of organic matter. This work aims to evaluate the effect of gypsum, limy and leguminous residues on calcium and organic carbon levels in sandy soil prone to cohesion. The experiment was conducted in a greenhouse located in the Technological Center of Rural Engineering of the Agronomy Course belonging to the State University of Maranhão. The soil collected with cohesive characteristics belongs to an area of capoeira with secondary vegetation. The soil and legume milled and dried were mixed in the proportions of 50% *Gliricidia sepium* and 50% *Leucaena leucocephala*. The experimental design was a randomized complete block design, using the 3x3x2 triple factorial system (organic matter, gypsum and limy) with four replications and 18 treatments. The data were analyzed with a variance analysis (ANOVA) and were compared using Tukey's test at the 5% probability level in the 3x3x2 triple factorial system. These analyzes were performed using RStudio software. In the 10-20 cm layer the limy always increased the calcium content in the soil, but with the plaster combination the calcium contents increased significantly. In the 10-20 cm layer, the limy decreased the organic matter content in the combination of (0 t.ha-1 of gypsum / 2 t.ha-1 of limy) and in the other combinations of doses of gypsum and limy there was no significant difference. The pH values in the 10-20 cm layer were always remained low in the 0 t.ha-1 limy combinations for the three gypsum dosages. The addition of calcium in the soil from the gypsum delayed the decomposition of the products derived from the leguminous biomass applied to the soil. The addition of limy increased the pH and therefore the decomposition of the organic matter, therefore, the dosage of 2 t.ha-1 of limy decreased the organic matter content of the soil. The addition of calcium in the soil from the gypsum delayed the decomposition of the products derived from the biomass of leguminous applied to the soil increasing the M.O. content. The addition of limy increased the pH and, consequently, the decomposition of organic matter.

Keywords: pH, limy, leguminous

(4298 - 1760) Effect of organic amendments and inorganic fertilization in the yield and quality of jalapeño pepper (*Capsicum annuum* L.)

Ana Alejandra Valenzuela-García[1]; Juan José Martínez-Ríos[1]; Uriel Figueroa-Viramontes[2]; Enrique Troyo-Dieguez[3]; Ignacio Orona-Castillo[1]; Miguel Ángel Gallegos-Robles[1]; Enrique Salazar-Sosa[4]
Universidad Juárez del Estado de Durango, Facultad de Agricultura y Zootecnia[1]; Instituto Nacional de Investigaciones Forestales, Agrícolas y Pecuarias[2]; Centro de Investigaciones Biológicas del Noroeste[3]; Instituto Tecnológico de Torreón[4]

In this work, the effect of different doses of organic fertilizers on a jalapeno pepper crop (*Caspsicum annuum* L.) and the effect on the content of nitrogen (N), phosphorus (P), electrical conductivity (EC), pH and organic matter (OM) in soil was evaluated. The study was carried out in the Experimental Field of FAZ-UJED, located in Venecia, Durango, Mexico (coordinates 25.75º N, 103.3º W). The fertilizers used were vermicompost (VC) with doses of 0 and 3 Mg ha^{-1}, in factorial combination with solarized manure (ES), in doses of 0, 40, 80, and 120 Mg ha^{-1}, and a treatment with inorganic fertilization, 150-100-00 Mg ha^{-1} of N-P-K. Microbiological analyzes were carried out to evaluate the innocuousness of the fruit, mainly about the presence of *Salmonella* spp. The obtained results suggest that the applied dose of VC had a non-significant effect on the yield and in the evaluated soil variables. ES had a significant effect on yield, the highest value was obtained with the dose of 120 Mg ha^{-1} (56.2 Mg ha^{-1}), although it was statistically equal to the doses of 40 and 80 Mg ha^{-1}. The highest values of P (70.7 mg kg^{-1}) and OM (3.7%) occurred at dosage of 120 Mg ha^{-1}. The lowest value of OM (1.1%) was found in the inorganic fertilization treatment. The nutrients provided by ES are sufficient to satisfy the needs of the crop. The values of pH, EC and N were not affected by the manure dosage and its quality was not affected by the application of organic fertilizers. The fruits of second quality were the most frequent (60% of the total fruits), followed by the first quality (25%). The microbiological analyzes resulted negative for *Salmonella*

spp., this could indicate that the solarization process is an effective process for its elimination.

(4889 - 1310) Influence of a afilsol's microbial activity under incorporation of ryegrass, white clover or poultry litter.

CAROLINE JERKE[1]; Adriana Cancian[1]; Cristhian Hernandez Gamboa[1]; Juan Cubillos Hinojosa[1]; Lucas Zulpo[1]; Mariana Fernandes Ramos[1]; Tiago Stumpf da Silva[1]; Victor Lucas Bassani[1]; Enilson Luiz Saccol de Sá[1]; Flávio Anastácio de Oliveira Camargo[1]
UFRGS[1]

The incorporation of residues and waste in the soil, practice widely used in conservationist agriculture, impacts on the physical, chemical and biological properties of the soil. Microbial respiration is a suitable parameter to be used as an indicator of soil microbial activity and determine effects caused by different soil management. We evaluate the microbial activity during 30 days of incubation of ryegrass, white clover or poultry litter, determining carbon evolution, at the 2nd, 3rd, 4th, 7th, 9th, 11th, 14th, 18th, 21st, 24th, 28th and 30th days of incubation experiment. Each treatment showed different behavior of microbial activity throughout the experiment. This Afilsol had low content of Soil Organic Matter and therefore was very sensitive to the applied management practices. The behavior of CO2 release in the treatments with cover crops was very similar, presenting a peak on the 4th day of incubation, however, the incorporation of poultry litter showed a different behavior, increasing rates of CO2 release and overcoming the microbial activity comparing the other treatments after the 18th day of incubation. The CO2 evolution was used to adjust equations to evaluate patterns of all treatments. The linear model was the best choice all treatments except the treatment of soil with ryegrass, which the logarithm model was the best fit. This suggests that the time of this experiment wasn't enough to observe microbial activity at the stage where the microbial community uses recalcitrant fractions of organic matter, however, the adjusted equations allowed to calculate the time to consume 50% of C available which showed that the mineralization of poultry litter regarded was twice times slow comparing to the ryegrass addition. The highest rates of mineralization were ryegrass, white clover, control, and poultry litter.

(9605 - 2840) Nepheline syenite rock powder as source of potassium to corn

Luis Valério C. Carvalho[1]; Julio Cesar Raposo de Almeida[1]; Ana Aparecida da Silva Almeida[1]; João Luis GAdioli[1]; Omar Vieira Vilella[2]; Hélio Minoru Takada[2]; Aluisio Ramos Ferreira[3]
UNITAU[1]; APTA[2]; Mineração Rio do Braço[3]

This work aimed to measure the supply of potassium (K) by nepheline syenite rock powder to dry matter of corn cultivated in dystrophic oxisol and to calculate its efficiency against the potassium chloride (KCl). Nepheline syenite is a plutonic rock characterized by 7.3% of K_2O, supplied by a mining company located at Lavrinhas, Sao Paulo state in Brazil. The application of rock powder to soil presents itself as an alternative to synthetic sources, taking advantage of its slow chemical dissolution what makes it less susceptible to lixiviation and a source of multiple minerals. The rock powder was applied raw (R) to the soil and after heating (H) in calcination oven mixed with calcium chloride (55%-45%) at 900 °C for 30 minutes. A 3x2+2 factorial experiment desing was set fractionating the rock powder into the granulometric ranges small (s) or below 0.053 mm, medium (m) or between 0.053 and 0.149 mm and large (l) or above 0.149 mm. A positive control treated with KCl and a negative control without any K source were set. The soil was incubated for 94 days and wet with distilled water up to 70% of its field capacity. Corn was cultivated thrice, 33 days each time. The dry matter masses, the K levels in soil and the K concentration in the plants were determined per treatment. The K contents were determined by the multiplication of the dry matter mass by its K concentration. The data obtained were submitted to analysis of variance and Tukey test at a confidence level of 5%. The agronomic efficiency was estimated comparing to the KCl treatment. The heating treatments Hs, Hm and Hl showed significant effects on the K levels in soil ($P < 0.01$) and on the concentration of K in the dry matter of the first cultivate ($P < 0.01$). The treatment Hs showed a significant effect on the total content of K in the dry matter ($P < 0.01$). Has been concluded that after heating the nepheline syenite rock powder acted closer to KCl as a fast dissolution fertilizer while the raw rock powder did not or did not have enough time to dissolve and supply potassium to the corn.

(4326 - 1047) Nitrogen mineralization and nitrous oxide emissions in a sandy soil amended with low-phosphorus broiler litter.

Ariel Szogi[1]; Paul D. Shumaker[1]; Kyoung S. Ro[1]; Gilbert S. Sigua[1]
USDA-ARS Coastal Plains Soil, Water, and Plant research Center[1]

Recurrent land application of broiler litter in regions with a high concentration of poultry farms result in soils with phosphorus (P) far beyond the agronomic requirement of crops. A new waste treatment technology developed by USDA-ARS, called "Quick Wash", chemically extracts and recovers P from broiler litter while leaving most of the nitrogen (N) and carbon (C) in the low-P treated litter. The low-P treated litter can then be either safely land applied at agronomic N rates. A laboratory test was performed to evaluate the N mineralization and nitrous oxide (N_2O) emissions in a Norfolk soil (Fine-loamy, kaolinitic, thermic Typic Kandiudults) amended with low-P litter. Two sets of undisturbed soil cores (15 cm x 5 cm diameter) received the following treatments applied onto the soil surface in triplicate: un-amended soil (control), untreated litter, pelletized untreated litter, loose low-P litter, and pelletized low-P litter. All cores were adjusted to 60 % water-filled porosity and incubated at 25°C for 68 days. Soil from one set of cores was sampled on a weekly basis. Soil samples were extracted with 2 molar potassium chloride and analyzed for ammonium (NH_4) and nitrate (NO_3) to estimate the net N mineralization (Nm) rate of each poultry litter amendment. Another set of cores were enclosed in plastic jars having a gas sampling port for periodic N_2O emission measurements by gas chromatography. The Nm rates were in the range of 4.0 to 5.7 mg/kg of soil/day for untreated litter, pelletized untreated litter, and loose low-P litter while pelletized low P-litter and the unamended soil control were significantly lower, in the range of 1.7 to 2.0 mg/kg soil/day. The cumulative N_2O production from the pelletized raw, loose raw, loose low-P, pelletized low-P litter, and un-amended soil were 1261, 894, 407, 287, and 80 µg N_2O-N/kg soil, respectively. Therefore, percent of N_2O losses from the total applied N were 1.4%, 1.0%, 0.5%, and 0.3% for pelletized untreated litter, untreated litter, loose low-P litter, and pelletized low-P litter, respectively. Since the treated pelletized low-P litter also had the lowest nitrification rates, it appears as an efficient solution to conserve N and mitigate losses by N_2O emissions or NO_3 leaching after soil application.

(5325 - 657) Organic Matter and Physical Attributes of the Soil with Underground Barrage in Agroecological Transition

Wanderson Benerval De Lucena[1]; Gizelia Barbosa Ferreira[1]; Maria

Sonia Lopes Da Silva[2]; Hugo Isaac Da Silva[1]; Maria José Sipriano Da Silva[1]; Igor Alberto Cabral Da Rocha[1]; Elisiane Martins De Lima[1]; Maria José De Freitas[1]; Ricardo Torres Da Silva[1]
Federal Institute of Pernambuco[1]; Brazilian Agricultural Research Corporation - Soils[2]

Underground barrage consist of a technique for capturing and storing rainwater to ensure agricultural production during the dry season. The accumulation of water in the catchment area of the barrage has demonstrated positive and negative aspects in the chemical, physical and biological attributes of soils. The difficulties of underground barrage are the result of several factors, including the use of conventional management techniques that can lead to soil erosion. The objective of this work was to evaluate the physical attributes and the organic matter of the soils with underground barrage in the brazilian semiarid, comparing with areas of conventional system and native forest. The study was carried out in two properties of the State of Bahia, both under semiarid climate. Property 01, which is located in the city of Serrolândia (latitude 11° 25' 7" S, longitude 40° 17' 40" W, at 447 meters altitude), property 02 is located in the city of Canudos (latitude 09° 53' 48" S, longitude 39° 01' 35" W, at 402 meters altitude). Sampling for the physical analysis was performed at the beginning of the rainy season, and obtained through a sample composed of each environment, collected in ten points in the zigzag direction, and in three depths, 0-10 cm, 10-20 cm and 20 -40 cm. It's verified that of all studied areas the organic matter was higher in the environment of native forest, when compared to the other environments. The removal of the caatinga, together with the long periods of drought, causes marked physical, chemical and biological degradation in these environments, in relation to the soils, these characteristics can be more accentuated, because it leaves them totally discovered and exposed to the climatic factors. Soil density in agroecosystem 01 was higher when compared to agroecosystem 02, due to soil particle density related to high sand content (in agroecosystem 01) and clay (in agroecossystem 02). These relationships in the formation of macro and micro pores of the soil can be observed in the porosity, which was higher in the agroecosystem 02 due to the clay and organic matter contents. It's concluded that both properties are still slowly moving towards a more sustainable agroecosystem, overcoming the environmental limitations of the brazilian semiarid region, placing the underground barrage as a technology with potential to perfect and balance the productive process, promoting greater stability of agroecosystems.

(4882 - 776) Soil microbial groups responses to application of garlic broth, essential oils and *Trichoderma spp.* used to control *Sclerotium cepivorum* Berk

Ezequiel D. Bigatton[1]; Boris X. Camiletti[1]; Matias Bonetto[1]; Martha Y. Conles[1]; Isabel Serdiuk[1]; Aylen Ocampo[1]; Leandro Carbelo[1]; Enrique I. Lucini[1]
Universidad Nacional de Córdoba[1]

Argentina is the second largest country in garlic (*Allium sativum* L.) production which is highly affected by the white rot caused by *Sclerotium cepivorum* Berk. This pathogen produce sclerotia that can survive in soil as the inoculum source. We previously demonstrated that applications of garlic broth (GB) obtained by hydrodistillation inducedearly sclerotial germination reducing the amount of final viable sclerotia. Essential oils (EOs) and *Trichodermaspp.* applications control *S. cepivorum*. The goal of this work was to study the effect of GB, oregano *(Origanum* spp. *vulgare*) EO, suico (*Tagetesminuta* L.) EO, *T. atroviride* (TA) and *T. harzianum* (TH) applications on final viable sclerotia and soil microbial groups. Assay was carried out inplots (45 x 45 cm) inoculated with 21 g of sclerotia at 5 cm depth (day 0). The treatments were: no applications (control); GB (80 mL) applied after 20 and 40 days; GB+ EOs of oregano and suico applied separately (1500 ppmapplied on the soil surface) after 60 days; GB + individual and combined applications of TA and TH ($4x10^8$ spores) after 90 days. Total heterotrophic and nitrogen-fixing microorganisms were determined by colony-forming unit. The most probable number method was used to quantify nitrifying, ammonia-oxidizing and cellulolytic microorganisms. All the groups were quantified after 7 days of each application. At the end of the assay, sclerotia were collected by sifting and quantify the soil samples (100g) using astereo-microscope. Viability of sclerotia was determined on agar-water (2%). Means were obtained by ANOVA and significant differences were detected using Fisher´s LSD test ($P< 0.05$). The number of nitrifying microorganism significantly decreased (9%) after GB applications. Similar results were obtained between GB + suico EO and GB + TA, reducing both the number of nitrifying (83 and 67%, respectively) and ammonia-oxidizing (7 and 12%, respectively). Ammonia-oxidizing microorganisms were also affected by GB+TA+TH (11%). GB+Oregano EO decreased the number of nitrifying and nitrogen-fixing (94 and 5%, respectively). The application of GB+TH had no significant effect on the soil microbial groups. The number of viable sclerotia was increased in control (40%) and reduced with the applications (40%). The greatest reduction was observed in GB + TA + TH (73%). Combined application of TA and TH provide additional control to GB treatment affecting ammonia-oxidizing microorganisms.

(7165 - 3086) Sustainable production of strawberry in Alfisols from coastal rainfed Chile

Alonso Matamoros[1]; Oscar Seguel[1]; Verónica Diaz[1]; Rodrigo Callejas[1]; Helen Osorio[1]; Gonzalo Arancibia[1]
Universidad de Chile[1]

The soils of the coastal range of Chile present clay textures and low organic matter contents. This condition leads the soil compaction as a common constraint to establish the strawberries, very important crop for small farmers. In the present study, different organic amendments were applied in two essays (Litueche: Alto Colorado Association, Typic Rhodoxeralf, Paredones: Asociación Curanipe, Typic Kandiustalf) to evaluate their effects on soil physical properties and strawberry yield. The treatments consider a control (T0, no amendment), compost (C, 20 Mg ha^{-1}); humic substance 1 (HS1, 100 L ha^{-1}) and humic substance 2 (HS2, 30 kg ha^{-1}), evaluating after 3 and 6 months of the start of the trial: bulk density, pore size distribution, aggregate stability, mechanical resistance and the yield components of the strawberry. The bulk density was not modified by the treatments, although in Paredones tends to decrease by the use of compost. In both essays the coarse porosity increased by the use of organic amendments, but the available water did not change consistently in the time. The aggregate stability increased in Paredones site in C and HS2 treatments, and the mechanical strength remained low in all treatments, but with densified subsoil. The treatment HS1 increased the average weight of the fruit and all amendments increase the °Brix concentrations compared to T0. Finally, the number of fruit per plant, the large and diameter were not affected by the use of organic amendments, but the use of external inputs (fertilizers, agrochemicals, irrigation) decrease with the proposed managements.

(4989 - 999) Swine slurry effect in the soil organic carbon at no tillage system

Ranier Vieira Ferreira[1]; Romulo Fuchs Brunetta[1]; Isabela Cristina Sousa Moura[1]; Sandrielle Furquim Medeiros[1]; Rose Luiza Moraes Tavares[1]

Universidade de Rio Verde[1]

The Rio Verde city is one of the largest producers of swine in the central-western region, generating around 21% of the total swine slurry (SS) produced in the Goiás state / Brazil. Due to the chemical benefits of swine slurry, rich in organic compounds besides macro and micronutrients, one of the possible destinations of this residue its use as soil fertilizer, being able to bring benefits to the agricultural crops by the addition of nutrients and mainly increase the soil organic matter. The objective of this work was to evaluate the soil organic carbon in no-tillage system with historic of swine slurry application for 16 years. For this, the soil sampling was made in the 2016/2017 harvest in a long-term experiment located in Rio Verde / Goiás / Brazil, which consists of an area under no-tillage system (soy/corn rotation)divided into experimental plots with SS applicated in different doses (0, 25, 50, 75 and 100 m^{-3} ha^{-1}). The soil sampling was made in six soil depth (0-10,10-20,20-40,40-60,60-90,90-120 cm). The determination of the soil organic carbon followed the Walkley and Black methodology - wet oxidation with dichromate and acid. The results showed that the dose effect of swine slurry did not increase the organic carbon content of the soil, possibly due to the low dry matter content of the SS, doing it more homogeneous in relation to the quantity to be applied. However, as the soil depth increases, the organic carbon is reduced, which can be concluded that the swine slurry application has the potential to increase the soil organic carbon in the arable soil depth.

(3835 - 1829) The effects of mix-seeding of barley and hairy vetch on increasing biomass and nutrient contents

Lee, Cho Rong[1]; Park, Kwang Lai[1]; Hong, Seung Gil[1]; Kim, Jin Ho[1]

National Institute of Agricultural Sciences(NIAS)[1]

Green manure crops have been widely used in organic farming. Grass-legume mixture or mixed seeding of legumes and non-legumes can complement shortcomings of the other type (i.e. the former low in biomass and the latter low in the provision of nitrogen). This study was conducted to identify the optimum seed mixture ratio of barley (B) and hairy vetch (H) in organic upland soils of South Korea. From November 2016 to March 2017, barely and hairy vetch as single crops (B: 160kg/ha, H: 90kg/ha) and mixtures of both seeds at different seed mixture ratios (B2:H1, B1:H2) were sown and the results are shown as below. The amount of biomass and nutrient productivity shows higher in grass-legume mixture. As the proportion of hairy vetch increases, nitrogen and phosphorus concentrations of barley become greater. Yet those of hairy vetch are not affected by the increased proportion of barley. The amount of biomass and total phosphorus content are greater in mixed seeding by 78~132% and 200% respectively than in single seeding of hairy vetch. Total nitrogen content is higher in mixed seeding by 44% than in single seeding of barely. The amount of biomass (5.60Mg/ha) and nutrient contents (87.7 kg N/ha, 23kg P_2O_5/ha) are found highest in the case of seed mixture ratio of B2:H1. Accordingly, this study concludes that the optimum seed mixture ratio of barely and hairy vetch is 2 : 1 (B2:H1) considering the amount biomass and nutrient productivity, which seems highly useful for organic farming.

(1628 - 1030) Variation of chemical attributes of the soil between two years of application of residue water of swine in agrofloresty system.

Adriane de Andrade Silva[1]; Regina Maria Quintão Lana[1]; Beno Wendling[1]; Alini Bossolani Rossino[2]; Mark Andrew Alves Pereira Andrada Silva[2]

UFU[1]; PPGMQ -UFU[2]

The use of wastewater reduces the amount of effluent discharged into water systems or improperly in soils and also establishes an additional source of water and nutrients for the productive systems, making it an economically viable alternative for reducing the use of fertilization mineral. Thus, the objective of this study was to evaluate the effect of swine wastewater (ARS) on an agroforestry system as a source of soil nutrient cycling. The agroforestry system was implanted under in soil dystrophic Red Latosol. Three experiments were studied: single *Urochoa decumbens* pasture; *Corymbia citriodora* in single line, spacing 2 meters between plants and 15 meters between *corymbia* lines; *Corymbia citriodora* in double line, spacing 2 meters between plants on the line + 3 meters between rows and 15 meters between double rows of *corymbia.* For the evaluation of soil chemical attributes, soil samples were determined: sum of bases(SB); and then calculated the potential CTC and base saturation (V%). Differences were observed between the experiments and between the applied doses. The area with *Urochoa decumbens* single showed a smaller increase in soil attributes evaluated after application with ARS. In relation to the sum of bases, it was observed that in the single *Urocloa* there was no effect of the increase of the dose of ARS in the two years of evaluation, indicating that this species is an excellent extractor of bases. This same behavior was observed in the system with double-line *corymbia*, but in these treatments it was observed an increase of the contents in relation to the experiment with *urocloa* pasture. In the system with single line, average increase in the doses of 400, 600 and 800 m^3 ha^{-1} was observed. These same changes observed in the SB contents influenced the potential CTC. At base saturation, it was observed that in the double line, mean values above 50% were maintained regardless of the dose in the two-year evaluation. While in the simple line the increase in saturation occurred due to the increase of doses, being higher in the first year than in the second year of evaluation. In the pasture experiment the base saturation was not influenced by the doses and on average did not exceed 35%. It is concluded that the application of ARS influences the base contents of the system, but that the agroforestry systems due to the greater exploitation of the soil profile, have a better use than the pasture.

Keywords: Sustentable Systeams; sum of bases(SB); base saturation (V%);

(2326 - 327) Visual evaluation of soil structural quality in organic strawberry production

Camila Pereira Cagna[1]; Osvaldo Guedes Filho[1]; Maria Caroline Garcia Paschoal[1]; Lucas de Oliveira Neves[2]; Daiane de Fatima da Silva Haubert[2]; Nádia da Silva Salatta[2]

Universidade Federal do Paraná[1]; Univesidade Federal do Paraná[2]

Organic agriculture is characterized by the absence of pesticides, mineral fertilizers, and the frequent addition of organic matter to maintain fertility and improve the soil physical structure. Strawberry is a culture that has aroused interest in organic farmers because of its high yield and economic value. However, it is necessary to improve the conditions of soil management, through the adoption of a conservation management as the no-tillage. To evaluate changes that occur in the soil physical structure because of the adopted management, laboratory methods are used, although they are quite accurate and often have a high cost. The visual assessment of soil structural quality may be, in a fast, reliable and inexpensive way, an

important tool to identify management practices. The objective of this work was to evaluate the soil structural quality through visual analysis in organic strawberry production under no-tillage and conventional tillage systems. The experiment was carried out in Sítio rochedo, 17-years cultivated for organic strawberry production in the conventional tillage system, which has three production areas, following a 3-year crop rotation system. For the planting of the strawberry seedlings were made holes. The experimental area was splited in two treatments: organic strawberry cultivation under conventional tillage and –organic strawberry cultivation under no-tillage system. Three samples were taken from each experimental area with 0.15 m width by 0.20 m depth and 0.10 m thickness. For the visual analysis of the soil structural quality , a soil evaluation chart (VESS) was used. Then, visual scores were assigned for each treatment. The organic strawberry treatment in conventional tillage showed a significantly lower score (Qe = 1.3) than organic strawberry in no-tillage system (Qe = 2.1). The visual score in the conventional tillage system demonstrates a soil with excellent structural quality when compared to no-tillage. However, the lower value found for the conventional tillage reflects the soil disturbance in the surface layer, and not necessarily better structural quality. Thus, the higher value of visual score for the no-tillage system reflects a more structured soil condition when compared to conventional tillage. The method of visual analysis of soil structural quality is a practical and sensitive tool for management changes, capable of evaluating soil quality.

(4977 - 1442) Water availability in organic and conventional citrus orchard

Marcelo Raul Schmidt[1]; Michael Mazurana[1]; Victor Hugo da Silveira[1]; Renato Levien[1]

Universidade Federal do Rio Grande do Sul[1]

Brazil is the largest producer of citrus in the world with about 19,217,000 tons per year. Periods with water lack associated with strong sunshine affect fruit growth that influence on yield and quality. Soil provide water to plants growth and their management allow greater storage of water in to profile, reducing and mitigating these problems. The objective was evaluate the impact of soil management systems (conventional – CM and organic – OM) and machine traffic on water storage in entire 0-0.4 m soil layer in orchard citrus cultivated in Ultisol (80 g kg-1 clay) in South Brazil. The orchards have been conducted in these two systems for 10 years and those are the main treatments. The subplots are the traffic conditions (with tractor runs over – TR – and without traffic, i. g. plants line – PL). Soil samples were collected in to five layers until 0.4 m deep, subjected in a Richards chamber between 10 and 1,000 matric potential point, to quantify the amount of available water, after subjected the Van Genuchten model (1980). Ours results show more water volume stored in 0-0.2 m layer, in OM (compared CM) and in TR (independently of soil management). In PL, the available water (m^3 ha^{-1}) in both layers (0-0.2 and 0.2-0.4 m) was 208 and 170 in CM, and 255 and 160 in OM. On the TR treatment for same layers, the available water (m^3 ha^{-1}) was 223 and 185 in CM and 305 and 180 in OM. Our data show that OM provided 9.5 L m^{-3} of water more than CM in the PL, and 19 L m^{-3} more in the TR. Thereby, considering about 33% receives machine traffic and 67% do not, we estimated approximately 50,870 L ha^{-1} of water more in OM than CM. We concluded that organic management systems could increase the availability of water after 10 years, mitigating dry periods seasons. Further studies are need to know if this factor can increase the productivity, quality of fruits.

Keywords: Citrus; organic management; matric potential.

(4775 - 1180) Yield of rocket under different amounts and *Sena uniflora* L.

José Denis Lopes Diniz[1]; Marcos Antonio Vieira Batista[1]; Sherida Rayanne Cristovão Fernandes[1]; Gilbenes Bezerra Rosal[1]; Luiz Romário Uchoa[1]; Raysse Cristóvão Fernandes[1]

Instituto Federal de Educação, Ciência e Tecnologia do Ceará[1]

Rocket (*Eruca sativa* L.) is a leafy vegetable widely used in salads, rich in vitamin C, potassium, sulfur and iron. It also has anti-inflammatory and detoxifying effect. The growing consumer demand for quality and food safety has increased the need to adopt alternative production techniques that aim to minimize or eliminate the use of mineral fertilizers. An alternative is the use of green manure. The use of plants of the Caatinga as green manure is an alternative technique of management to vegetable production in Brazilian Northeast. One of these plants is *Sena uniflora*, however there is a need to evaluate it in cultivation with vegetables. The present work was carried out to evaluate the effect of *Sena uniflora* as green manure in yield of rocket. The experiment was conducted in horticulture sector the Federal Institute of Education, Science and Technology of Ceará, campus Iguatu in the period from October to December of 2017. The rocket was fertilized with *Sena uniflora* and the treatments were the different amounts incorporated in the soil (6.0, 12.0, 18.0 and 24.0 t ha -1 , on dry basis), plus the witness (bare soil). The samples were collected and used for chemical analyzes of nutrients of the *Sena uniflora* with the following results: N=1,41 %; P= 0,50 %; K=2,55 %; Ca = 1,78%; Mg= 0,26%; S= 0,21%; Fe = 443 mg kg^{-1}; Zn = 52 mg kg^{-1}; Cu = 4 mg kg^{-1}; Mn = 34 mg kg^{-1}; B = 22 mg kg^{-1}; C/N = 33:1; humidity= 7,5%. The green manure was incorporated into the soil ten days before planting. The experimental design was used in randomized complete blocks, with four replications. The evaluated characteristics in the rocket were: plant height, fresh mass of the aerial part, dry mass of the aerial part and number of leaves per plant. There was no significant difference for leaf number, plant height and fresh mass. There were significant differences for dry mass, with increasing linear response. The larger dry mass was 5,69 g $plant^{-1}$, 51% higher than zero amount that was 3,77 g $plant^{-1}$. Similar results were observed in other studies. It can be concluded that it is viable produce rocket using *Sena uniflora* as green manure.

Keywords: *Eruca sativa; Sena uniflora*, green manure.

(6337 - 2015) Soil physical quality and root development of citrus under a biodynamic production system in a Ultisol Dystrophic Hapludalf in Rio Grande do Sul

Caroline Valverde dos Santos[1]; Renato Levin[2]; Lucas Zulpo[2]; Joelma Divina Murliki[2]

UESB[1]; UFRGS[2]

The need to increase world food production leads to an intensification of the use of agricultural machinery and implements. Intensive use of this equipment in perennial plants promotes heterogeneous changes in the physical quality of the soil, resulting in the reduction of pore space responsible for root development. The objective of this work was to evaluate soil physical quality indicators and their relationship with root development of perennial plants. They were analyzed between lines of 'Montenegrina' bergamots (*Citrus deliciosa* Tenore) grafted on *Poncirus trifoliata*, managed with harrowing, logs in "V", mowing and knife roller, cultivated in Ultisol Dystrophic Hapludalf, located in the municipality of Montenegro, central region of Rio Grande do Sul, Brazil. Soil evaluations were performed at wheel tracks of the tractor (WT), between the wheel tracks (BWT), and in the area under the line projection of the canopy (CLP), at depths of 0.0-0.15, 0.15-0.30, 0.30-0.45 and 0.45-0.60 m layers, in four replicates. The soil physical quality indicators evaluated were soil density, macro and microporosity and total porosity, as well as the mechanical resistance of the soil to the penetration of a conical stem. The density and root

length of the rootstock were analyzed, with diameter <1.0 mm, 1.0-2.0 mm and >2.0 mm, by volume of soil. The results were submitted to analysis of variance, according to the design in subdivided plots, arranged in bands and comparison of means by Tukey's test ($p < 0.05$). The soil density ranged from 1.11 to 1.64 Mg m^{-3} with higher values found in WT, followed by BWT and CLP, in which the planting line managed with the use of the grid and trimmer showed higher values in relation to the others, as a consequence, in the reverse order, changes occurred in the pore space of the soil with a reduction of macroporosity, which presented values between 0.06 and 0.19 m^3 m^{-3}. Soil compaction was accentuated between 15 and 30 cm, evidenced by higher values of PR at this depth. CLP presented lower resistance to penetration, whereas BWT and WT presented moderate to high values, regardless of the type of implement used. The rootstock of the bergamots presented a higher density of roots at the site of the crown projection line, in all the depths, concentrated in the class of diameter <1.0 mm. The promoted soil movement promoted a reduction in the volume of soil explored by the bergamot root system, as evidenced by the use of the harrow in the orchard.

C3.2.3 - Artificial drainage systems: maintaining soil functions and protecting water resources

(4253 - 1793) Colloids control the transport and the fractionation of REEs in a river impacted by ion-adsorption rare earth mining

Wen-Shen Liu[1]; Meng-Yuan Zheng[1]; Le-Lan Wu[1]; Keng-Bo Ding[1]; Xi Zhong[1]; Chun-Mei Zhao[1]; Yuan-Qing Chao[1]; Hermine Huot[1]; Ye-Tao Tang[1]; Rong-Liang Qiu[1]
School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou, China; Guangdong Provincial Key Laboratory of Environmental Pollution Control and Remediation Technology, Guangzhou, China[1]

Middle rare earth elements (MREEs) and heavy REEs (HREEs) enrichment have been observed in most of the natural waters, while the reasons are still incongruent. In ion-adsorption rare earth deposits, REEs occur at trivalent cationic state (60%-95% of the total REEs) and are adsorbed onto clays and readily extractable by a simple leaching technique with an aqueous ammonium sulfate solution via an ion-exchange process. The objective of this work was to study the contribution of the colloids and the complexation by ligands to REE fractionation in a river impacted by ion-adsorption REE mining activities. In particular, the complexation of REEs by SO_4^{2-}, present in high concentrations at the upstream and by natural organic matter (NOM) at the downstream of the river were investigated. We sampled thirteen sites (3 parallels of each) along with a river influenced by ion-adsorption rare earth mining and one site of control at Dingnan, Southern China. REEs (<0.45 and <0.22μm), anions and cations (<0.45 and <0.22μm), pH, NOM (<0.7μm) were tested. Results showed a high REEs concentration in the water samples (<0.45 μm), which had a significant positive correlation with SO_4^{2-} and nitrogen concentrations, indicating mining activities sources. There was a transfer from MREEs to HREEs enrichment (normalized with Post-Archean Australian Shale (PAAS)) from upstream to downstream. At the downstream REEs were predominantly concentrated in 0.22-0.45-μm colloid fraction (59-94% of the <0.45 μm water). The proportion of REEs in the 0.22-0.45-μm colloids increased with the content of TOC in <0.45 μm water. In addition, the REEs in 0.22-0.45 colloids enriched HREEs at downstream, indicating a possible REE-NOR composition of 0.22-0.45 colloids in the downstream. These results were congruent with the results of the modelling by WHAM, which showed that NOR-REE colloids induced an enrichment in HREEs and were the dominant form of REEs (87-96% of the <0.45μm water) at the downstream. The results modeled by WHAM also showed that the major speciation of REEs was present in REE^{3+} (12-44% of the <0.45 μm water) and $REE(SO_4)^+$ (16-66% of the <0.45μm water) at the upstream water. In all, our results support that NOR-REEs colloids control the transport and fractionation of REEs in the river impacted by ion-adsorption rare earth mining activities. This stresses the need of ecotoxicological evaluation of REE-NOR colloids in such water bodies.

(7984 - 2361) Diagnosis of the conflict of use and occupation of soil in hydrical quality: a study in the córrego da olaria watershed – Pindorama, São Paulo, Brazil

Maria Conceição Lopes[1]; Antonio Lucio Mello Martins[2]; Mariana Bárbara Lopes Simedo[1]; Teresa Cristina Tarlé Pissarra[1]; Renato Farias do Valle Junior[3]; Renata Cristina Araújo Costa[1]
São Paulo State University (UNESP), Faculty of Agrarian and Veterinary Sciences, Jaboticabal Campus[1]; Polo Regional Centro Norte of São Paulo Agribusiness Technology Agency (APTA)[2]; Federal Institute of the Triangulo Mineiro – IFTM, Uberaba Campus[3]

The analysis of the ecosystem in the watershed, with respect to the use and suitability of the soil and the physical characteristics, of a given region should be managed in order to improve the knowledge to the quality of the water resources. The objective of this work was to identify the areas of conflict of land use, monitoring the physical-chemical parameters of the water, differentiating the variables in the area of environmental conflict according to the methodology of the roughness coefficient, which together with the mapping of the current use allowed to identify areas of conflict regarding the use and occupation and suitability of the soil in Córrego da Olaria watershed, Pindorama, São Paulo State, Brazil. Geographic Information System were used, and information integration was performed with overlapping information plans, identifying conflicts of use that correspond to 40.02% of the area of forests and agriculture, occupied by agricultural activities. The physical-chemical parameters: Temperature, Electrical Conductivity, Turbidity and Dissolved Total Solids differed according to the areas of environmental conflict of use and soil suitability.

Keywords: water resource, environmental monitoring, potential land use.

(1457 - 3134) Forest litter evaporation on Cerrado woodland

Lívia M. P. Rosalem[1]; Edson Wendland[1]
University of Sao Paulo[1]

Understanding hydrological and erosive processes are crucial to improve the efficiency of agricultural production. In many countries efforts have been done to better comprehend the processes and impacts related to the erosion process. Studies present that the forest litter helps the maintenance of moisture on soil and can affect the availability of water for runoff and soil infiltration. Regardless the impact of the forest litter, few studies evaluated the water evaporated from forest litter. For directly measurements of forest litter evaporation, an equipment called LID (Litter Interception Device) was installed in a Cerrado woodland area. From 1st June to 20th December

the total rainfall and the forest litter evaporation were recorded each 10 minutes. The collected data were separated into intervals of 3 hours and only the intervals without rainfall record were analyzed. It was observed lower values of total forest litter evaporation (2.3 and 3.7 mm) in June and September, respectively. The total forest litter evaporation was 71.0 mm that corresponds to 16.7% of the total rainfall (423.9 mm) for the period. Although the monitoring was just along 6 months, the results pointed that the evaporation of forest litter may be considered a significant hydrological process to the total evaporation in forests of Cerrado woodland. Thus, if the forest litter does not intercept this significant quantity, it would affect some processes as infiltration or runoff. Therefore, the forest litter interception should not be neglected. The monitoring must be carried out for more periods to achieve better analysis of variation of this interception along the year.

Keywords: Evaporation; Forest litter interception; Unsaturated zone; Available water.

(6828 - 1082) Monitoring of available water content variation on different upland soils using undisturbed weighable lysimeters

Junghun Ok[1]; Kyunghwa Han[1]; Yongseon Zhang[1]; Heerae Cho[1]; Kangho Jung[1]; Dongjin Kim[1]

Soil and Fertilizer Division, National Institute of Agricultural Sciences[1]

The droughts can be assessed based on soil moisture by monitoring of available water content (AWC) change in upland soil. The AWC is the range of available water that can be stored in soil and be available for growing crops. However, the AWC in the soil varies greatly depending on soil texture and bulk density. Therefore, the monitoring of AWC is difficult to know precise exact change value continuously in upland field. The aim of this study was to evaluate the effect of AWC change on crop growth using weighable lysimeters. The experiment was conducted at NAS lysimeter station (35°49'29.0"N, 127°02'46.4"E) with 18 weighable lysimeters (diameter 1 m, depth 1.5 m) with upland soil monoliths. The each 6 weighable lysimeters filled upland soils for silty clay loam, loam, and sandy loam, respectively. The tensiometers and soil moisture sensors (UMP-1) were installed at 10 ㎝, 30 ㎝, 55 ㎝, 85 ㎝ and 125 ㎝ soil depth from the surface, respectively. And the weight sensors were installed on the bottom of the lysimeter vessel to measure changes in water content in real times. The target crop was selected soybean because a large cultivation area and relatively high water consumption in Korea. The water management was treated irrigation at 50 kPa and no irrigation. In 2016, it showed low precipitation and high solar radiation compared to the last 30 years average. The yield of soybeans was reduced to 30% when the AWC for 10 days was continuously maintained at 15-45% without precipitation compared to the appropriate irrigation treatment. In addition, the whole leaf of the soybean was stunted when AWC was maintained lower than 15% for more than 7 days continuously. Therefore, the prediction of available water content variations in advance is considered necessary for appropriate water management.

Keywords: available water content, weighable lysimeter, soil texture, upland

(4256 - 1772) Spatial variability of soil attributes in a cultivated area of underground dam in the State of the Paraíba, Brazil

Maria Sonia Lopes da Silva[1]; Alexandre Ferreira do Nascimento[2]; Hilton Luís Ferraz da Silveira[3]

Embrapa Solos UEP Recife. Rua Antônio Falcão, 402. Boa Viagem. Recife, PE. 51020-230. E-mail: sonia.lopes@embrapa.br[1]; Embrapa Agrossilvipastoril. Rodovia MT, 222, Km 2,5, s/n. Zona Rural, Caixa Postal 343. Sinop, MT. CEP: 78550-970. E-mail: alexandre.nascimento@embrapa.br[2]; Embrapa Solos UEP Recife. Rua Antônio Falcão, 402. Boa Viagem. Recife, PE. 51020-230. E-mail: hilton.ferraz@embrapa.br[3]

The implementation of several municipal, state, and federal government programs aiming to facing the water scarcity has substantially improved the number of underground dams in the semiarid region of Brazil. That technology consists in the building of a waterproof wall transversal to drainage water preventing the lateral flow of water in and on the soil, stream bed, and River. So, the water is stored into the soil pores and may be used to crops "in situ" or to irrigate areas "ex situ", as well as to animal watering. Among the advantages in adopting the underground dams we highlight the functionality, low cost to building, low risk of contamination, low water loss by evapotranspiration, moreover it is possible to use the land around to crops. The areas of the underground dams are disturbed environments once it changes the natural water flow and its dynamic. Knowing the spatial variability of soil attributes in this colluvial/alluvial areas would aid to choose the better soil management that should be adopted to guarantee the sustainable food production in this environment. Geostatistic is a powerful tool for this purpose, allowing showing the special variability of soil attributes. This work aimed to assess the spatial variability of chemical and physical soil attributes of an underground dam located in Solânea county, Curimataú region, state of the Paraíba, semiarid area in northeast Brazil. Disturbed soil samples were collected from depth of 0-0.2 m and 0.2-0.4 m of 16 points distributed in a grid of 25 m x 30 m within the area of the underground dam. Soil attributes assessed were: pH, Ca^{2+}, Mg^{2+}, K^{+}, Na^{+}, Al^{3+}, H^{+}, P_2O_5, Organic Carbon, clay, silt, sand, and bulk density. The model applied to elaborate the maps to show the spatial variability was the Spline. The whole maps elaborated for each soil attribute did not show spatial dependence, indicating that even changing the environment by building a wall into the soil, there were no significantly disturbs in the soil attributes. Actually, the soil of the underground dam showed high fertility, high organic matter content, low acidity and Al^{3+} exchangeable, and with texture suitable to store water and to cropping. Therefore, underground dams did not trigger soil processes that can lead to soil degradation, as ions accumulation, acidity, low level of exchangeable bases, and high bulk density, however, we have realized just the opposite, very good condition to plants growing.

(1641 - 3104) Standardized difference vegetation index in the relationship of productivity and nitrogen content in corn cultivated in ilpf system

Hugo Miranda Faria[1]; Vinícius Marchioro[1]; Henildo De Sousa Pereira[1]; José Eduardo Corá[1]

UNESP Jaboticabal[1]

Knowledge about the possible interactions of components of the crop-livestock-forest integration system (ILPF) can help in the selection of management techniques that optimize the production system. In this way the objective of the work was to evaluate if there are synergic, null or antagonistic effects of the forest component in the productivity and nitrogen content in corn plants. The study was developed at the Teaching, Research and Extension Farm of UNESP, Campus de Jaboticabal. The experiment was composed of two areas, cultivated with maize in the intercropping, intercropped with Brachiaria, in the ILPF system, being the first area cultivated with Eucalyptus clone Urograndis I144, and the second, with the species Corymbia citriodora, in a double row system, spaced of 20 m. Nitrogen content

and yield of maize plants were evaluated. The normalized difference vegetation index (NDVI), obtained by means of an RGB optical sensor, drone board, was used for correlation with the nitrogen contents of corn plants and yield. In the maize plants closest to the eucalyptus renques, a higher concentration of nitrogen was observed, due to their development being affected by the shading caused by eucalyptus, with nutrient accumulation in the plant. It was also observed, in the plants near the roots, lower productivity. In the area with Urograndis, there was a greater antagonistic effect of the forest component, observing a reduction in the development of corn plants. The NDVI showed efficiency in determining the relationship of nitrogen contents with maize crop yield.
Keywords: remote sensing; *Zea mays*; NDVI.

(7264 - 1900) Environmental assessment of the Romão dos Reis basin, Viçosa, MG: case study

Saulo Henrique Barroso[1]; Agnaldo Roberto de Jesus Freitas[1]; Danilo Cesar Mello[2]; João Luiz Lani[1]
Universidade Federal de Viçosa[1]; Universidade de São Paulo[2]

The use of natural resources beyond the capacity of support causes negative impacts to the environment. As a result, several evidences reflect: water scarcity, reduction of water quality of streams, soil compaction, loss of fertility and fertile soil layers, erosion, salinization and loss of native vegetation in certain environments. Land use planning is a alternative measure of prevention that aims to the rational use of natural resources within the capacity of support of each environment and with a personalized management, taking a watershed micro-basin as a management unit, with a view to sustainability of the agroecosystem. From these principles, the environmental conditions of the Romão dos Reis sub-basin were evaluated with a view to better planning of land use, to provide better use and occupation of the soil, mitigating environmental impacts, and enabling the socioeconomic development of the population included in it. The sub-basin Romão dos Reis is located in the municipality of Viçosa, MG. It has an approximate area of 229 hectares and is inserted in the São Bartolomeu basins. For the preparation of the project was made field evaluations and as a mapping tool was used the software ArcGis 10.1. With the use of this software, the areas occupied by native vegetation (25.28% of the total area, 57 hectares) and other uses were delimited. It was found that there is a need to expand the area of PPAs(Permanent Preservation Area), as there are evident erosive processes at the edges of the streams. The predominant relief in the sub basin is from wavy to strong wavy (average slope of 29.33%). Given this, a differentiated use and occupation of slopes is suggested, according to their respective slope classes. In addition, the presence of an area favorable to the construction of dams was identified in places with bottlenecks in the stream channel, by means of level curve analysis (2-meter elevation). Finally, it is concluded that the planning of land use and occupation in watersheds is fundamental for a better balance of environmental conditions with this, it is proposed the implementation of small earth dams with the objective of acting as reserve of the supply system of water from Viçosa city, and to promote a physical barrier, retaining part of the sediments that are carried to the dams of the São Bartolomeu stream located in the Campus of the Federal University of Viçosa, thus reducing the silting process present in the dams.

C3.2.4 - Nutrient and contaminant transport in drained soils

(1622 - 1247) Agricultural land uses and their effects on water quality in Navarre (Spain)

I. Hernández-García[1]; D. Merchán[1]; E. Luquin[1]; M.A. Campo-Bescos[1]; R. Giménez[1]; J. Del Valle de Lersundi[2]; J. Casalí[1]
Department of Projects and Rural Engineering, IS-FOOD Institute (Innovation & Sustainable Development in Food Chain). Public University of Navarre[1]; Department of Rural Development, Environment and Local Administration, Government of Navarre[2]

Nitrate and phosphate leaching from agricultural areas is considered an important problem. The surplus of nitrogen (N) or phosphorus (P) applied in fertilization, often over the crop necessities, contributes to an increase in the soil emissions to the hydrosphere. Soil management, land use and, to a lesser extent, soil properties (texture, organic matter content, pH…) are recognized as factors that affect the leaching of nutrients and, therefore, water quality in receiving water bodies. N and P affect the water quality for human consumption or contribute to its eutrophication. On the other hand, an intensive management of agricultural soils not only affects nutrient leaching, but also implies an increment in soil erosion. Suspended sediment generated in erosion has several impacts in water bodies (reservoir siltation, vector of pollutants…). In agricultural areas of Navarre (Spain), soil erosion and nutrient export is a relevant problem. For that reason, the former Department of Agriculture, Livestock and Food (Government of Navarre) implemented a network of experimental watersheds in order to provide data for assessing the effect of agricultural activity on erosion and water quality. These watersheds are under typical management practices of the region and cover the most representative agricultural land uses in Navarre. The network is composed of four watersheds: Oskotz (grazed pastures and forests), La Tejeria and Latxaga (rainfed winter cereal) and Landazuria (pressurized irrigation). In these watersheds, a gradient of nitrate export has been observed, with irrigated areas exporting more nitrate than any other land use due to a higher N surplus whereas pastures and forests exported the lowest amounts. Differences in phosphate exports were explained by differences in soil pH and higher P inputs from livestock excrements in the pastures. Sediment export was greater in arable lands than in permanently covered soils (pastures and forests) or than in flat irrigated areas. Differences were found in the two rainfed winter cereal watersheds regarding sediment and nitrate exports, which were probably due to differences in drainage conditions, presence of riparian buffers and other site-specific characteristics. In this context the aim of this contribution is to summarize the knowledge generated so far on the effects of agricultural management and soil properties in the concentration and exported mass of nitrate, phosphate and suspended sediments in Navarre.
