nutrient, which affects the development of plants. It's necessary to understand the dynamics of this element in soils in order to obtain a better efficience of borated fertilizations. The objective was to evaluate the loss of boron by leaching, when this element is applied on the soil. The experiment was conducted in a completely random desing whose scheme was 6 x 2 factorial. For this study it was used 6 sources (fertilizers) of boron (boric acid, borax, boron monoethanolamine, sodium octaborate, ulexite and control treatment without addition of boron) which were applied in 2 different soil textures (médium and clayey), with 4 replicates. The dose of boron applied was 2 mg per dm^3 of soil, which represented 6.28 mg per column. Each experimental unit was prepared with a leaching column of 40 cm lenght (tubes of PVC) and these columns received irrigation in a period of 4 days, simulating a 20 mm – rain. The experimental lasted 64 days and after this period the loss of this nutrient was measured by ICP-OES. The interection of factors among the different sources was significative ($F < 0,05$).In general, the quantity of leached boron, for each applied fertilizer, was two more times for soils with medium texture when compared to clayey soils. However, the sources control and boron monoethanolamine showed similar results for the different kinds of soil (Turkey, $p < 0,05$). The higher clay in the soil, the higher adsorption of boron in the form of iron, aluminium oxids and kaolimite, which decreased the loss of this nutrient by leaching. The control source presented, in average, a loss of 6 % of boron in the two different soils, probably beacuse of boron which was in the soil and in the water during the irrigation period. The caly soil which received borax (fertilizer) showed a leaching superior to 24 % when compared to ulexite, octaborate and control sources. Besides, it showed the double of leaching when compared to boron acid (14%). In the soil with medium texture the fertilizer borax showed the biggest leaching, in avarege a loss of 18% more when compared to the sources of monoethanolamine, boric acid, ulexite and octaborate. The dynamic of boron in the soil depends on solubility of the added source and on pH; it also depends on the charges of adsortion of the nutrient in the soil. However, regardless of the texture of the soil, borax promoted the biggest losses of boron in the system.

(4813 - 2464) Contamination risks by potentially toxic elements into Oxisol irrigated with treated sewage effluent

Aline Michelle da Silva Barbosa[1]; Rogério Teixeira de Faria[2]; Luciana Maria Saran[2]; Yane de Freitas da Silva[2]; João Alberto Fischer Filho[1]; Anderson Prates Coelho[1]; Alexia Morello da Silva Cascaldi[1]

São Paulo State University (UNESP), School of Agricultural and Veterinarian Sciences, Jaboticabal, São Paulo, Brazil[1]; São Paulo State University (UNESP), School of Agricultural and Veterinarian Sciences, Jaboticabal, São Paulo, Brazil.[2]

The treated sewage reuse is promising to precision agriculture due to high water demand of irrigation and nutritional crops. In addition, to reduces environmental impact negative by avoiding discharge of effluent into bodies of water. However, in the long term, sewage treatment season effluent application (EETE) can cause chemical, physical and biological soil degradation. The aim of this study was to evaluate the impact the application of EETE, via fertirrigation, on the soil of an experimental area cultivated with Brachiaria crop at Jaboticabal, SP, Brazil. The EETE was applied during 4 years (2013 to 2017) in experiments using a triple sprinkler system, with delineated tracks, with four replicates. Five treatments were established by uniform application, but gradual irrigation blade of EETE, with following fractions of effluent in water: E5 = 100% effluent; E4 = 87%; E3 = 60%; E2 = 31%, E1 = 11% and E0 = 0. The treatment E0 were used only water and received fertilization with urea, triple superphosphate and potassium chloride, equivalent to what was applied to E3 treatment via effluent. In efluente the contents of As, Cd, Cu, Hg, Mo, Ni, Pb, Se, Zn. In soil, after 4 years of application of EETE concentrations of Ca, Mg, Na, K, Mn, Zn, Cd, Fe, Cd, Cr, Cu, Ni, As, Hg, Se and Mo. The application of EETE in soil cultivated with Brachiaria for 4 years resulted in a risk of soil contamination by Cu, Cd, Hg and Mo. However, it should be emphasized that the contents of these elements may be due to the soil characteristics of the region or due to the application of fertilizers. The concentration of Mo found in the soil, mainly in the treatment E5 (5.9 mg kg^{-1}), may be due to the content of this element in the effluent (4.38 mg L^{-1}), which was higher than the limiting concentration for Mo (0.001 mg L^{-1}) established in Resolution N. 430/2011 of the National Environment Council (CONAMA). Thus, it was concluded that the application of EETE of Jaboticabal, SP, Brazil, has low risk of contamination of the soil by these potentially toxic elements.

(4016 - 2817) Dissolved organic carbon and nitrate flow in surface waters of two mini watershed of the rio das mortes river watershed

Tulio Gonçalves dos Santos[1]; Ricardo Santos Silva Amorim[1]; Rodolfo Luiz Bezerra Nóbrega[2]; Edwaldo Dias Bocuti[1]; Luiz Augusto Di Loreto Di Raimo[1]

UFMT - PPGAT[1]; University of Reading - Department of Geography and Environmental Science[2]

The present study was carried out in Campo Verde - MT to evaluate the anthropic interference on dissolved organic carbon (DOC) and nitrate (NO3) flows in the surface waters of two mini watersheds. Water samples were collected in two mini watersheds with different soil use (regenerated savanna and an agricultural area) from January 2014 to April 2015. In the rainy season, the samples were collected every 15 days and in the dry period every month. The composite samples were collected by an automatic sampler in the stream. The water flow monitoring was performed with a sensor that measured the hydraulic load on the sill of the triangular spillway installed in each of the mini watershed. Three rain gauges were also installed in each of the mini watersheds to quantify the mean precipitation. The DOC and NO3 contents were analyzed in a UV-Vis spectrophotometer. The flow was estimated with the values of flow and concentrations of DOC and NO3. The mini watershed under cerrado has a higher average flow than the agricultural mini watershed. The increment in the values of specific flow in the days with rainfall is greater in the mini watershed under cerrado. The nitrate concentrations in the two mini watersheds are the same for rainy and dry days. The mini watershed under cerrado has the highest concentrations of dissolved organic carbon, regardless of rainfall. In both watersheds there is a significant increase in the concentration of nitrate and organic carbon dissolved in rainy days. The flows of dissolved organic carbon and nitrate are higher in the Cerrado microbasin, independent of the occurrence of rainfall.

(6867 - 2344) Exportation of chemical elements in particulate and soluble forms during rainfall events in a small rural catchment in southern Brazil.

Cláudia Alessandra Peixoto de Barros[1]; Tales Tiecher[1]; Rafael Ramon[1]; Jean Paolo Gomes Minella[2]; Marcos Antônio Bender[3]

Federal University of Rio Grande do Sul[1]; Federal University of Santa

Maria[2]; Emater, RS-ASCAR[3]

One of the major off-site consequences from soil water erosion is the contamination of waterbodies, by manure, chemical fertilizers and agrochemicals. Chemicals in the streamflow may be natural (e.g.: weathering), but the magnitude of erosive process can intensify the transference process of elements to the waterbodies. However, this process of chemical elements to waterbodies is still few explored. This study aims to investigate the relationship between the magnitude of erosive process and the transfer of chemical elements in their preferential form, soluble or particulate. The study was carried out in Lajeado Ferreira Creek catchment (1.23 km²) in Arvorezinha, RS, Br. The water and sediment flows were automatically monitored at 10 min-intervals. Manual samples for chemical analysis of the *water + sediment* mixture collected from 2011 to 2013, in the catchment outlet. An aliquot of the sample was filtered at 0.22 µm to characterize the soluble fraction. Another aliquot containing *water + sediment* was digested using aqua regia (HCl + H_2NO_4) assisted by microwave characterizing the total of elements. By the difference in the total and soluble element concentration, the particulate form was estimated. The chemicals exportation in each form was calculated from the element concentration multiplied by solid and/or liquid discharge data. Al, B, Ba, Be, Ca, Cd, Co, Cr, Cu, Fe, K, La, Mg, Mn, Na, Ni, P, Pb, Sb, Se, Si, Sr, Ti, V and Zn concentration were determined by ICP-OES. The samples were collected during eight rainfall events with peak flow that varied between 36 and 3399 L s^{-1} and sediment yield between 0.01 and 70.6 t. Observing the average of the events, Be, Ca, K, Na, Se, and Sr were the main elements carried out in the soluble form (>50%) whereas other elements had greater transference in the particulate form. It was observed that two events occurring in September and October of 2013 presented the largest sediment mobilizations, of which 91 and 92% of transference occurred in the particulate form, respectively. These months are when farmers carry out the tobacco transplantation, generating low soil covering and matching with the period of greater rainfall erosivity. Moreover, when analyzing them separately, it is verified that the chemical elements did not present similar behavior among the events. Therefore, the magnitude of the event and the availability of sediments have a large impact on the predominant fraction of chemical elements transference.

(8455 - 270) Improvement of a simplified model for Phosphorus Thresholds in soils receiving pig slurry in Santa Catarina State, Brazil

Luciano Colpo Gatiboni[1]; Daniel João Dal'Orsoletta[1]; Djalma Eugênio Schmidt[1]; Thomas Jot Smyth[2]; Rodrigo da Silveira Nicoloso[3]
Santa Catarina State University[1]; North Carolina State University[2]; Embrapa Swine and Poultry[3]

The state of Santa Catarina is the largest pork producer in Brazil. This activity is usually carried out on small farms (< 20 ha) in regions with steep slopes (20-40%), where pig slurry is applied to the soil surface as fertilizer for plants. Until 2014, the States' environmental legislation allowed the application of a maximum rate of 50 m^3 ha^{-1} $year^{-1}$ of pig slurry. However, this rule did not consider important factors such as the concentration of phosphorus (P) in the waste, the P sorption capacity of the soil, the removal of P by harvested crops and the use of other nutrient sources. After 2014 the legislation was improved, establishing a P-threshold, which is the maximum environmentally safe P concentration in the soil, beyond which the soil is a source of P to the environment and P fertilization should be stopped. The model was adjusted from studies using soils from the state and considered that soils with higher clay content sorb more P, so they could receive larger rates of manure. The model established was P-threshold = 40+Clay% (where *P-threshold* is the maximum content of P by the Mehlich-1, in mg dm^{-3}, in the 0-10 cm soil layer, and *clay%* is the clay content of the soil in percentage). This method has been used since then, and if a soil has a P content above the P-threshold, no inorganic or organic P application to the soil is allowed. However, the developed method infers only about the soil sorption capacity and does not consider the transport factors contributing to P loss by runoff. Thus, two field experiments were carried out using soils with contrasting textures (22 and 64% clay), three land slopes (10-15%, 20-25%, and 30-35%) and four rates of pig slurry (0, 110, 220 and 440 kg ha^{-1} $year^{-1}$ P_2O_5) in bermudagrass pastures. In these experiments water and sediments from the runoff were collected during 18 months and analyzed. In the sandy loam soil, the amount of P lost by runoff is less dependent on the slope due to the higher water infiltration rate of the soil. In this soil, increasing the slope from 15 to 35% increased by 37% the P lost into runoff. Conversely, in the clayey soil, increasing the slope from 10 to 30% increased by 95% the P lost into runoff. Thus, we are proposing to change the previous model, including the land slope as a factor for P-threshold reduction in soils susceptible to runoff. The adjusted model proposed is *P-threshold = (55+Clay%) - (0.03*Clay%*Slope%)*, where *Slope%* is the land slope in percentage, with R^2=0.96.

(7129 - 2251) Influence of land use and management on the quality of the water resource

Mariana Bárbara Lopes Simedo[1]; Teresa Cristina Tarlé Pissarra[1]; Antonio Lúcio Mello Martins[2]; Maria Conceição Lopes[1]; Renata Cristina Araújo Costa[1]
São Paulo State University (UNESP-FCAV)[1]; Polo Regional Centro Norte of São Paulo Agribusiness Technology Agency (APTA)[2]

The anthropic actions developed in the agricultural production system have threatened water resources. The watershed is a territorial unit of work that develop the anthropic activities, being essential the understanding of this productive space of occupation. The according to National Agency of Sanitary Surveillance, Brazil is the largest consumer of pesticides, and studies indicate that in the coming years there will be a high risk in water quality, due to the excess of substances used in agriculture. The National Environmental Council (CONAMA), through Resolution 357/2005 establishes a classification for water bodies and provides environmental guidelines for its framework. The objective of this study was to evaluate the quality of the water bodies in the Córrego da Olaria subbasin, correlating with the land use. This subbasin presents an extension of 9.18 km² and is located in the Polo Regional Centro Norte of the Agência Paulista de Tecnologia dos Agronegócios (APTA), Pindorama County, São Paulo State, Brazil. The surface water samples were collected at four points of the watershed (Cacau; Onça; Usina; Voçoroca). Soil uses include native forest, annual crop, pasture and reforestation. The physical-chemical parameters of water: nitrate (mg L^{-1} NO_3- – N), total nitrogen (mg L^{-1}), total phosphorus (mg L^{-1}), were analyzed at Laboratory of the International Institute of Ecology, Brazil. The data analysis was submitted to descriptive statistics, and in analysis of variance in a 5% of significance level. Total nitrogen is present with high values in all subbasins: Cacau 1.30; Onça 1.72; Usina 1.72 and Voçoroca 1.72, being the limit value allowed by CONAMA of 1.27 mg L^{-1}. Nutrients such as nitrogen and phosphorus are essential for plant growth, but excess in water can cause adverse ecological effects. Total phosphorus was high in the subbasins Cacau 0.105 and Usina 0.076. The maximum allowed value is 0.020 mg L^{-1}. The nitrate presented higher value in Cacau 12,29, with the limit value allowed of 10.00 mg

L^{-1} NO_3- – N. In the surroundings of these subbasins there is a large planting of sugar cane, which during the rainy season occurred the rupture of the crop level curves, collaborating for the surface runoff and deposition of sediments and nutrients in the water resource. It was concluded that the use and management of the soil influence the quality of the water resource, demonstrating the need for a set of conservationist practices in the agricultural system.

(5419 - 1544) Water, soil and phosphorus losses in no-tillage under long-term application of liquid dairy manure and simulated rainfall

Jair Augusto Zanon[1]; Nerilde Favaretto[1]; Gabriel Democh Goularte[1]
Federal University of Paraná[1]

Liquid dairy manure (LDM) has been worldwide applied as source of nutrients in agricultural production, however, the excessive application may generate environmental problems, such as pollutants associated with surface runoff. The aim of this work was to evaluate the effect of long-term application of LDM (12 years) in no-tillage in water, soil and phosphorus losses by surface runoff under simulated rainfall. The experiment was installed in 2005 at the ABC Foundation Experimental Station in Ponta Grossa, Paraná, Brazil, in a dystrophic red-yellow oxisol; sandy clay loam texture with 13% slope. The treatments consisted of four rates of LDM (0, 60, 120 and 180 m^3 ha^{-1} $year^{-1}$) with three replicates, totaling 12 experimental units. The simulated rainfall with intensity of 60 mm h^{-1} was applied in 1 m^2 with corn straw as plant residue; 120 days after the last application of LDM, which was carried out in the corn seedling. The surface runoff was measured at different time intervals until constant rate, with at least 90 minutes of sampling period. The analyses of water quality were performed in composed samples (10, 20, 30, 60 and 90 minutes). The following parameters were determined: pH, turbidity, sediments, electrical conductivity and phosphorus (soluble, particulate, total and bioavailable fractions). The results show similar trends for water and soil losses; 120 m^3 ha^{-1} $year^{-1}$ of LDM had the highest water loss and consequently the highest s oil loss. In general, the accumulated losses of water and soil were low compared to the applied rainfall which may be associated to higher soil aggregation and stability in no-tillage system. The concentration and losses of phosphorus in all fractions increased with application of LDM. These results indicated that intensive rainfall (60 mm h^{-1}) even in long-term application of LDM, which improves the soil structure, represents a potential for water contamination if the surface runoff reaches the water bodies. So, it is recommended best management practices to keep the generated runoff in the field, as for example the terraces, even in no-tillage system.

C3.2.5 - Soil erosion modelling: Global Alliance

(9945 - 520) Assessment of water erosion dynamics by connectivity indices in an agricultural watershed

María Guadalupe Ares[1]; Luisa Fernanda Fajardo[2]; Celio Chagas[3]; Marceo Varni[4]; Joaquín Mozo[5]
Consejo Nacional de Investigaciones Científicas y Técnicas; Instituto de Hidrología de Llanuras; UNCPBA, Facultad de Ingeniería[1]; Comisión de Investigaciones Científicas; Instituto de Hidrología de Llanuras; UNCPBA, Facultad de Ingeniería[2]; UBA, Facultad de Agronomía[3]; Instituto de Hidrología de Llanuras[4]; Agencia Nacional de Promoción Científica y Tecnológica; Instituto de Hidrología de Llanuras[5]

Water erosion is a global issue which affects soil quality and nutrients availability, and threatens agricultural productivity. The hydrological and sedimentological connectivity approach to study this process is being developed to understand its spatial heterogeneity and complexity and the dynamics of connections between hillslopes and drainage networks which redistribute the eroded soil. In this context, connectivity indices constitute important tools for erosion modelling. The objective of this work is to assess the sedimentological connectivity during three rainfall-runoff-soil loss events registered in a small basin (560 ha) under no-tillage agriculture by two indices. The first index, the index of sediment connectivity (IC), evaluates the structural connectivity, and is a measure of potential connectivity. It is calculated by geographical information system, using data derived from a digital elevation model (slope, flow direction, flow accumulation) and a map of factor C from Universal Soil Loss equation to consider the resistance to water and sediment fluxes by vegetation during each event. The second index corresponds to the index for physically connected compartments (Cpc), which considers aspects of structural and functional connectivity: the area physically connected, expressed as the area of the drainage network, and the rate of transported sediment during the events. This index complements IC, because it takes into account the variability of each storm and its hydro-sedimentological response. The IC index showed values of 1.35, 1.85 and 1.63 for event 1, 2 and 3, respectively, while Cpc values were 7.9, 16.4 and 175.9 for event 1, 2 and 3, respectively. The indices evidenced the low connectivity induced by the sheet erosion and the good vegetation cover conditions during event 1. Comparatively, during events 2 and 3 the indexes showed discrepancies: high potential connectivity (IC) for fallow period, but medium Cpc in relation with the connected area and the erosivity of the storm event. In contrast, the IC was medium for case 3, with good land cover condition, but Cpc was the highest related to the high erosivity of the rainfall which generated rills in the area. The results indicate that low vegetation cover and rill formation are two key factors which induce connectivity in the area. The adjustment of these indexes and their incorporation in erosion models may improve the understanding of the temporal dynamics of the erosion process.

(4104 - 2801) Different scale rainfall simulation methods and their applicability for erosion modelling

Boglárka Keller[1]; Judit Szabó[2]; Csaba Centeri[3]; Zoltán Szalai[2]; Gergely Jakab[2]
National Agricultural and Research and Innovation Centre[1]; MTA Research Centre for Astronomy and Earth Sciences[2]; Szent István University[3]

Rainfall simulation is widely applied instrument in soil erosion modelling within soil conservation planning since it is fast and more cost-effective than other soil erosion measurement methods. In the same time there are many criticisms due to the non-standardized circumstances and the difference between simulated and natural environment. Besides many studies emphasize that the results coming from different scale rainfall simulations aren't comparable and the resulted values aren't suitable for long term erosion modelling just for event-based modelling which reflects on soil erosion dynamic and hydrology. In our experiments Cambisol was investigated under two different scale rainfall simulation, in situ and ex situ circumstances. The comparative measurement was carried out in a laboratory on 0,5 m^2, and in field (Shower Power-02) on 6 m^2 plot size. The main idea was to examine and compare the results and its applicability in

different type soil erosion models concerning for long term and event-based methods. The mean compared parameters were the soil loss and soil erodibility. The applied model calculations originated from the USLE, USLE MM, GUEST and PESERA. The given results show high variability between the different rainfall experiments and calculation methods. The question is that: Which is the most suitable estimation method for event-based soil erosion modelling.

(9479 - 3148) Erodibility of a Yellow Latosol (LA) under pasture and SAF in the southern region of Amazonas, Brazil by two Indirect Methods

Tatiana Acácio da Silva[1]; Miqueias Lima Duarte[2]; Heron Salazar Costa[3]

Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, 786, Centro, Humaitá, 69800-000, Brasil (tatianaacacio1909@gmail.com)[1]; Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, 786, Centro, Humaitá, 69800-000, Brasil (miqueiaseng@hotmail.com)[2]; Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, 786, Centro, Humaitá, 69800-000, Brasil (hescosta@ufam.ed.br[3]

Despite the technological advancement of agriculture, soil erosion is still one of the most troubling economic and environmental problems, because, according to data from FAAO (2015), the global cereal production losses due to erosion here estimated at 7.6 mi t/year. The K factor, which corresponds to the inherent susceptibility of each soil to erosion, is a variable of the Universal Soil Loss Equation (USLE), a tool of great value in land use planning. It has been little used, either by lack of data or by ignorance of your practical value. This study aimed to evaluate the erodibility of a Yellow Latosol (LA), in the municipality of Apuí, southern of Amazonas State, using two methods: (I) Wischmeier & Smith (1978) and (II) Denardin (1990). , Ten samples deformed were collected randomly at the depth of 0-0.2 m of a LA, being five from an area under from pasture, and five from an area under Agroforestry System (SAF). The structure and permeability of the soil were determined directly in field as method proposed by Wischmeier et al. (1971). Particle size was determined by the total dispersion method with NaOH solution to 1.0 mol L^{-1} as chemical dispersant. For determining the dimensions of the solid particles (DMP) was held the screening of solid mineral fractions using a sieve Shaker. Organic exist when the issue has been estimated based on total organic carbon according to Yoemans & Bremner (1988). Considering the 0.20 m from the soil analyzed, LA studied presented predominantly silty texture franco silty (24.13% sand, 74.80% 2.19% silt, clay), and 0.268 mm average DMP structure predominantly moderate, small to medium granular. Moderate to rapid permeability can be observed is associated to the presence, on average of 63.23 $g.kg^{-1}$ of organic matter. The maximum and minimum values of soil erodibilidade, by method I, were: 0, $t.ha^{-1}.MJ^{-1}.mm^{-1}$ and 0.0065 $t.ha^{-1}.MJ^{-1}.mm^{-1}$, respectively, with average of 0.0012 $t.ha^{-1}.MJ^{-1}.mm^{-1}$. By method II: 0, 0224 $t.ha^{-1}.MJ^{-1}.mm^{-1}$ and 0 1.mm, 0045 $t.ha^{-1}.MJ^{-1}.mm^{-1}$, also respectively to the maximum and minimum, and average of 0.93 0143 $t.ha^{-1}.MJ^{-1}.mm^{-1}$. No significant difference was observed between the averages of the K values calculated for the area under pasture and under SAF. Considering the values observed in the literature, the soil was evaluated high erodibility. The data will be used to draw up a map of vulnerability to erosion associated with the distribution of rains in the region.

(7871 - 3185) Erodibility of soils in southern Amazonas State for two Indirect Methods

Larissa Carvalho Gato[1]; Heron Salazar Costa[2]; Miqueias Lima Duarte[3]

Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, 786, Centro, Humaitá, 69800-000, Brasil (larissambiental@gmail.com)[1]; Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, 786, Centro, Humaitá, 69800-000, Brasil (hecosta@ufam.edu.br)[2]; Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, 786, Centro, Humaitá, 69800-000, Brasil (miqueiaseng@hotmail.com)[3]

The erodibility of the soil is represented by the factor K in the Universal Soil Loss Equation (USLE). It expressed the susceptibility of soil to the erosive process. Such geological process causes degradation of agricultural soils, generating losses. According to data from FAAO (2015), the global cereal production losses due to erosion were estimated at 7.6 million tons per year. Such losses can be avoided with management techniques indicated for each condition of erodibility of each soil. The aim of this study was to estimate the erodibility of different classes of soils in southern Amazonas State through two indirect methods. We used published data of the attributes necessary for the application of the method proposed by Dernadin (1990) and the proposed by Mannigel et al. (2002). The study area is located in southern Amazonas State, where collections were carried out in a toposequences (four sampling points), as well as in Black Land sites in depth Archaeological 0-22 cm (seven sampling points). For application of the proposed methods, has evaluated the structure, permeability, texture, organic matter and weighted average particle diameter (DMP). By the Mannigel et al. (2002) method, were found the following maximum, medium and minimum values of the index K for each soil, expressed in $t.ha.h.ha^{-1}MJ^{-1}.mm^{-1}$: Gleysols: 0.0271; 0.0239 and 0.0207; Cambisols: 0.0354, 0.0329 and 0.0313; Acrisol: 0.0364; 0.028925 and 0.0219 and Neossolo: 0.0972; 0.07645 and 0.0557. By the Denardin (1990) method, the maximum values of K were equal in all soils (0.0134 $t.ha.h.ha^{-1}MJ^{-1}.mm^{-1}$). However, Gleysols presented maximum, medium and minimum only (0.0134 $t.ha.h.ha^{-1}MJ^{-1}.mm^{-1}$). Cambisols, Acrisol and Neossolo presented the same minimum value (0.0089 $t.ha.h.ha^{-1}MJ^{-1}.mm^{-1}$), while the average value differentiated for classes Cambisols (0.0104 $t.ha.h.ha^{-1}MJ^{-1}.mm^{-1}$), Acrisol (0.010025 $t.ha.h.ha^{-1}MJ^{-1}.mm^{-1}$) and Neossolo (0.01115 $t.ha.h.ha^{-1}MJ^{-1}.mm^{-1}$). Relating the values obtained by different methods, it was observed that those found by the method of Denardin proved to be lower than the values observed by the method of Mannigel, contrary to results observed in the literature. Considering the lack of information on the topic for the region, emphasized the importance of this work to obtain data that will enable the construction of maps of vulnerability to rain erosion of soils of the region studied.

(7993 - 2120) Estimation of erosion and proposal of soil conservation practices in Florencia and El Llano in Zamorano, Honduras

Mariana Gómez Botero[1]; Gloria E. Arévalo[1]; Carlos A. Gauggel[1]

Escuela Agrícola Panamericana, Zamorano[1]

Erosion is a process of disintegration, transport and deposition of soil materials by wind and water, resulting in the loss of about 40 billion tons per year. The objectives were: i. Calculate soil loss by erosion

under current management conditions and by changing the sowing direction in Florencia and El Llano in Zamorano, Honduras, ii. Design conservation practices under current management conditions and by changing the sowing direction. The universal soil loss equation USLE was used. The precipitation pattern, soil properties, length and degree of the slope, cover, land management and soil conservation practices were analyzed. These are loamy soils, slopes between 0 and 30% and length of the slope between 37 and 506 m. Currently, it is lost between 6 and 31 $t \cdot ha^{-1}$ $year^{-1}$. By changing the sowing direction, soil erosion varies between 3 and 16 $t \cdot ha^{-1} year^{-1}$. The proposal is to construct broad-base terraces of variable widths of 20, 50 and 100 m, separated by channels of 1 m width and maximum 30 cm depth, which allows the passage of machinery and does not interrupt the sowing lines, or change the sowing direction perpendicular to the slope. Elaborate collecting drains at distances varying between 50 and 575 m. Also, put water energy dissipators in the channels and sowing in covered beds and furrows to prevent erosion on slopes <5%.

Keywords: Broad-base terraces, collector drains, USLE, water energy dissipators.

(1417 - 2653) Estimation of water erosion by Erosion Potential Method in a watershed of southern Minas Gerais.

Natanael Rodolfo Ribeiro Sakuno[1]; Augusto César Guiçardi[1]; André Silva Tavares[1]; Lucas Emanuel Servidoni[1]; Diogo Olivetti[2]; Ronaldo Luiz Mincato[1]
Federal University of Alfenas[1]; University of Brasília[2]

Water erosion is the phenomenon that most affects tropical soils with losses of arable areas and support to ecosystems. Thus, studies estimating rates of water erosion are essential for assessing the impacts of soil degradation and consequent production and loss of sediment. The aim of this study was to estimate the potential soil losses due to water erosion in a Hydrographic Basin in the south of the State of Minas Gerais, by the Erosion Potential Method. For this, geological, topographic, pedological and climatic data were obtained from a database based on soil analysis and land use and occupation using geoprocessing techniques. Besides the occupation, the digital mapping of the soils of the area was also carried out, being found Red Latosols in flat relief to soft, wavy, undulating and strongly undulated. Data were compared with those obtained and by the Revised Universal Equation of Soil Loss. The coefficient of erosion intensity, Z, was 0.325, which is indicative of low erosion intensity. Potential mean losses for the basin were 49 Mg ha-1 year-1 by the Erosion Potential Method and 40 Mg ha-1 year-1 by the Revised Universal Soil Loss Equation. The application of this methodology demonstrated the potential of both soil loss prediction models for tropical regions. Erosion Potential Method estimated higher loss rates in pasture areas, which occupy a larger area, while the Revised Universal Soil Loss Equation estimated the greatest losses for exposed soil areas. Values of the soil losses indicate the presence of management and occupation of the sustainable soils in the basin. Anthropic actions do not have a deleterious bias and the high permeability rates indicate conservationist management, which means that the average slope does not prevent the agricultural occupation, provided that with sustainable management practices. The lack of data obtained from experimental plots of data validation indicates that soil losses are potential. Pearson correlation coefficient was 0.96 between the two models and indicates that the Erosion Potential Method is effective and can be applied in the estimation of soil losses in tropical regions.

Keywords: Modeling of water erosion; Erosion Potential Method; Revised Universal Equation of Soil Losses; Tropical Soils.

(4620 - 1730) Hidrossedimentological Simulation using the WATERSED Model

Ana Letícia Sbitkowski Chamma[1]; Jean Paolo Gomes Minella[1]
Federal University of Santa Maria[1]

The objective of this study is to verify the modeling efficiency of surface runoff and sediment yield with a physics based model found in rainfall events and with high potential for applying to soil and water conservation programs at catchment scale. The erosive processes that occur at catchment scale are, in many cases, difficult to describe, with hydrological monitoring associated with modeling, which is indispensable for the hydrological and environmental degradation behavior to be predicted and understood. Considering the existing diversity of hydrological and erosive models, it is crucial to choose/develop those that are representative of local hydrological processes and sensitive (parameters) to conservation practices to be defined in the catchment. In this study, the WATERSED model is used in the Arvorezinha experimental catchment, which is located in the Municipality of Arvorezinha, Rio Grande do Sul State. The WATERSED model is a relatively simple hydrological and erosive model that considers the dominant factors of the erosive process in the catchment through the formulation of decision tables, which require a smaller amount of input data. The evaluation of the model in the description of the processes is performed in twenty pluviometric events with significant surface runoff and sediment production. The results obtained by the simulation of the WATERSED model were compared to the data of the monitored events.

Keywords: Hydrological Modeling. Catchment Scale. Erosive Processes. Physics-based models.

(4328 - 2996) Hydrosedimentological dynamics in a hydrographic basin covered by Red Oxisols in Southeast of Brazil

Joaquim Ernesto Bernardes Ayer[1]; Lucas Emanuel Servidoni[2]; Marx Leandro Naves Silva[3]; Sueli Yoshinaga Pereira[1]; Ronaldo Luiz Mincato[2]
UNICAMP / IGE[1]; UNIFAL-MG / ICN[2]; UFLA / DCS[3]

Sixteen samples of deformed and undeformed soil of Red Oxisols were collected from 0.0 to 0.2m depth to evaluate the hydrosedimentological dynamic in the Pedra Branca River Basin (PBB), southern Minas Gerais, Brazil. The distribution of the attributes of soil pH, aluminum toxicity, organic matter, cation exchange capacity (effective and potential), soil texture, clay flocculation, aggregate stability, soil permeability, and data from the literature, were used to evaluate the hydrosedimentological dynamic. Physical and chemical attributes of Red Oxisols were spatialized by geostatistical and geoprocessing techniques. Several maps of this basin were generated by GIS, as digital terrain model, trend surfaces and interpolations of soil attributes, vegetation index (NDVI), flow direction and susceptibility to erosion. These results make it possible to show the inputs and outputs in the hydrosedimentological system. The basin studied has 2.642 ha of area and the climate of the region is Tropical Mesothermic (CwA-Köppen), with mean precipitation of 1,500 mm/year. The region is characterized by the transition between Atlantic Forest and Savanna biomes but with only 10% of native forest remnants. The geological substrate is dating from Proterozoic with gneissic and granulitic rocks, and have relief slightly undulated to undulated where slopes between 2 to 20% prevail and Red Oxisols dominate. Sampling points in the floodplain areas with indiscriminate tropical soils and in low slopes, when compared to areas with higher slope and altimetry elevation, have more acidic pH, increase in cation exchange capacity, increase of small grains and reduction of permeability, indicating changes in soil attributes, when compared to previous studies. The high slope areas have more organic matter, because of difficulty of mechanization by the agriculture while in the slopes with low and middles declivity present higher rates of erosion, carrying to the river sediments and many agrochemicals, since the

region is the world's largest coffee producer and makes extensive use of these products. As shown by the maps of flow direction and NDVI, the erosion channels are completely degraded, and most of the sediments are carried into the river. Therefore, the characterization of and spatialization of the bio-physiographical attributes of the landscape, had shown changes of soils by wrong soil practices management, resulting in soil erosion and silting in rivers.

(5256 - 234) Hydrosedimentological modeling with a high level of detail in an urban basin with a high slope

DaríoTomas Rodriguez[1]; Gerardo Adrián Riccardi[2]; Pedro Abel Basile[2]; Sergio Daniel Vera[1]; José Javier Fernandez[1]; Juan Antonio Sanchez[1]
FI-UNaM[1]; FCEIA-UNR[2]

Changes in the land uses of the basins triggered by the urbanization processes cause an increase in surface volumes and higher runoff velocities, processes that directly affect the generation and transfer of sediments by water erosion. Particularly, the basins of the mountain range of Misiones, Argentina have rugged topography and are subject to severe pluviographic events of convective fronts, which increase the erosion potential of the fine soils that cover the region. Product of previous investigations is counted on a hydrological-hydraulic model with a high level detail, built in the SWMM, in the Mbotaby basin of the city of Oberá, which has allowed the characterization the runoff of one of the most densely populated urban basins of the Central Sierra` Misiones. The present work details the coupling of the hydrological-hydraulic model available with algorithms of production and transfer of sediments of the Mbotaby basin. The model implemented allowed us to disaggregate the sediment production of both permeable and impermeable areas, as well as to simulate the accumulation of sediments during the dry periods prior to the storms. For the calibration process hydrosedimentological measurements were made in 10 events and were contrasted with results calculated in terms of levels, flows and TSS, reaching a satisfactory level of approximation. In the modeling carried out, the net precipitation range varied between 30.4 and 177.5mm, producing sediments between 0.28 and 1.77T/ha. The results indicate that the sediment discharges have values of TSS closer to values determined by the methodologies that predict higher volumes of sediments, 6.44 [T/(ha year)]. A subsequent sensitivity analysis indicated that the model shows a greater sensitivity to the C11 coefficient (drag exponent of the permeable areas), followed by C10 (drag coefficient of permeable areas), while the coefficient of lower sensitivity is C8 (coefficient of dragging of impervious areas). It is concluded that the technological tool achieved is suitable for future exploitations where it is expected to evaluate the performance of structural and non-structural measures tending to control the processes of erosion-sedimentation in this type of basins before different design events and hypothetical future scenarios.

(9934 - 3039) Mapping of rain erosivity in mato grosso state

Luis Augusto Di Loreto Di Raimo[1]; Ricardo Santos Silva Amorim[2]; Eduardo Guimarães Couto[2]; Edwaldo Dias Bocuti[1]; Wellington de Azambuja Magalhães[1]; Rodolfo Luiz Bezerra Nóbrega[3]
Federal University of Mato Grosso, Postgraduate Program in Tropical Agriculture, , Cuiabá, MT, Brazil[1]; Department of Soil and Agricultural Engineering, Federal University of Mato Grosso, Cuiabá, MT, Brazil[2]; Department of Geography and Environmental Science, University of Reading, Reading, United Kingdom[3]

The rainfall capacity to cause erosion on unprotected soils is denominated rainfall erosivity. Due to the oscillations of soil coverage, agricultural lands present variable susceptibility throughout the year and, depending on the erosive characteristics of the local rains, can stimulate the erosive processes. Mato Grosso state, the largest national grains producer, it has wide farming areas that, along year, they stay through long exposure periods. In that way, this study aimed to predict and to map the spatial and temporal variability of rain erosivity for Mato Grosso state. To estimate the rainfall erosivity, it was used regression equations, taking as an independent variable rain coefficient (Rc), which was obtained from rainfall data. Therefore, monthly (EI_{30}) and annual (R) rainfall erosivity were calculated for 158 stations, distributed over the Mato Grosso territory and with a minimum historical series with ten years of data. Sequentially, to obtain the maps, the EI_{30} and R values were spatialized from kriging method. The R values, in MJ mm ha^{-1} h^{-1} $year^{-1}$, were classified as low (less than 2452), average (2452 to 4905), medium high (4905,1 to 7357), high (7357,1 to 9810) and very high (greater than 9810). The EI_{30} values, in MJ mm ha^{-1} h^{-1}, were classified as very low (less than 250), low (from 250 to 500), average (from 500,1 to 750), high (from 750,1 to 1000) and very high (greater than 1000). The R values were correlated with latitude, longitude and height, aiming to a better understanding of spatial variation of erosivity in Mato Grosso state. To discuss the peculiarities of each region, the EI_{30} and R maps were subdivided into macroregions (northwest, north, northeast, middle north, west, south center and southeast). At the northwest, north, west and middle north macroregions of Mato Grosso state occur the highest values of the R. The R values in the very high class predominate in the north and, classes high and medium high, in the south. The average value of R for Mato Grosso state is equal to 8835 MJ mm ha^{-1} $year^{-1}$ (classified as high). Between October and April, related with the rainy season, occur 91% of R, being October, January and February the most critical months, due the high erosivity values (responsible for 41% of R) in planting and harvesting season, when the soil surface is exposed. The variations of latitude and height, up to 300 meters, are the factors that best explain the spatial variations of R in Mato Grosso state.

(6442 - 1425) Modeling Ephemeral Gully Erosion in Agricultural Fields of Southern Ontario, Canada

Prasad Daggupati[1]; Swapan Roy[1]; Kevin McKague[2]; Cliff Patterson[3]; Asim Biswas[1]; Ramesh Rudra[1]
University of Guelph[1]; Ontario Ministry of Agriculture and Rural Affairs[2]; Kettle Creek Conservation Authority[3]

Erosion of agricultural fields due to climatic and land use changes is very severe on many unprotected farmlands around the world. Ephemeral gully (EG) erosion significantly contributes to total soil losses from upland area to stream channels and is a serious environmental and productivity problem. In the last couple of decades, a few physical and semi-empirical based prediction models have been developed to estimate EG erosion so that appropriate conservation measures can be implemented. In this study, the Annualized Agricultural Non-Point Source (AnnAGNPS) model will be used to investigate the mechanics of EGs and quantify EG erosion and also overland erosion in selected fields across several watersheds in southern Ontario. In the selected fields, inputs of Digital Elevation Model (DEM) is being generated from Unmanned Aerial Vehicles (UAVs) equipped with high resolution camera, soil characteristics are being manually measured. Other inputs such as implemented management practices and available daily climate data are also being collected. Inputs collected in selected fields will be incorporated in AnnAGNPS model in which overland erosion is simulated using

Revised Universal Soil Loss Equation (RUSLE) and EGs are simulated using Revised Ephemeral Gully Erosion Model (REGEM). Simulated results of overland and EG erosion will be used to understand the mechanics of EGs and their contribution to total erosion in Ontario. In addition, economic impact analysis of EG and overland erosion will be performed.

(7123 - 3173) Monitoring of accelerated erosion in recovered slope using Bioengineering of soils in the state of Alagoas, Brazil

Diego Medeiros1[1]; Jonas Olímpio de Lima Silva[2]; Erivaldo James Rocha do Rego[1]; Luiggi Canário Cabral e Sousa[1]; Claudia Lins[3]; Regla Toujaguez La Rosa Massahud[1]

CECA-UFAL[1]; CECAUFAL[2]; IGDEMA-UFAL[3]

At the Northeast of Brazil, the state of Alagoas, followed by the state of Pernambuco are the most affected places for the intense rainfall and flooding according to the Nacional Center of Monitoring and Warnings of Natural Disasters (*Centro Nacional de Monitoramento e Alertas de Desastres Naturais*). Into the state of Alagoas the town called Rio Largo, located at the region of Zona da Mata, is one of the most affected as acknowledge by the historical disasters registers especially due to occurrence of strong rainfalls between 2010 and 2017, presenting accelerated erosion registers in excavated slopes uncovered by vegetation with over 60º rise. Therefore, the aim of this research was apply the Bioengineering of Soils associating the grass Vetiver (*Chrysopogon zizanioides*) to the biodegradable geotextiles (BG) made of fibers of banana tree bark to counter the accelerated erosion in three experimental areas (controlling area without BG and Vetiver, an area with BG and Vetiver applied and an area with only Vetiver applied) of a degraded slope (84 m² - 14 m x 6 m) at the Center of Agricultural Science (Centro de Ciências Agrárias) of the Federal University of Alagoas. Also, monitoring the efficiency of this method using date collected by land surveying techniques and computational modeling by the software AutoCad Civil 3D between February and August of 2017. The growth of the part above of the ground of the Vetiver was noticed all over the areas where it was applied. However, the efficiency of BG could not be quantified by the method applied; the vegetation cover could be clearly noticed over the land surveys the area BG and Vetiver presented the smallest ground loss. By the models generated from the areas a increasing of the ground loss was noticed all over the experiment between the first and third (and last) land surveys, increasing from 0,14 m³ to 0,89 m³ of volume. Associated to a uncommon volume of rain on th town during April and May of 2017. In conclusion, the use of land surveying techniques and computational modeling at hard access areas required appropriateness in the method and instrument used to data collecting to achieve more reliable results. Increase the point's density to represent the natural ground and use others algorithms to refine the models. The use of Vetiver associated to BG made of banana tree bark showed itself a low cost technique useful to recover slopes affected by accelerated erosion.

(8905 - 2821) Natural potential of water erosion for Mato Grosso state, Brazil

Luis Augusto Di Loreto Di Raimo[1]; Ricardo Santos Silva Amorim[1]; Eduardo Guimarães Couto[1]; Edwaldo Dias Bocuti[1]; Tulio Gonçalves dos Santos[1]; Rafael Vinicius Rodrigues[2]

Postgraduate Program in Tropical Agriculture, Federal University of Mato Grosso[1]; Postgraduate Program in Water Resources, Federal University of Mato Grosso[2]

Currently, Mato Grosso state has a prominent position in the Brazilian agricultural production, it is responsible for 25% and 13% of the production of grain and the national cattle herd, respectively. Clearly, such high rate of agricultural production requires wide areas of Mato Grosso. However, it is known that unduly exploited areas, without regarding the land use capacity, can be severely eroded, becoming quickly unusable. Therefore, the spatial characterization of soil susceptibility to erosion is a decisive tool for future land use planning, allowing the identification of critical areas, which should be studied and explored with greater attention. Thus, the aim of this study was to estimate the spatial variability of natural potential erosion (NPE) along the Mato Grosso territory. In order to obtain NPE, the universal soil loss equation (USLE) was used, considering the erosivity (R), erodibility (K) and topographic factor (LS) values. The R values were obtained for 158 points by means of regression equations that use rainfall data as independent variable. Values of K were estimated from equations proposed by Wischmeier and Smith, in 1978, and Denardin, in 1990, to 427 points distributed by the state. The spatialization of R and K values were achieved by using geostatistics and kriging methods. The LS map was obtained by applying the LS factor equation, proposed by Bertoni and Lombardi Neto in 1985, on a slope map, got from the union and processing of SRTM images. The NPE values, in t ha^{-1} $year^{-1}$, were classified as low (less than 100), average (from 100 to 200), high (from 200.01 to 600) and very high (greater than 600.01). Aiming a better visualization of critical regions, the Mato Grosso state was subdivided into macroregions of agroeconomic similarity (northwest, north, northeast, middle north, west, south center and southeast). In Mato Grosso state predominate PNE values in the average, low and high classes, that covers 59%, 20% and 22% of its territory, respectively. The areas of low NPE are situated mainly in the flat regions of state, showing relief as a preponderant factor for attribution of such NPE class. The regions with high NPE, considered critical, cover greater proportions in the northwest (46.69%), north (32.70%) and west (30.06%) macroregions. The wide extensions of high NPE used with agriculture, on north of west macroregion, illustrate a problematic region, which might be monitored according to annual rates of soil loss.

Keywords: NPE, soil conservation, erosivity, erodibility, USLE

(9845 - 2033) Organic matter content under coverage plants

Dione Pereira Cardoso[1]; Lucas Rodrigues Nicole[2]; Fábio Ribeiro Pires[2]; Kerwin Araujo Costa[2]; Vinícius Soares de Oliveira[2]; Alessandra Ferreira Belo[2]; Raquel Cristina Ramos[2]; Benedicto Barbosa Netto[2]; Gabriel Marcarini de Aguiar Sousa[2]

Federal University of Lavras[1]; North University Center of Espírito Santo – Federal University of Espírito Santo[2]

The content of organic matter is of utmost importance for the construction of soil fertility. However, the increase of this content is difficult, mainly in sandy soils. In this context, the objective was to evaluate the organic matter content provided by the cultivation of coverage plants in sand dystrophic yellow agrisol, submitted to two additional irrigation regimes. The randomized blocks design has been used, in split plots, in a 2 x 6 scheme, with four replicates (48 experimental units). The plots were two additional irrigation schemes, water regime 1 (I_1) and with 50% of the water volume, the water regime 2 (I_2). The subplots were six covering plants, four cultivars of *Pennisetum glaucum* L. - Millet (ADR 300, ADR500, ADRf 6010 and BRS 1501), *Canavalia ensiformis* DC. (Jack bean) and - *Brachiaria ruziziensis* (Brachiaria), evaluated at depths of 0-0.20 m and 0.20-0.40 m. The determination of the organic matter has been achieved by humid

carbon oxidation with potassium dichromate in acidic medium. The values were submitted to analysis of variance anf the Tukey mean test was performed, at a significance level of 0.05, using the Sisvar software. The highest organic matter content in the soil was observed in the I2 regime, that is, the reduction in availability has favored the increase in soil. There was no difference in the organic matter content between the cover crops evaluated. The values differed from 1.43 dag kg^{-1} for brachiaria to 1.61 dag kg^{-1} for pork. In relation to the depths, the superficial layer (0-0.10 m) provided the largest contribution of organic matter (1.87 dag kg^{-1}) in relation to the depth of 0.20-0.40 m (1.20 dag kg^{-1}). This is due to the deposition of the vegetable remains on the surface of the soil. Therefore, it is economically viable to grow these cover crops under reduced irrigation. With successive experiments, it is possible that there will be a differentiation in the organic matter content between these cover plants.

(3820 - 2076) Probable causes of the return of erosion in areas with no-tillage system

Claudia Maria do Prado Furquim[1]; Adriana Pereira da Silva[1]; Lucas Augusto de Assis Moraes[1]; Eliane Araújo[1]; João Tavares Filho[1]

Universidade Estadual de Londrina[1]

The State of Parana, Brazil, has in its agribusiness main economic activity with more than 30 million hectares for the production of grain under no-tillage system (NTS). However, this technology, until then considered effective in erosion control, has increased gradually in the soil loss. The objective was to understand the likely causes of the return of erosion in areas under NTS, in rural properties in the North of Parana. The municipalities which were analyzed were Lerroville, Tamarana and Ortigueira, being the predominant soil class were Oxisols. The methodology used was a questionnaire for the survey of information pertaining to soil management and use of agricultural terrace, with 145 farmers which were selected through information obtained by the rural extension and agricultural cooperatives. Of the 145 questionnaires answered, 41% got elementary school, 53% high school and 6% higher school. Of this total, 37% properties ≤ 30 ha, 38% properties between 30-100 ha and 25% properties ≥ 100 ha. 100% of respondents stated that the NTS held the property comprises permanent soil cover, crop rotation and the minimum tillage exclusively on sowing line. However, when the questions were more specific, 70% declared low residual straw when they observe the sowing of a new culture and 97% are sown annually the same crops, such as soybeans, corn and wheat because has such influence the market value of the grain. Still, 88% declared using every 3 years some kind of equipment with the goal of breaking the surface layer more compact the soil. The use of implements on the ground soon after the winter culture seems to be a common practice. However, the effect of the tickler is short term with little or no modification is preserved in the soil structure after this period. The issues relating to the use of agricultural terrace showed that 74% consider that only the NTS is enough in erosion control, eliminating the use of terraces in the fields. In addition, 81% considered that the removal of the terraces facilitates soil management and the application of pesticides in the direction of the slope, without cause problems to the soil, thus increasing, according to 72% of respondents, the efficiency in the use of machines. It was concluded that the erosion has as causes the lack of crop rotation for a repeatability of same year species; The tickler to decompression of the surface layer; the removal of agricultural terraces and consequent slope planting.

(9891 - 1516) Ratio between rare earth element fluxes in suspended sediments and bedload under watershed-scale

Yuri Jacques Agra Bezerra da Silva[1]; Fábio Farias Amorim[2]; Clístenes Williams Araújo do Nascimento[2]; Ygor Jacques Agra Bezerra da Silva[2]; Vijay P. Singh[2]; José Ramon Barros Cantalice[2]

Federal University of Piaui[1]; Federal Rural University of Pernambuco[2]

Rare earth elements (REEs) have been recently recognized as potentially emergent pollutants in rivers. However, data regarding REE fluxes in suspended sediments and bedload are scarce. Aiming to fill this gap, we determined the concentration and flux of La, Ce, Pr, Nd, Sm, Eu, Gd, Yb, Lu, Dy, Er, Ho, Tb and Tm in bedload and suspended sediments of a representative and polluted Brazilian River. Suspended and bedload sediments were collected from upstream and downstream cross sections, using the US DH–48 and BLH-84 sampler, respectively. The REE concentration in suspended sediments and bedload were determined using inductively coupled plasma optical emission spectroscopy. Light rare earth elements (LREEs) comprised more than 94% of the total REE associated with suspended sediments and bedload. Suspended sediments accounted for more than 95% of the REE flux. Thus, suspended sediments controlled REE flux to the ocean. The Ce and Nd fluxes of about 7 t $year^{-1}$ were higher than those reported for Cd, Cr, Cu, Hg and As. On the other hand, bedload often transported less than 0.0007 t $year^{-1}$ for each element and did not play an important role for the REE flux. It draws attention to the importance of including REEs in future estimation of global element flux carried by suspended sediments. Bedload does not play an important role in transporting REEs in Ipojuca River; however, it might have some influence at short distances.

(7742 - 910) Resistance of acrisols to erosion in soils in brazilian semi-arid environment

Rennan Cabral Nascimento[1]; José Ramon Barros Cantalice[1]; Wagner Luis da Silva Souza[2]; Douglas Monteiro Cavalcanti[1]; Elves Obede dos Santos Nunes[1]; Sergio Monthezuma Santoianni Guerra[1]; Fábio Farias Amorim[1]

Universidade Federal Rural de Pernambuco[1]; Instituto Federal de Pernambuco[2]

In the Brazilian Semi-Arid, many areas under exposed soil conditions, potentiate the erosive actions of rain, and the consequent desertification process. The objective of this work was to determine the erodibility in pre-formed rills on acrisols in the semi-arid environment of Brazil, through field experimentation. The study was carried in the Exu Riacho watershed, sub-basin of the Pajeú River, of the state of Pernambuco (Brazil). The soil was classified as Acrisol red-yellow. The region has a hot semi-arid climate, with annual mean precipitation around 647 mm. For the determination of erodibility (Kr) and critical shear stress (τc) experimental erosion procedures were performed on preformed rills with concentrated runoff simulations. The rills were preformed with 3m in length and 0.15m in depth. The experimental design was completely randomized, with four flow rates (treatment) and four replications: 20.66; 40.22; 60.2 and 79.3 L min^{-1}, totaling sixteen flow simulations. The samples liquid and solid samples were collected at the bottom of each channel for four minute intervals, being the first one after the initiation of the flow. The total time for each simulation was 12 minutes. the results were submitted to analysis of variance ($p>0.05$) and tukey test. For the determination

of the Kr and τc, linear regression analysis was performed between the shear stress values of the concentrated surface runoff and the soil detachment rates. The Kr was considered equal to the angular coefficient of the line, and τc was determined by the intercept value of the shear stress when the soil detachment rate is zero. The angular coefficient of the line, which determines the Kr of the soil, was 0.0176kg$N^{-1}s^{-1}$. In addition, the τc, which represents the intercept between the straight and the abscissa, was 4.72 Pa. The Kr and τc in preformed rills obtained here are greater than other results obtained on acrisols, from experimentation, as in Braida and Cassol (1996) (Kr = 0.0104 kg$N^{-1}s^{-1}$), Schäfer et al. (2001) (Kr=0.012 kg$N^{-1}s^{-1}$/τc = 2.61 Pa) and, Cantalice et al. (Kr = 0.0024 kg $N^{-1}s^{-1}$/τc = 2.75 Pa). The lower content of the clay fraction, may have minimized the cohesive forces between the particles, increasing the susceptibility to detachment and consequent transport. Therefore, the acrisol presented erodibilid attributes and critical stress of steepness indicated that this class of soil in the semiarid environment presents greater susceptibility to erosion in rills.

Keywords: erodibility, critical shear stress, concentrated runoff.

(9878 - 2285) Sediment fingerprinting using geochemical tracers: a global meta-analysis

Rafael Ramon[1]; Tales Tiecher[2]
Graduate Program in Soil Science, Federal University of Rio Grande do Sul, 7712, Bento Gonçalves Avenue, 91540-000, Porto Alegre, RS, Brazil[1]; Department of Soil Science, Federal University of Rio Grande do Sul, 7712, Bento Gonçalves Avenue, 91540-000, Porto Alegre, RS, Brazil[2]

Fingerprinting approach has been recently widely used to trace the sources of sediments in catchment scale. This method is based on the fact that the chemical characteristics of eroded sediments are related to the characteristics of the potential sediment sources. Two of the main prerequisites for the use of physic-chemical characteristics as tracers of sediment origin are: (i) to be conservative during the process of erosion and transport and (ii) to show differences in the concentration among the potential sources. Tracer selection for this purpose is a key step of the fingerprinting procedure, but the tracers selected are often very site-specific. Therefore, a review of the main procedure and the tracers most successfully used in these studies could be helpful to guide applications of this methodology. This study aims to review scientific publications that have used geochemical composition as a tracer of sediment sources in order to provide information regarding (i) the conservativeness behaviour of geochemical tracers and (ii) the tracers most frequently selected to use in apportionment models. We reviewed 112 scientific papers published from 1988 to 2018 that used the geochemical composition as potential tracers, involving a total of 319 different modelling approaches. Of these tracers, 26 papers and 73 approaches were removed from the analysis because of limited information provided about statistical procedure used. Altogether, 75 geochemical tracers were tested as the potential ones. We focused our analysis on the 30 most frequently tracers used (Al, As, Ba, C, Ca, Cd, Ce, Co, Cr, Cu, Fe, Ga, K, La, Mg, Mn, Mo, N, Na, Ni, P, Pb, Rb, Sb, Sr, Ti, Tl, V, Y and Zn). Only 42% of these papers applied a conservative test. Ba (n=100, 55%), Y (n=74, 55%) and Rb (n=61, 54%) were considered as the most conservative. On the other hand, elements that are part of the biogeochemical cycle, such as C (n=51, 81%), N (n=34, 81%) and P (n=83, 78%), were considered as non-conservative. Al (n=107, 46%), Ti (n=140, 36%) Sr (n=145, 30%), K (n=208, 29%) and Ba (n=151, 28%) were the most frequently selected elements in the final set of tracers to model sediment sources contribution, while N (n=126, 15%), Na (n=198, 14%), As (n=170, 14%), Sb (n=114, 14%) and Tl (n=81, 11%) were the less selected elements. Studies are needed to optimize and make feasible the application of the fingerprinting approach, giving directions to the choice of tracers and their evaluation methods.

Keywords: Soil erosion, suspended sediment, catchment scale, fingerprinting review.

(4849 - 2161) Sediment production by different intensity and duration of simulated rainfall

Wilk Sampaio de Almeida[1]; Fernandes Antônio Costa Pereira[2]; Daniel Fonseca de Carvalho[2]
Federal Institute of Education, Science and Technology of Rondônia / Federal Rural University of Rio de Janeiro[1]; Federal Rural University of Rio de Janeiro[2]

Erosivity is the main meteorological parameter studied to know the erosive potential of rainfall. However, the physical characteristics of rainfall provide completely different levels of soil erosion, even when the total erosivity of these rainfall is equal. We studied the effect of the intensity and duration of rainfall with the same total erosivity on soil particles detachment. For this, two types of rain were applied with five repetitions each using a portable rotating disk simulator, with constant intensities of 44.5 mm h^{-1} and duration of 106 min and rains of 75 mm h^{-1} and duration of 38 min. After the soil tillage (two plowing scales and a leveling harrow) the plots (1.0 m x 0.70 m) were fixed in the experimental area. Before the application of rainfall in the field plots, the soil was moistened to standardize soil water content prior to rainfall application. When was observeted the runoff beginning, at every minute the runoff was quantified and every five minutes, a sample of the runoff was collected to determine the sediment production. The total rainfall erosivity was 871,404 MJ mm ha^{-1} h^{-1} ± 0,139 MJ mm ha^{-1} h^{-1}. The accumulated sediment production varied from 3.33 g m^{-2} (rain of 75 mm h^{-1} and 38 min of duration) to 6.23 g m^{-2} (rainfall of 44.5 mm h^{-1} and 106 min of duration). The sediment yield rate ranged from 0.011 g m^{-2} min^{-1} to 0.092 g m^{-2} min^{-1} for a greater intensity of 0.059 g m^{-2} min^{-1} to 0.065 g m^{-2} min^{-1} to the lowest intensity of rain. The pattern of rainfall occurrence due to its physical characteristics influence in the total erosivity and, consequently, on precipitated volume, on surface runoff and on detachment of the soil particles. However, the rainfall with the shortest duration and the high intensity also have high potential to produce soil particles detachment (in our study 53.45% of sediments in relation to rainfall of 44,5 mm h^{-1}). Thus, the potential of rainfall to erode the soil is not only related to its total rainfall erosivity, but also to the form of precipitation.

(8572 - 2134) Soil loss by water erosion in the Oxisols of a hydrographic sub-basin, affluent of a hydroelectric power plant reservoir, Brazilian southeast

Augusto César Ferreira Guiçardi[1]; Natanael Rodolfo Ribeiro Sakuno[1]; André SIlva Tavares[1]; Joaquim Ernesto Bernardes Ayer[2]; Lucas Emanuel Servidoni[1]; Marx Leandro Naves Silva[3]; Ronaldo Luiz Mincato[1]
Universidade Federal de Alfenas - UNIFAL-MG[1]; Universidade Estadual de Campinas - UNICAMP[2]; Universidade Federal de Lavras - UFLA[3]

In natural conditions the surface's erosion is compensated by the continuous alteration of the rocks. However, the lack of adequate soil management increases erosion, which causes socio-economic and environmental havocs. The study was conducted between November 2016 and October 2017 in the Pedra Branca Stream Hydrographic Sub-basin, located in the city of Alfenas, affluent of the Furnas Hydroelectric Power Plant reservoir, an important hydric resource in the Brazilian southeast. The aim was to apply the Revised Universal Soil Loss Equation using a geographic information system for the spatialization of soil losses considering potential and current erosions. In the potential erosion mapping, which considers the topographic, soil erodibility and rainfall erosivity factors, it was observed that of the total area, 51.14% presented losses up to 100 Mg ha^{-1} $year^{-1}$, 32.67% losses ranging from 100 to 200 Mg ha^{-1} $year^{-1}$ and 16.19% losses above 200 Mg ha^{-1} $year^{-1}$, mainly conditioned by relief. In the current erosion mapping, obtained by the incorporation of the vegetation coverage, land use and management, and soil conservation practices factors regarding the potential erosion, the highest losses were 98.78 Mg ha^{-1} $year^{-1}$, occurring in bare soil areas, followed by the eucalyptus, maize, pasture, sugarcane and coffee crops representing 14.25, 14.19, 10.98, 6.99 and 4.62 Mg ha^{-1} $year^{-1}$, respectively. On the other hand, the areas that suffered least losses of soil due to hydric erosion, with 1.63 Mg ha^{-1} $year^{-1}$, were native forest areas, reiterating their protective role in the sediment detachment and sediment transport processes. 33.65% of the area presented losses above the tolerance limit of soil losses, calculated in 9.52, 9.99 and 8.94 Mg ha^{-1} $year^{-1}$ for the Red Oxisols with slope up to 8%, from 8% to 20%, and higher than 20%, respectively. However, simulating a scenario with all crops associated with conservation techniques such as no-tillage, contour farming, increased crop densities in the case of coffee, no burning in the harvest in the case of sugarcane and adequate pasture management, the average losses would fall from 8.00 to 2.20 Mg ha^{-1} $year^{-1}$, and only 2.04% of the area would be above the soil loss tolerance limits, showing that conservationist management should be widely spread among agricultural producers, hence drastically reducing the erosive potential of tropical regions.

(4846 - 1561) Space distribution of rainfall erosivity in climate change scenarios for the state of Tocantins, Brazil

Wharley Pereira dos Santos[1]; Junior Cesar Avanzi[1]; Marcelo Ribeiro Viola[2]; Nilton Curi[1]

Department of Soil Science, Federal University of Lavras, Brazil[1]; Department of Engineering, Federal University of Lavras, Brazil[2]

Improper soil management and land use can lead to degradation of available natural resources. This is a fact that tends to worsen with the climatic changes that are taking place on Earth. Among the aggravating factors, water erosion due to rainfall potential is a relevant factor in studies involving climatic variables. Thus, modeling rainfall erosivity (R-factor) to locations where rainfall data in series are scarce is imperative. The objective of this work was to predict rainfall erosivity by the middle of the 21st century in two scenarios of future climate change of the IPCC's Fifth Assessment Report (AR5) ("representative concentration pathways") for the state of Tocantins, located on the last Brazilian agricultural frontier. The two RCPs span a range of year 2100 radiative forcing values from 4.5 to 8.5 W/m², RCP 4.5 and RCP 8.5, respectively. For this, daily precipitation data were obtained from downscaling performed through the regional climate model (RCM) Eta-MIROC5. After correction of the precipitation biases found in the simulated model in relation to the observed climate (1985 to 2005) from rain gauge stations, an overlap on baseline period of the regional climate model, and the statistical validation of the model, we proceeded to use equations available in the surroundings of the state considering as an independent variable the mean monthly precipitation or the modified Fournier index for calculating the R-factor. Lower annual mean erosivity values were found in the future climate simulation compared to the historical period of climate events, with a mean reduction of 12.4% for RCP 4.5 and 12.5% for RCP 8.5. The mean annual erosivity presented values between 5,181.05 and 14,499.93 MJ mm ha^{-1} h^{-1} yr^{-1} for RCP 4.5 and between 4,724.72 and 14,927.90 MJ mm ha^{-1} h^{-1} yr^{-1} for RCP 8.5. The lowest reductions in the erosivity factor occurred in the north, west and southeast regions of the state for both scenarios. The results provide a future overview for soil and water conservation planning on Tocantins state with higher-skill of RCM-based climate-change impact studies.

(6231 - 267) Surface soil erosion assessment in a Protected Area on Paraty Municipality coast, Rio de Janeiro State, Brazil

Luana de Almeida Rangel[1]; Antonio Jose Teixeira Guerra[2]

D.Sc in Geography at Federal University of Rio de Janeiro – Geography Department, Federal University of Rio de Janeiro - Athos da Silveira Ramos Avenue, 274, Rio de Janeiro State, 21940- 590, Brazil (luarangel24@gmail.com)[1]; PhD in Soil Erosion at London University - Geography Department, Federal University of Rio de Janeiro - Athos da Silveira Ramos Avenue, 274, Rio de Janeiro State, 21940- 590, Brazil[2]

In humid tropical areas, water erosion is a major cause of soil loss. An analysis of the microtopography, soil compaction and soil quality allows inferring areas that are suffering with erosive processes. The use of trails in Protected Areas, can cause impacts when there is no planning and management suitable for their implementation and use. This research work aims at analyzing soil quality on a trail located on the coast of Serra da Bocaina National Park (PNSB), in Paraty Municipality, Rio de Janeiro State. To reach this target, soil microtopography was monitored using the erosion bridge method (EB), between 2016 and 2017. Soil compaction, through penetrometry (PN) was also assessed at two sites, on the trail. In addition, physical and chemical quality of the soils was assesed in three sites of the trail (PT), at 0-10 cm depth. Soil aggregates stability was performed according to the Yoder method (1936), texture and organic matter analysis were carried out following the methods of EMBRAPA-Brazil (2013). The trail is suffering with the effect of trampling, mainly in PN2, where the resistance to penetration was 29.12 kgf/cm², and with the removal of sediments by water erosion, mainly in EB 2, where the eroded area was approximately 0.21m². Regarding aggregate stability, PT3 was less stable (88.34%), while PT2 presented greater stability (97.73%). Organic matter contents corroborate the values found in the analysis of aggregate stability, PT3 presented the lowest values (3.43%) and PT2 presented the highest values (6.55%). Soil texture varied between Clay Loam (PT1), Sandy Clay Loam (PT 2) and Loam (PT 3). The highest concentrations of silt + fine sand, fine particles more susceptible to erosion were found in PT1 (45.07%) and PT3 (40.88%). In conclusion, the trail is suffering from intense trampling of the users, which is negatively affecting soil quality and influencing the occurrence of erosive processes, associated with runoff, such as the occurrence of microrills and rills.

(4596 - 2912) Use of tracer and digital filters for runoff separation: an aid to modeling soil erosion in catchments

Felipe Bernardi[1]; Jean Paolo Gomes Minella[1]; Claudia Alessandra Peixoto de Barros[2]; Daniel Allasia[1]; Alexandre Schlesner[1]
Federal University of Santa Maria,[1]; Federal University of Rio Grande do Sul[2]

Modeling sediment production requires precise hydrological control to quantify erosion processes. Erosion processes occur mainly due to the high kinetic energy of surface hydrological processes. In catchments, the water outlet is recorded in a hydrograph and composed of surface and subsurface flows. Thus, a valuable strategy for hydrological control and understanding of the erosive processes by modeling is the separation of these components in relation to their trajectory. For this, the use of conservative elements or properties of the hydrological system have been widely used. Tracers are elements that are conserved in specific phases of the hydrological process, thus allowing, through mass balance, to quantify different components. Another widely used method for separating flow is recursive digital filters (RDF), which are computational routines applied over the flow that remove the large amplitudes of the hydrograph associated to surface flow. Recursive digital filters are empirical models and numerous studies have shown positive correlation between RDF and tracers. Additionally, the responses of RDF are calibrated and validated by tracer observations, which enables the separation of the entire series. The Lajeado Ferreira catchment area, which is located in the municipality of Arvorezinha-RS in southern Brazil, was the subject of different sediment modeling studies. In order to verify the participation of the different flows, sample collection of the dissolved silica (DSi) tracer was performed to verify the behavior of the plot of each component in the hydrograph. With the use of these observations, the parameterization of the RDF model, which is called the Eckhardt filter, allowed flow separation of the river catchment, in addition to being coupled to erosion prediction models. Separation of the flow facilitates interpretation by the model of hydrological processes, such as infiltration, resulting in greater quantitative control over the superficial processes responsible for the production of sediments.

C3.2.6 - Agricultural management to protect soil resource to support a growing population

(4809 - 2742) Abundance of microarthropods in conventional tillage and direct systems in areas under cultivation of *Nicotiana tabacum*

Vanessa Aparecida dos Santos Silva[1]; Gleidson Gimenes Rieff[1]; Victor Lucas Bassani[1]; Enilson Luiz Saccol de Sá[1]
Universidade Federal do Rio Grande do Sul – UFRGS, Laboratório de Microbiologia do Solo, 91540-000 - Porto Alegre - RS – Brasil.[1]

Management practices such as soil rotation in the conventional tillage system and the maintenance of straw in the no-tillage system and the use of monocultures can affect the diversity of mites and collembolans. The aim of this study was to verify the population dynamics of mites and collembolans and to monitor the degree of influence of soil management systems in areas under tobacco cultivation and to evaluate the potential use of these organisms as bioindicators.This work was conducted in Arvorezinha (Rio Grande do Sul state) watershed in two areas under tobacco cultivation, one under no - tillage system and another under conventional tillage system. Samplings were also made in native forest areas as a reference of the site. Soil samples were collected during the period of one crop cycle. The soil samples were removed with a metal cylinder (0 - 7.5 cm). Subsequently, the extraction of mites and collembolans has been performed by the Berlese-Tullgren Funnel method and the captured micro-arthropods were cataloged and identified. A total of 4744 individuals were captured, 2599 mites and 2145 collembolans,the lowest abundance was in the area under conventional tobacco cultivation. The native forest area located below the crop was also affected by the conventional cropping system. This cropping system had a greater impact on edaphic diversity than the no - tillage system.The same occurred also in the native forest area located below conventional cultivation, with a reduction in the abundance of Oribatidae families. From these results it is possible to observe the potential bio-indicator of the mites and collembolans. Tobacco cultivation systems have an impact on the diversity of microarthropods. However, we can see that in no-tillage there is less impact.

(7858 - 656) Aggregate tensile strength in sugarcane areas with different cover crops and soil tillage system

Lenon Henrique Lovera[1]; Camila Viana Vieira Farhate[1]; Ingrid Nehmi de Oliveira[1]; Zigomar Menezes de Souza[1]; Elizeu de Souza Lima[1]; Diego Alexander Aguilera Esteban[1]; Fabio Henrique Barbosa Sandoval[1]; Euriana Guimarães[1]; Felipe Freitas Barbosa[1]
Unicamp/Feagri[1]

Aggregate tensile strength, defined as the force per unit area required to cause aggregate disruption, is a measure sensitive to the effects of land use and management systems on soil structure. Our aim was to assess aggregate tensile strength by applying different cover crops and soil tillage systems to sugarcane cultivation. We carried out the study at Santa Fe Mill experimental field, located in the municipality of Ibitinga-SP covering an area of typic Ultisol. The experiment implementation occurred in blocks in a subdivided-plots scheme containing four cover plants (sum hemp, millet, peanut and high biomass sorghum) and four soil tillage systems (no-tillage, minimum tillage, deep subsoiling, and conventional tillage), with three replicates. To establish the aggregate tensile strength, we collected deformed soil samples on the layers of 0.00-0.05, 0.05-0.10, 0.10-0.20, 0.20-0.30, and 0.30-0.70 m, while dry aggregates were obtained by a dry sieving in the size classes of 19.0 to 12.5 mm for carrying out the tests using a dynamometer. The aggregate tensile strength variability occurred mainly in depth, where the soil surface layers presented the formation of aggregates with lower tensile strength than the surface layers. Such results were probably influenced by the presence of the textural B horizon, peculiar to the Ultisol soil. As for the treatment effect, the use of legumes as cover plants (sum hemp and peanut) associated with deep subsoil system provided the formation of aggregates with higher tensile strength, 79 and 62 kPa, respectively. In contrast, the treatment with no-tillage for the millet presented the formation of aggregates with higher tensile strength, 71 kPa, 30% above the remaining treatments. The treatment with high biomass sorghum indicated no differences because of different soil preparation systems. Therefore, our results point out that each cover plan requires the use of a specific soil tillage system during sugarcane planting, aiming at the formation of more resistant aggregates to adverse management conditions.

(9420 - 1226) Application of hydrogel and organic residue and their effects on soil chemical and biological attributes

Mirian Cristina Gomes Costa[1]; Mário Rógeson de Abreu Vasconcelos[1]; Paulo Furtado Mendes Filho[1]

Universidade Federal do Ceará[1]

Reforestation is a conservation practice needed to combat soil degradation in the Brazilian semi-arid region. Nevertheless, due to water deficit and low fertility of degraded soils, alternatives are necessary to enable reforestation in the region. Polyacrylamide hydrogels and the organic residue from carnauba palm, bagana (leaf fibers, byproduct of wax production), have been proposed for reforestation in the semi-arid region because, besides retaining water, these materials are believed to release nutrients and improve biological attributes in the soil. The present study evaluated soil chemical attributes and the presence of arbuscular mycorrhizal fungi (AMF) in response to hydrogel doses, with and without the addition of bagana. In February 2014, an experiment was installed in a degraded Haplic Planosol, using a randomized block design, in 2 x 4 factorial arrangement, with five replicates. Treatments consisted of four hydrogel doses (0.0, 4.0, 5.0 and 6.0 g L^{-1}), with and without the addition of bagana as top-dressing. Hydrogel was applied in the holes to which *Enterolobium contortisiliquum* (Vell.) Morong. seedlings were transplanted. In October 2015, soil samples were collected in the 0-20 cm layer to determine the contents of phosphorus (P), calcium (Ca), magnesium (Mg), potassium (K), sodium (Na), copper (Cu), iron (Fe), manganese (Mn) and zinc (Zn) in the soil, and to evaluate AMF colonization. The data were subjected to analysis of variance; regression analysis for the quantitative factor and means comparison for the qualitative factor. The highest hydrogel dose (6 g L^{-1}) reduced soil Ca and K contents in the treatments with and without bagana, which may result from the greater growth and higher absorption of nutrients by plants in this treatment. Without hydrogel (zero dose), soil Ca content was higher (1.6 $cmol_c$ kg^{-1}) without addition of bagana. With the hydrogel doses, soil Ca contents increased in the treatment with bagana. At the hydrogel dose 0.0 g L^{-1}, soil K contents were similar in the treatments with and without bagana (0.25 $cmol_c$ kg^{-1}), but from the hydrogel dose 4 g L^{-1} on, soil K contents increased in the treatment with bagana and decreased in the treatment without bagana. Zn contents linearly decreased in the soil that did not receive bagana. Mycorrhization was 54.4% under bagana application and 30.6% without the organic residue. Hydrogel doses also contributed to the increase of mycorrhization.

(2819 - 2774) Assessment of crop combinations in small farms for local adaptation to rainfall variability and soil types in the semi-arid tropics

Yenumula Gerard Prasad*[1]; Ashok Kumar Singh[2]
ICAR-ATARI, HYDERABAD[1]; Indian Council of Agricultural Research[2]

Small farmers in the semi-arid tropics face increasing rainfall uncertainty during the crucial South-West monsoon cropping season (June-September). Crop performance is adversely affected due to late onset of monsoon leading to early season drought or prolonged dry spells after normal onset leading to mid season drought and sometimes early withdrawal of monsoon leading to terminal moisture stress. Soil type is a also crucial factor in responding to contingency situations in rainfed areas with low rainfall. Productivity and profitability of soybean is low when planted after the normal cut-off planting date (mid July). On-farm assessment of intercropping in soybean with pulse crop (pigeonpea) over four seasons gave higher grain equivalent yield and net returns over sole soybean especially when planting was delayed. Foxtail millet intercropped with pigeonpea (5:1) gave significantly higher average grain equivalent yields and net returns across the years compared to sole cropping. In case of cotton, intercropping with short duration pulse crops was particularly beneficial during deficit rainfall seasons. Intercropping of pearlmillet with short duration pigeonpea ensured higher grain equivalent yield along with fodder for livestock and enhanced profitability. Choice of crop cultivars of sorghum (*Sorghum vulgare*) and soil management practices depending on rainfall and soil type enhanced productivity and profitability for farmers in the semi-arid tracts. The evidences from on-farm assessment of appropriate crop choices and their combinations are being incorporated in local adaptation plans at the district level to combat changes in rainfall and enhanced the resilience of small farmers.

(8094 - 2442) Assessment the efficient management indicators of irrigation in the production of avocado Hass (*Persea americana* Mill) in Colombia

Grajales Guzmán Luis Carlos[1]; Dorado Guerra Diana[1]; Rebolledo Roa Alexander[1]; Tafur Hermann Harold[2]
Corporación colombiana de investigación agropecuaria-Corpoica[1]; Universidad Nacional de Colombia sede Palmira[2]

The objective of this study was to evaluate environmental sustainability indicators to assess the efficiency of water supply and productivity in Hass avocado (Persea americana) in commercial orchards of three regions with the highest production in Colombia (Morales-Cauca, Rionegro-Antioquia and Herveo -Tolima). Edaphic variables (texture, usable water sheet and movement of water in the soil) and climatic variables (precipitation, temperature, relative humidity, wind speed and solar radiation) were considered in relation to the indicators evaluated. The indicators were Relative Water Supply (RWS), Relative Irrigation Supply (RIS), Relative Supply of Rainwater (RRS) and Water Use Efficiency (WUE), evaluated in two cycles of production, for three irrigation treatments based on the evapotranspiration of reference-ETo calculated by the FAO Penman-Monteith method (0.5ETo, 0.75ETo, 1.0ETo). The values of RWS were between 3.05 and 1.97, higher values 1.5, suggested as a minimum limit to establish that the water resource is being used efficiently and there is no overexploitation of the resource. The RRS allowed to establish that the irrigation satisfied the water needs of the crop in the deficit periods. The RIS indicator showed values between 2.46 and 0.91, indicating that the irrigation treatments supply the water requirements of the crop, with the treatment T2 (0.75ETo) being the most adequate. The highest WUE values were obtained with treatment T1 (0.5ETo) for the three localities, Herveo 9.55 kg / m^3, Morales 4.4 kg / m^3 and Rionegro 11.26 kg / m^3.

(6361 - 1354) Availability of land for sustainable sugarcane production: Case study for Colombia

Felipe Haenel Gomes[1]; Marcelo Melo Ramalho Moreira[2]; Mariane Romeiro[2]; Rafael Aldighieri Moraes[3]
UEM[1]; Agroícone[2]; Unicamp[3]

Modern and sustainable bioenergy production may be an effective way to substitute substantial portions of energy demand for transportation in the future. Since the overall scale of bioenergy production will in part depend on the availability of fertile land with good climatic conditions, it's clear that the world will consider the Latin America, the Caribbean and Africa for future expansion of bioenergy. The objective of this work is to provide a database of

potential areas for sustainable expansion of biofuels in Colombia, focusing on sugarcane for ethanol production, and is part of a bigger Project (LACAf/GSB – Latin American, Caribbean and African Countries/ GSB – Global Sustainable Bioenergy) with the objective to create a robust and updated perspective for sustainable bioenergy development in these regions. A logical sequence of updating, elaboration, overlapping and interpretation of satellites images, maps and databases with different characteristics to identify geographies with good potential for sustainable sugarcane ethanol production was proceeded. Land use and land cover map was updated using satellite images and deforestation data. Then, an edaphoclimatic map was obtained through a sequence of data crossing, including temperature, water deficit and soils. Areas with strong restrictions were excluded, generating a map of the edaphoclimatic potential for the sugarcane expansion. Finally, areas with moderate constraints were excluded, obtaining the map of soil and climatic potential for the sustainable sugarcane expansion. The results shown about 84.000 km² of suitable areas to expansion of sugarcane crops, and most of these areas are concentrated in the departments of Meta and Vichada, in the "Llanos Orientales", considering moderate and strong restrictions simultaneously. Although the area is suitable, soils do not present high potential, being limited by their chemical conditions, with low CEC and base saturation and often with the presence of exchangeable aluminum, but which can be easily corrected. They are, however, mostly fine textured, with good water storage capacity. It should be emphasized that in the Llanos Orientales it is possible that the expansion of sugarcane culture occurs in the extensive areas of underutilized pasture. And projects such as the use of hydrolyzed bagasse combined or not with the intensification of agriculture with integrated systems can, in the end, even increase the production of meat considering the same area.

(6382 - 1925) Can terracing in no-till systems of South Brazil be a strategy to mitigate the water deficit in soybean cultivation?

Tiago Hörbe[1]; Jean Minella[1]; Paulo Gubiani[1]; Dinis Deuschle[1]; Ana Londero[1]; Alenxandre Schlessner[1]; Fábio Schneider[1]
UFSM[1]

Strategies to mitigate food and water safety are recurrent issues in agricultural research. The aim of this study was to evaluate terracing in no-tillage systems of South Brazil as a strategy to optimize soybean yield through the increase of moisture in the rooting layer of the crop. The study was conducted in the municipality of Júlio de Castilhos, in the middle plateau region of Rio Grande do Sul State during the agricultural year of 2016/17. The soil of the experimental area is classified as Nitisols, well drained and with low natural fertility. To conduct the experiment, two slopes, which are called zero-order catchments, with similar hydrological characteristics were chosen with the purpose of comparing them in terms of management. The management adopted in the experimental area of both catchments represents the most usual production system in the region, which is soybean cultivation in the summer and wheat/oats in the winter using no-tillage systems. Thus, the main difference between the paired catchments is the complementary practice of controlling surface flow (5 infiltration terraces) in one of them. The size of the study units is approximately 2.3 hectares each. The strategy of the study was to evaluate soybean yield through 5 paired transects between the catchments, totaling 47 georeferenced sampling points, with a sampled area to estimate the crop production of $2m^2$ per point. Four points were installed to monitor the available water refilling (R_{aw}) in eight layers in a profile of (0.0-1.5 m). One at the base and another at the top of each catchment. Sensors CS616 were used for soil water content measurement (Θ_i). Soil samples were taken to determine field capacity (Θ_{fc}) and the permanent wilting point (Θ_{pwp}) in order to estimate the maximum available water storage (S_{maw}, cm). With the summation in the monitored profile of (Θ_i-Θ_{pwp}), the current available water storage (S_{caw}, cm) was estimated. Hence, it was possible to calculate R_{aw} through the relation $R_{aw}= S_{caw}/S_{maw}$. Soybean yield differed between the monitored catchments, and the final mean for the catchments with and without terrace was 4.531 and 4.032 kg ha^{-1}, respectively. Similarly, the R_{aw} was higher in the terraced catchment, with an the average increase of 13%. In this way, the use of terracing optimized soybean yield and increased water productivity (kg/mm) by 12.4% even in a scenario of 667 mm accumulated and well distributed rainfall in the crop cycle.

(4418 - 551) Carbon stock of physical fractions of organic soil matter in different management systems

Jean Sérgio Rosset[1]; Diego Henrique de Oliveira Morais[2]; Carla Aparecida da Silva[2]; Thais Melissa Dias dos Santos[2]; Leandro Marciano Marra[2]; Selene Cristina de Pierri Castilho[2]; Jefferson Matheus Barros Ozório[2]
State University of Mato Grosso do Sul, UEMS E-mail: jsrosset@hotmail.com[1]; State University of Mato Grosso do Sul, UEMS[2]

The present work had as objective to quantify the carbon stocks of the particulate organic matter (EstPOM) and mineral (EstMOM) of the soil under the influence of the different management systems in the municipality of Eldorado, MS. Four areas with different management systems were evaluated: permanent pasture area with *Brachiaria brizantha*, 12 years old (PP); area of no-till system in succession soybean/corn and cassava with 15 years of cultivation (NT); area of sugarcane cultivation for 11 years (SC) and an area of native forest (NF). Four areas of 400 m^2 were demarcated in the areas and the deformed and undisturbed samples were collected in the 0-0.05, 0.05-0.1 and 0.1-0.2 m layers. Soil density analysis was carried out to calculate the carbon stock of the soil organic matter (SOM) fractions, and the physical fractionation (sorption) separating the SOM in particulate organic matter (POM) and organic matter associated with minerals (MOM). C-POM contents were determined via wet, C-MOM obtained by difference between total organic carbon (TOC) and C-POM. From the results obtained from C-POM and C-MOM, the organic carbon stocks of each of these fractions were calculated according to the equivalent mass method. For the EstPOM, in the 0-0.05 m layer, the MN area presented the highest value, 6.12 Mg ha^{-1} and the SC area the lowest value, 2.68 Mg ha^{-1}. For the remaining layers, again the lowest values were found in the SC area. The smaller soil rotation in the NT and PP areas contributed to the fact that these areas did not have low EstPOMs such as the SC area. Observing the EstMOM in the most superficial layers of 0-0.05 and 0.05-0.1 m, the four areas studied were considered similar. MOM is not always considered a good indicator of the effect of soil management, as its cycling is slower and consequently takes longer to modify the inventory standards. For the 0.1-0.2 m layer, the MN and NT areas had the lowest values when compared to the PP area. The contribution of organic materials associated to the lower rate of soil rotation are the reasons for the higher carbon stocks of particulate organic matter that occurred in the PP, NT and MN areas in relation to the SC area. Particulate organic matter stocks were more efficient in detecting differentiated patterns of carbon accumulation in relation to mineral organic matter stocks.

(5695 - 1447) Characterization of chemical attributes on soil management function

Elaine Araújo[1]; Katiaíres Evangelista Delpin Malvezi[1]; Luiz Gustavo Garbelini[1]; Gislaine Silva Pereira[1]; Igor Matheus Oliveira dos Santos[1]; Lucas Augusto de Assis Moraes[1]; Paula Pinheiro Sanches[1]; Laura Feuser Acco[1]; Adriana Pereira da Silva[1]
Universidade Estadual de Londrina[1]

The sustainability of agroecosystems is directly influenced by the effect of agricultural practices on soil structure. The aim of this study was to evaluate chemical attributes, in a dystroferric Red Latosol, with 24 years under no-tillage (NT) and conventional tillage (CT), in succession of cultures. The experimental area consisted of plots with 7.5 m wide by 30.0 m in length (225 m^2), with four repetitions per treatment, distributed with experimental design in randomized blocks, with two systems of soil management in succession soybean (summer) /corn (winter). The soil samples were collected in the winter of 2017, at the depth of 0-10 cm. The total organic carbon (TOC), total nitrogen (TN), C:N ratio, pH in $CaCl_2$, potential acidity (H+Al) and available phosphorus (Pavb.) have been evaluated. Only the TOC have showed significant difference between the managements, and superior content has been found in the NT (34.32 g dm^{-3}) compared to the CT (23.40 g dm^{-3}). On average, the increase of TOC in the NT has been 31.82% superior to the CT. This difference can be attributed to minor and maintenance of tickler plant residues on the soil surface that preserves its structure and contributes, through aggregation, for protection and stabilization of organic matter in that system. The value of the NT was 1.15 and 1.01 g dm^{-3}, respectively, to the NT and CT, whilst the C:N relationship was 30.05 and 23.62, respectively, for the same management. That result, possibly could be associated to the time of soil sampling, which corresponded with the dry and low temperatures, contributing to the maintenance of the N. The dynamics of this element in the soil is directly related to the content of organic matter, type of crop, especially its C:N relationship predecessor and soil type, the process of immobilization/mineralization regulated by weather conditions. For the H+Al attribute value was 5.97 and 6.33 cmolc dm^{-3}, respectively, to the NT and CT, while the pH in $CaCl_2$ was 5.15 and 5.09, respectively, for the same management. The absence of differences in these attributes coincided with the application of limestone (2 tons ha^{-1}) in all the plots before the summer harvest 2016/2017. For the Pavb, also there was no difference between NT (23.43 mg dm^{-3}) and CT (23.86 mg dm^{-3}), assigned to lower microbial activity at the time of collection, since microorganisms play a key role in the biogeochemical cycle of P and its availability in the soil.

(2893 - 754) Chemical P recovery from dairy manure using the Quick Wash process and use of low-P washed manure solids as soil amendments

Virginia Takata[1]; Ariel Szogi[2]; Paul Shumaker[2]
Facultad de Agronomía – Universidad de la República Oriental del Uruguay, Av. Garzón 780, 12900, Uruguay[1]; USDA-ARS Coastal Plains Soil, Water, and Plant Research Center, 2611 W. Lucas Street, 29501, Florence-SC, United States of America[2]

Large volumes of manure generated by intensive dairy production and their final land disposal is a significant environmental problem. Due to the imbalance of N and P (4;1), emendation of soils with dairy manure entails a raise in available soil P levels beyond the crops' capacity to absorb P. When emendations are applied to the soil at an agronomic N dose, there is an unnecessary P accumulation in the soils. In order to improve the N and P balance in animal waste prior to soil application, USDA-ARS, Florence, SC researchers developed a process for extracting P from manure solids using mineral or organic acid solutions, and recovery of P from the extract by adding lime and an organic polymer forming a calcium-containing P precipitate. The quick wash process has two products: 1) a washed manure solid with a N:P ratio optimal for use in crop production; and 2) a concentrated solid P material that can be used as an effective P fertilizer. This method can recover P in concentrated solid Ca phosphate. An experiment was made in order to evaluate P removal from dairy manure using the Quick Wash process. The experiment had two treatments (T1 and T2) and a control, with two replicates. In T1, the manure was acidified prior to being passed through a coarse sieve (12-mm). In T2, the manure was first passed through the 12-mm sieve before acid addition. The acid dose used in both treatments was 25 mmol L^{-1} of H_2SO_4. Thereafter, solids and liquid in the control, T1 and T2 were separated, and the acid extract was used to recover P by precipitation with lime at 2.2 g L^{-1} of 10 % $Ca(OH)_2$. Results for the control, T1 and T2 showed recoveries of 35, 44 and 58 % of P in the precipitate with respect to the initial P manure content. XRD analysis revealed that precipitated P was amorphous calcium phosphate with contents of 4, 7 and 8 % P_2O_5 for control, T1 and T2. We concluded that these precipitates can be used in a comparable way as fertilizer. Thereafter, the N:P ratios of the washed solids in control, T1 and T2 were 6.5, 8.8 and 11.3. Since the majority of C and N remained in washed solids, soil emendations with wash solids were further evaluated with respect to raw dairy manure application for their rate of C and N mineralization in a 70-day soil incubation. Further detailed discussion of the potential use of low-P manure emendations for soil C and N recycling will be included in our presentation.

(9902 - 3004) Comparing point assessments of soil loss rates with RUSLE estimates in Fogo Island, Cape Verde, Africa

Tomás de Figueiredo[1]; Maria Clotilde Carré Chagas[2]; Zulimar Hernández[3]; Felicia Fonseca[4]
Instituto Politécnico de Bragança (IPB), Portugal[1]; Universidade Federal de Pelotas, Brasil/ Instituto Politécnico de Bragança, Portugal[2]; Universidade Autonoma de Madrid[3]; CIMO/ESA/Instituto Politécnico de Bragança, Portugal[4]

Soils developed on volcanic ash in dry climates, in general, are poorly structured and have a low bulk density, which are relevant factors when appraising their erodibility. In dry climates, intense rainfalls (in the short wet season) and scarce vegetation cover combine with high soil erodibility to export off-site large sediment volumes from eroded hill-slopes. Hence, soil conservation measures are required to reduce soil loss and improve food security. The volcanic Fogo Island, Cape Verde, depicts impressive erosional features all over the strong relief landscape. Conservation structures were built along the country's history and stone walled check dams are common in thalwegs, however, not always coupled with hillslope soil protection measures. Severe soil loss rates during erosive rainfalls lead to a quick decline in check dams performance. The study aimed at mapping soil erosion rates using the RUSLE equation in volcanic Island, and comparing model estimates with field assessments of sediment volume trapped in check dams. Data for mapping erosion rates consisted in: a detailed topographic map (5x5m resolution) to derive LS factor; 10-year daily

rainfall records from 12 stations to estimate R factor; field data from soil profiles description to calculate K factor; Landsat satellite images to identify vegetation index and estimate C factor. A published agroecological map supported map validation. Spatial data treatment, model run and map generation were performed in GIS environment. On check dams, built for erosion control in dry thalwegs, field measurements were taken on wall size, slope gradients of soil surface upstream, of thalweg and of contributing hillslopes. Enquiries to local farmers helped retrieving dates of check dam construction and infilling. Volume of sediment trapped was estimated from field measurements, referred to contributing area and to time of infilling, resulting in an erosion rate when converted to mass with soil bulk density determined from samples collected in the check dam infill. The erosion map generated matches with the main erosion-borne geomorphological features observed in the field, where higher erosion rates are mapped. Estimates from sediment trapped averaged 100 ton ha-1 year-1 in a 2 years infilling period. Model output in checkdam sites approaches this rate. Results confirm the need of combined hillslope and thalweg soil conservation measures to increase checkdams performant life-time.

(6966 - 2921) Conservationist use potential of the Manso river watershed, Minas Gerais - Brazil

Adriana Monteiro da Costa[1]; Hugo Henrique Cardosos de Salis[1]; Antônio Henrique Noronha Ribeiro[1]; Dayane Caroline Freitas Carvalho[1]; João Herbert Moreira Viana[2]
Federal University of Minas Gerais, 6627 Antônio Carlos Ave, 1st floor, room 108, Belo Horizonte – MG, 31270-901, Brazil, nucleoisza@gmail.com[1]; Embrapa Milho e Sorgo, MG 424 Highway Km 45, Rural Area, Sete Lagoas - MG, 35701-970, Brazil, João.herbert@embrapa.br[2]

The growing demand and the human pressure on the water resources are causing scarcity in many places in Brazil. The Environmental Productive Zoning System is the method used in Minas Gerais State for the environmental and socioeconomic characterization of the watersheds, and aims to guide the conservationist use of the resources, to simplify and to straight forward the management and the monitoring of the soil and water uses. It has three steps, the land use mapping, the conservationist use zoning and the water demand diagnostic. This work presents the conservationist use potential zoning, applied in the Manso river watershed, in the metropolitan region near Belo Horizonte, in Minas Gerais State (Brazil). For this purpose, the following materials were used: the Minas Gerais State soil map (1:650.000), the Minas Gerais State geological map (1:1.000.000) and the ALOS PALSAR digital elevation model (12.5 m resolution). The data were processed with the software SPRING v. 5.4.3, Quantum GIS v. 2.18.13 and Google Earth Pro ® 7.1.8.3036. Five potential classes were identified. The broader one is the average potential class, occupying 64% of the area. It presents Ultisols and Inceptisols in a hilly topography, overlying orthogneiss, mafic, ultramafic and meta-ultramafic rocks. The second broader one is the low potential class, with 26% of the area, presenting mainly Inceptisols in a very hilly topography. The regions with the high and the very high potential classes sum 8.5% of the area, and present Ultisols and Inceptisols. The former presents smooth rolling topography and the later a flat one, located in the depressed areas, with lowland Inceptisols. The region with the very low potential class is about 1% of the area, and presents Entisols in a mountainous topography, in the crests over itabirite rocks. The topography and the soils were the main determinant factors for the conservationist use potential in the watershed, and adequate soil use practices are recommended to warrant the sustainability of the watershed.

(7494 - 269) Corn consortium with *BRACHIARIA CV PIATÃ* submitted to soil management and phosphorus doses in the crop-livestock integration system on western Amazônia.

Gabriel Ferreira soares[1]; Fabio Regis de Souza[1]; Anderson Cristian Bergamin[1]; Ramom Antônio de Souza[1]; Melissa da Silva Pereira[1]; Luciana Sônia da Silva[1]; Weder Vinicius de Oliveira SilvaWeder Vinicius de Oliveira Silva[1]; Ana Claudia Scheer Willers[1]
Federal University of Rondônia Foundation[1]

The systems of crop-livestock integration arise to be an alternative for recuperate the pastures degraded and promoting a greater contributing with the vegetables waste, that improve the physics, quimical and biological quality of the soil. The work have as objective value the agronomic characteristics in consortium with corn (*Zea mays*) and *Brachiaria brizantha* cv. Piatã in the crop-livestock integration system submitted an a management of the soil with phosphorus doses in degraded pasture area at Zona da Mata Rondoniense. The work was carried in the municipality of Pimenta Bueno-RO at Fazenda Alto Alegre located at RO 010 Km 30, in area of degraded pasture in a Red-Yellow Latosols. The experimental delineation was completely randomized blocks in arrangement of subdivide parcels. The principal parcel consist in two treatments of soil management, limestone harrowing incorporated, limestone harrowing incorporated with subsoiling, limestone applied in surface, preparation just with harrowing, prepare with harrowing and subsoiling and parcel with no management. The sub-plots received phosphorus doses, which are: 133, 247, 362 476 e 591 kg de P_2O_5 ha^{-1}. The variables of the corn evaluated was: diameter of stem, the insertion height of cob, plant height, cob length, cob diameter, number of grains in each row, number of row in each cob and productivity. The variables of forage evaluated were: leaf blade, stem + sheath and total dry mass. Data collect was submitted an analyses of variance with 5% of probability, and when significant in the F test, was applied a Tukey test with 5% for qualitative factor, and a regression analyses for the quantitative, using a computer program ASSISTAT – STATISTICAL ASSISTANCE. The soil management with limestone incorporated increase the dry mass of leaf blade and the total of *Brachiaria brizantha* cv. Piatã cultivated in consortium with corn. The dose of 342,2 kg of P_2O_5 ha-1 presents an increase of 133,05% in relation of the witness, provide a dry mass of 1139,6 $kg.ha^{-1}$ result in a greater production of dry mass in the leaf blade for *Brachiaria brizantha* cv. Piatã. The production of corn is linearly respond the phosphate fertilization.

Keywords: *Brachiaria brizantha*. Pasture degraded. Phosphate fertilization.

(6806 - 799) Dynamics of Carbon´s handling indices in management systems in the Conesul´s region of Mato Grosso do Sul

Camila Beatriz da Silva Souza[1]; Jean Sérgio Rosset[1]; Paulo Guilherme da Silva Farias[1]; Elias Faria[1]; Luan Soares Bispo[1]; Thais Melissa Dias dos Santos[1]; Leandro Marciano Marra[1]; Selene Cristina de Pierri Castilho[1]; Jefferson Matheus Barros Ozório[1]
UEMS[1]

Fractionation techniques of soil organic matter (SOM) provides detailed and conclusive results on the dynamics of SOM under

different forms of soil use. The objective of this work was to evaluate the dynamics of carbon management indices from the physical fractions of SOM in different management systems over time in the municipality of Mundo Novo, in the Conesul´s region of the state of Mato Grosso do Sul. Between 2016 and 2017 in Sandy-red Argissolo of sandy texture in three study areas: degraded pasture area with coast-cross (*Cynodon dactylon*) (pasture area - PA), degraded pasture area that was isolated and native tree species (reforestation) for recovery (area in recovery - AR) were planted, as well as a reference area of native forest (NF). Soil samples were collected in four replicates in each area, in the 0-0.05, 0.05-0.1 and 0.1-0.2 m layers at time zero month (March / 2016), after six months (September / 2016), and after 12 months (March / 2017) (time counted from the isolation and planting of native species in AR). After the sampling, the samples were processed in the laboratory, after which physical fractionation of the SOM was performed, particulate organic matter (POM) and mineral organic matter (MOM), with subsequent calculations of the following indexes: carbon stock index (CSI), lability of SOM (Lab), lability index (ILab) and carbon management index (CMI). AR had an increase in CSI values over time (0, 6 and 12 months). This results expresses the potential of increase of the organic carbon due to the adoption practices of recovery areas. The highest values of Lab were found in the MN area in layers of 0.05-0.1 and 0.1-0.2 m, both in the first collection, reaching 2.32 for the 0.05-0 layer, 1 m. Only the ILab was not efficient in detecting the main changes in the quality of the organic material. The BMI values of the AR were numerically higher than 100 (reference value), showing improvement in soil quality, being this characteristic more evident in the 0-0.05 m layer, where the values were 87.69, 106.92 and 134.52, in the first, second and third collection, respectively. The isolation and planting of native tree species in the recovering area significantly improved carbon management indices, especially in the 0-0.05 m layer, after 12 months.

(4789 - 820) Effect of inoculation with arbuscular mycorrhizal fungi and blanching on heavy metals chemical forms in edible parts of water spinach (*Ipomoea aquatic* Forsk)

Chun-Ming Lam[1]; Hung-Yu Lai[2]

Department of Post-Modern Agriculture, MingDao University[1]; Department of soil and Environmental Sciences, National Chung Hsing University[2]

The tolerance and detoxification mechanisms of plants for heavy metals are associated with chemical forms. In this study, water spinach (*Ipomoea aquatic* Forsk) was planted in the heavy metals-contaminated soils and inoculated with arbuscular mycorrhizal fungi. The objective is to assess the effect of changing the phosphorus concentration in the water spinach on the chemical forms of heavy metals in the edible parts. Blanching's effect on the concentration of trophically available heavy metals was also assessed. Experimental result showed that inoculation of arbuscular mycorrhizal fungi could improve the plant growth. It also decreased the accumulation of nickel but was opposite for cadmium. Inorganic form of cadmium and nickel are the major proportion in the water spinach. Blanching could decrease concentration of cadmium and nickel.

Keywords: arbuscular mycorrhizal fungi; chemical form; trophically available

(8815 - 1463) Effect of nitrogen doses on absorption, distribution and accumulation of sulfur in banana williams variety

Wilson Iván Torres Díaz[1]; Brayan Manuel Zabaleta Gonzalez[1]; Jaime Torres Bazurto[1]

Universidad Nacional de Colombia[1]

In the process of adjusting fertilization in banana for export, one of the elements that has been worked is nitrogen (N), whose effect on the absorption dynamics of other nutrients such as sulfur (S) is being studied. The objective of this investigation was to evaluate the effect of different doses of N on the absorption, distribution and accumulation of S in Williams variety banana in two production cycles, in a sixth generation crop. The S was quantified in plant tissue of all organs of the plant and in soil during five development stages per cycle. Five treatments were used, replicated four times taking into account the soil variability, namely; absolute control, 0 kg ha^{-1} of N, 161 kg ha^{-1}, 321.8 kg ha^{-1} and 483 kg ha^{-1} of N, using urea as a source. For data processing, the multivariate approach was used for the analysis of variance of the design in repeated measurements. The univariate and multivariate statistical analysis for plant accumulation and soil content showed significant differences between development stages and cycles, but not between treatments. The descriptive analysis for S content in soil, showed to harvest for the second cycle, values lower than 16 mg kg^{-1} in all treatments except in the 161 kg ha^{-1} of N, its behavior for the remaining development stages differs in the two cycles, this effect is associated with the changes in precipitation that occurred during the development of the investigation. Regarding the analyzes in vegetal tissue, the dose of 483 kg ha^{-1} of nitrogen stood out for obtaining the highest content of S in leaves. The values of S found and evaluated by organ, plant and soil, for each stage of development, allowed to select the doses of 161 and 483 kg ha^{-1} of N as the highest concentration.

(3731 - 1855) Effect of severe fire disturbance on soil mites community assembly in greater xing'an mountain,china

Lin Yinghua[1]; Wang Jing[1]; Liu Dandan[1]; Jin Yusong[2]; Li Huiren[3]; Liu Fangrui[3]; Liu Xueshuang[3]; Wei Changlei[3]; Wang Lizhong[3]

Institute of Wetland Research, Chinese Academy of Forestry, Beijing 100091,P.R China.[1]; School of Forestry, Northeast University of Forestry, Harbin, Heilongjiang, 150040 ,P.R. China[2]; Research Institute of Agriculture and Forestry, Daxing'anling Forestry Group, Jiagedaqi, Heilongjiang,165000, ,P.R. China[3]

Fire disturbance is an important disturbed factor in the forestry ecology, which s often lead to changes in environmental conditions, soil animal species diversity and ecosystem function, while the effect of servere fire disturbance on soil animal community assembly is poorly understand in Coniferous broad-leaved mixed forest at Great Xing'an Mountain, China. To understand how ground dwelling soil mite community assembled after severe fire disturbance, we studied ground dwelling soil mite community assembled under servere burned Coniferous broad-leaved mixed forest with a history of more than 10 years of servere fire disturbance area at Nan wenghe National Nature Reserve, Great Xing'an Mountain, Northeast of China. Using a spatially delimited sampling design, 81 samples were collected by pitfall traps in a 20m×20m area, and soil samples were taken to quantify several soil properties (soil organic carbon, soil total nitrogen, soil total phosphorus, pH, soil moisture). Results of variation partitioning showed that 10 years after servere fire,soil mites community composition was controlled by space of independent of environment (10.71%) at scale of quadrate (20m×20m). The contribution of environmental filtering was relatively low and only soil moisture had significant effect on soil mites assembly based on RDA analysis($p < 0.01$). The null model revealed soil mite community was non-random co-occurrence pattern, and a weak function of biotic

interaction based on body size ration and environment niche overlap. Our result indicate that dispersal limitation is a important regulators in soil mite community composition at Coniferous broad-leaved mixed forest with a history of more than 10 years of the servere fire disturbance.This study was supported by National Natural Science Foundation of China (No.31570603)

(8387 - 1513) Effect of the application of copper on the communities of mites and collembolans edaphic in an area under grape cultivation

Gleidson Gimenes Rieff[1]; Vanessa Aparecida dos Santos Silva[1]; Naihana Schaffer[1]; Victor Lucas Bassani[1]; Lucas da Ressurreição Garrido[2]; Enilson Luiz Saccol de Sá[3]

Universidade Federal do Rio Grande do Sul – UFRGS, Laboratório de Microbiologia do Solo, 91540-000 - Porto Alegre - RS – Brasil[1]; Embrapa Uva e Vinho, Laboratório de Fitopatologia, 95700-000 - Bento Gonçalves, RS – Brasil[2]; Universidade Federal do Rio Grande do Sul – UFRGS, Laboratório de Microbiologia do Solo, 91540-000 - Porto Alegre - RS – Brasil.[3]

The use of monitoring of mites and collembolans diversity can contribute to the study of changes in soil biological quality. The edaphic mesofauna responds to many environmental variables, with variations in the densities and alterations of the community structures and, therefore, may indicate environmental stresses. In the vines the application of Bordeaux ($CuSO_4$) was used as a fungicide for the control of mildew caused by *Plasmopara vitícola*. However, according to Normative Instruction 46/2011 of the "*Ministério da Agricultura Pecuária e Abastecimento*" limits the maximum amount of copper 6 kg ha^{-1} ano^{-1}. However, toxic amounts are being observed in grape growing area in the RS State, above 100 mg $CuSO_4$ kg^{-1} soil. Over time, copper can accumulate in the soil causing changes in edaphic biodiversity. Changes in the soil contribute to the reduction of biodiversity, impacts on the biogeochemical cycles, problems in the cycling of nutrients, etc. The objective of this study was to monitor the mites and collembolans population in areas under grape cultivation with a long history of $CuSO_4$ application. Soil samples were collected during the years 2016 and 2017 in three areas, two under grape cultivation with over 100 years of $CuSO_4$ application and one native forest area (reference). From each point a sample was withdrawn by inserting a metal cylinder (7.5 cm high by 7.0 in diameter). The samples were wrapped in plastic wrap and packed in polystyrene boxes to be transported to the Laboratory of Soil Microbiology - UFRGS. The methodology used for extraction, capture and identification of the groups of micro-arthropods was that of the Berlese-Tullgren funnel. The specimens of mites and collembolans were visualized in a stereoscopic microscope, with an increase of 40x and fixed in microscopic slides. The identification of the families was performed under a phase contrast microscope. Areas under cultivation of vines with high copper content affected the specimens of mites and collembolans. This shows the potential bioindicator of these edaphic mesofauna to diagnose changes in soil biological quality caused by the excessive use of $CuSO_4$ applications above the pre-established limit.

(5887 - 329) Evaluation of physical soil attributes of subirrigated lowland in the Araguaia Valley

Marcio Nikkel[1]; Saulo de Oliveira Lima[1]; Danilo Pereira Ramos[1]; Guillermo Arturo Herrera Chan[1]

Universidade Federal do Tocantins[1]

The evaluation of soil physical attributes is important for soil behavioral prediction. Physical attributes help to evaluate the situation of an agricultural soil and once compared to a nearby native area, it can be interpreted if the management in the area is maintaining its natural attributes or promoting degradation. The northern region of the Araguaia Valley, in Tocantins, Brazil, has been shown to be a region of strong agricultural ability, with soybean, common beans and cucurbit under subirrigation system. Therefore, the objective of this work was to evaluate soil physical attributes of two subirrigated areas in the south of Tocantins and to compare them with soil from an adjacent native area. The work was carried out in the municipality of Lagoa da Confusão in October 2016. The soil, classified as PLINTHOSOL, was covered with the cultural remains of the previous crop (soybean), awaiting the sowing of rice, 2016/2017 season. In the agricultural areas as well as in the adjacent native area, undisturbed soil samples were collected from 0 to 0,10 m; 0,10 – 0,20 m and 0,20 – 0,30 m for total porosity, macro and microporosity and density. PR were obtained with an impact penetrometer. The comparison of the means was done by the Scott-Knott test, at 5% probability. Macroporosity had a statistical difference between the areas and depths, with relatively higher values in the native area. One of the agricultural areas had lower value while the other area and native area presented higher values. At the superficial layer one of the areas presented greater value when compared to the other area and forest area. There was a statistical difference on soil density between the evaluated areas, with higher values in the agricultural land compared to the native area. Regarding PR, there was a statistical difference in the mean of the areas, however, the depths did not present statistical difference. The comparison between the three areas showed values above 2.5 MPa, considered restrictive. In general the values ranged from 2.36 to 4.16 MPa. The conclusion was that soil physical attributes such as macroporosity and density were altered by soil management. Soil compaction was observed in one of two areas analyzed, with values considered restrictive to root development. However, when comparing with values of the native forest, the soil management has been conducted in a satisfactory way, not promoting soil deterioration in a large scale.

(3728 - 2718) Evaluation of the biometric characteristics of eucalyptus clones at different degrees of soil compaction

Jéssica Conceição Nunes Silva[1]; Júlio César Lima Neves[1]; Teógenes Senna de Oliveira[1]

University Federal of Viçosa[1]

The increase of the operations with machines on and in the soil are modifying their physical condition, favoring the reduction of the porous space, with repercussions in several properties of the soil and also in the development of plants. In view of the above, the objective of this work was to evaluate the growth in height, diameter, leaf area and mass production of shoot dry matter (MMSPA) of eucalyptus seedlings when submitted to three levels of soil compaction under controlled conditions. The experiment was conducted in a greenhouse, using material from a Red Yellow Latosol (LVA) collected in the 20-40 cm layer of the area, in Viçosa-MG. Eucalyptus seedlings of 16 clones from the (Eucalyptus grandis Hill ex Maiden x Eucalyptus urophylla ST Blake) crossing of the company Celulose Nipo-Brasileira S / A (Cenibra) were used in a three-compaction structure: 80% of the soil) (GC1); 87% (GC2) and (92%). Humidity was maintained at field

capacity, soil chemically corrected for requirements and plants conducted for 60 days. The cultivation of the seedlings was carried out in pots formed by PVC pipes of 0,25 m of height and diameter of 0,10 m, totaling a volume of 0.0020 m³ of soil per pot. The evaluations involved the biometry of the aerial part (height, dry mass and leaf area) with the aid of a ruler and digital caliper for the measurements of the aerial part and the meter of leaf area Liquor model LI-3100. The experimental design was a completely randomized design, in a 3 x 16 factorial scheme, with three degrees of compaction and 16 clones, using four replications, totaling 192 sample units. The data were submitted to analysis of variance, the means being compared by the Tukey test at 5% of probability, using SPSS software. Significant differences were observed among clones evaluated for growth in height and diameter ($p < 0.000$), especially clones C7, C9 and C2, which obtained the highest growth in density of 1.20 kg / dm³ (GC2). The clones that obtained the largest increases in diameter were C7, C1 and C5, being the diameter significantly influencing by the degree of soil compaction. The specific leaf area was higher in GC2 (195.48 cm² / g). There were significant differences in the evaluation of MMSPA as a function of the evaluated densities and clones ($p < 0.01$) with 19.95 g in GC2 and 16.67 g in GC3 showing the influence of the increase in density on the dry mass clones.

(4664 - 2975) Historical overview patterns of agricultural areas and natural vegetation cover in São Paulo state

Paulo André Tavares[1]; Gerd Sparovek[1]

Escola Superior de Agricultura Luiz de Queiroz[1]

Compensation is one of the ways to comply with the liablities provided from the Brazilian Law as a counterbalancing mechanism for non-mitigable environmental impacts, which allows owners or holders of rural properties not to comply with their Legal Reserve (LR) compensante in another propreties with surpluses of native vegetation. Non-fulfliment to with liabilities leads to the owners punishment with administrative sanctions. However, according to article 68 of New Forest Act (NFA - 12.651/2012), rural owners that made a supression before 2008 july 22, area required to coply wih the liability in accordance with the legislation in frce at the time, withtout adaministrative sanctions. The complexy of the article's understanding in function of, for example, the different conceptualizationson vegetation contained in the previous laws, added to the difficulty of historical supression verification in relation to the legal framework, maskes the processes of deficit cover vegetation analisys anda consequently the signing of a "Term of Commitment" foreseen in the Environmental Regularization Program (ERP) a weak process. This project aims to analyze an interpretation of the rules for demarcation of areas conserved in rural properties in laws prior to Federal Law 12.651/2012, to generate models of potencial areas of native vegetation cover and agricultural operations in the 1920's, for understand the evolution of agriculture, providing the public authority a tool for effective implemetation of the ERP in São Paulo State

(2099 - 1167) Hydrological monitoring in small rural catchments as a tool in adopting soil and water conservation practices

Danrlei de Menezes[1]; Jean Paolo Gomes Minella[1]

Universidade Federal de Santa Maria[1]

The hydrological monitoring of small catchments makes it possible to understand soil and water degradation mechanisms and, consequently, can help in planning conservationist practices at landscape scale. However, hydrological data, such as runnoff and its associated processes, in small catchments are rare, consequently making it difficult to define the most efficient practices at this scale, since most studies are focused on plots or large catchments. The interpretation of the temporal pattern of the characteristic variables (precipitation, streamflow and sediment concentration) and their relationships contribute to: a) the description of degradation control mechanisms, b) the parameterization of hydrological and erosive processes, and c) aiding in choosing soil and water management measures. The objective of this work is to demonstrate, from a case study, how the hydrological monitoring of a small catchment can be used to infer about soil and water degradation processes, in addition to contribute to the recommendation of conservation practices. The study site is an experimental catchment with 120 ha, which is located in Arvorezinha (RS). Rugged relief, shallow soils and intensive farming system with high sediment production rate are typical characteristics of the experimental area. Monitoring is mainly based on obtaining data of precipitation, streamflow and sediment concentration at high frequency (10 min intervals), as well as monitoring variations in land use and management over time. Analysis of the processes occurs through the interpretation of the hydrographs and sedimentgraphs as a response to the rainfall events (hietograms) and different conditions of use and soil management. The main analyzes involved: a) determination of the magnitude of water and sediment losses in each event, b) variation of the relationship between streamflow and sediment production in response to climate influence, and c) determination of typical hydrological and erosive parameters of the study site The results express the influence of climate and use and management of water and soil losses along the events during the years, which enabled the selection and design of the best conservation practices in the catchment. The results also express how techniques of hydrological monitoring of small rural catchments can serve as a tool to support planning public policies aimed at soil and water conservation.

(5692 - 2345) Identification of soil use and occupation on the performance of center pivot

João Alberto Fischer Filho[1]; Yane de Freitas da Silva[1]; Katherine Viana Batista[1]; Aline Michelle da Silva Barbosa[1]; Anderson Prates Coelho[1]; Alexia Morello da Silva Cascaldi[1]; José Renato Zanini[1]; Alexandre Barcellos Dalri[1]

UNESP - Jaboticabal[1]

It is of great importance the preservation and recovery of natural resources in view of the high degree of environmental degradation, both in the urban and in the agricultural area. The use and the occupation of the soils exert influence in the superficial runoff and transport of sediments, being able to alter the quality and the availability of the water. The use of irrigation has the objective of increasing profitability, with increased production and quality, besides allowing cultivation in areas with a scarcity of rain, in which it would not be possible to cultivate without the application of water through irrigation. The study of irrigation systems with the appropriate use of the soil is of fundamental importance for the rational management of the water resources and contributes directly to avoid wastes and to promote an increase of the productivity of the cultures. The current study aimed to analyze the land use with the central pivot areas in the Northeast region of the state of São Paulo, Brazil. It was observed that 20% of the area is formed by forest region and 5% by urban area and that sugarcane is cultivated in more than 50% of the studied area, being of great importance for the development of the region. It should be noted that in several properties, the limits of permanents preservation area and the amount of water granted are not respected, causing influences to water resources. Center pivot irrigation is

present in approximately 10% of the area, corresponding to a total of 358 hectares, mainly irrigating annual crops such as beans, corn, and soybeans. The center pivots are installed in areas with an average slope of 1.8%, is considered ideal for maintenance, as well as future irrigation projects. The literature shows that center pivot systems are capable of operating on land with up to 30% slope. Nevertheless, very intense precipitations can be produced, favoring the erosive process; therefore, it is recommended that the terrain slope does not exceed 15%. It is concluded that the slope conditions in which the center pivots are present are favorable to this irrigation system, because they provide correct application of the amount of water, saving in electricity and an adequate use of the soil, avoiding losses due to erosion and leaching.

(6768 - 1320) Impact of Rice production on soil health parameters: a study of two contrasting rice-growing Regions of Mozambique

David Fangueiro[1]; Obinna Ezeokoli[2]; Rasheed Adeleke[2]; Belo Afonso Muetanene[3]; Ana Ribeiro-Barros[1]; Ana M. P. Melo[1]; Irene Fraga[4]; Joao Coutinho[4]; Alexis Ndayiragije[5]

Instituto Superior de Agronomia, Portugal[1]; Agricultural Research Council, South Africa[2]; Lúrio University-Mozambique[3]; Universidade de Trás-os-Montes e Alto Douro, Portugal[4]; International Rice Research Institute[5]

Most of the rice (*Oryza sativa* L.) produced in Mozambique is cultivated in rainfed systems on clayey and hydromorphic soils with poor soil management. Rice yields vary significantly between geographical regions and indications are that it is due to differences in soil management practices which impact in soil quality. But, Information regarding the impact of rice cultivation on soil health parameters in Mozambique are lacking. Our study undertaken to investigate impacts of rice cultivation on soil health properties and identify some soil characteristics that potentially limit rice production. Soil samples were collected in Chokwe and Umbeluzi districts, where Makassane rice variety was grown. In each region, virgin areas (10 years fallow) were sampled as reference soils. Soil samples were collected at 10-cm depths for analyses of physical-chemical properties, enzymatic activity (urease, β-glucosidase, acid and alkaline phosphatases) and metagenomic analysis of soil bacterial (16S rRNA gene) communities using high-throughput sequencing. A significant decrease ($P < 0.05$) of organic matter content was observed in Chokwe region with rice cultivation. In both regions, a significant decrease of electrical conductivity was observed with rice growth compared to virgin areas, while soil pH followed the opposite trend. Rice production had a significant impact on acid and alkaline phosphatase but no clear effect was observed in other enzymes. Bacterial communities of rice-field soils significantly differed (PERMANOVA $P < 0.001$) between reference soils and rice-cultivated fields in both regions with up to 20.1% and 35.8% variations in the bacterial community in Chokwe and Umbeluzi, respectively. Taxonomic analysis revealed that the phylum Proteobacteria was most abundant in both locations. However, the relative abundance of Actinobacteria reduced with rice cultivation in Umbeluzi but not in Chokwe. A species indicator analysis further revealed that the relative abundance of certain plant-growth promoting bacteria like *Desulfobulus, Dechloromonas*, *Azospira*, or *Massilia* statistically differed between reference sites and rice-field soils. Over all, these preliminary results indicate that rice cultivation impacts the physico-chemical properties of soil and microbial communities. We also showed that physico-chemical properties might not be enough to identify soil alteration, highlighting the need to explore functional diversity and quantity of soil microbes.

(6305 - 3213) Impact of the underground dam on soil chemical characteristics in of Arara the municipality, Paraiba State

Roseli Freire de Melo[1]; Anderson Ramos de Oliveira[1]; Jose Barbosa dos Anjos[1]; Tony Jarbas F. Cunha[1]

Embrapa Semiárido[1]

Study of the impact of the underground dam on soil chemical characteristics is of paramount importance for crop planning. For this environment to be closed there is a tendency of accumulation of sediments, and can contribute to the improvement of soil fertility. The aim of this study was to evaluate the impact of the underground dam on soil chemical characteristics in the cultivation or rainwater harvesting area. Composite soil samples were collected after the rainy season in three depths and in four environments; three environments in the dam area and one environment in a reference area (outside the dam in a cultivated area).The three environments, in the dam area, were divided in the beginning (area closest to the spillway), middle (approximately the middle of the dam) and end (considered the farthest part of the spillway). In its turn, each environment was separated into three positions: right side, left side and middle. The study was carried out in an underground dam located in the Arara municipality, Paraiba State, in 2016, approximately seven years after its construction The chemical analyzes of the soil samples were carried out in the soil laboratory of Embrapa Semiárido. The experiment was analyzed using a completely randomized design in a 12 x 3 factorial scheme, (12 environments and 3 depth), with three replications. According to the results, it was possible to verify that the soil chemical characteristics of the dam varied according to the location. The highest values of P, K, Ca, Mg, CEC and BS were found in the environment near the spillway and in the middle position, in the 0-20cm layer, decreasing in depth. These values are statistically higher than those found in the reference area, thus showing the contribution of the subterranean dam construction to the improvement of soil fertility. Additionally, the dam does not present soil salinity risks, presenting EC values varying from 0.12; 0.18 and 0.22 dS m-1 at depths of 0-20; 20-40 and 40-60cm, respectively. It was observed that the highest levels of organic matter were found in the surface of 0-20 cm, varying in the different environments and in depth, but in all dam environments presented higher values than the reference area. It was observed that the underground dam contributed to a positive change in the chemical characteristics of the soil, with greater evidence in the area near the spillway and in the superficial layer.

(2251 - 2772) *In vitro* dissolution of a remineralizer as an estimate of its performance in soil

Roseclênia Alves Santos[1]; Renata Alcarde Sermarini[1]; Rafael Cipriano da Silva[1]; Antonio Carlos de Azevedo[1]

ESALQ - USP[1]

Remineralizers (RM) are powdered rocks applied to soil to improve its quality and crop quantity and/or quality, and had their use regulated by the Brazilian Agriculture Ministry in 2016. Because the dissolution rate of RMs in soil are usually small, there is a necessity of a simple method to provide a rough and fast estimate of RM performance in soil. We tested the shaking of RM particles into centrifuge tubes. The results will be contrasted to an ongoing field experiment with the same RM. Here, the objective is to investigate if, among the three variables tested, there is a dominance of any of these factors on the RM dissolution. The RM particles were dry sieved, and three particle

sizes were chosen, Coarse Sand (CS = 1.0 to 0.5 mm); Fine Sand (FS = 0.25 to 0.125 mm), and Filler (FL = smaller than 0.05 mm) to be shaken in 50 mL Falcon tubes suspended into three solvents, deionized water (W), 0.01 mol L^{-1} citric acid solution (C), and 0.01 mol L^{-1} oxalic acid solution (O). The particle mass and solvent volume ratio was 1:4 (5.0000 g of particles into 20 mL of solvent) The RM grains were shaken for 14 hours (end-over-end shaker (120 cycles per minute), centrifuged and the supernatant removed and replaced by fresh solvents. Each run of 14 hours was one extraction (E). The experiment had 5 extractions. Electrical Conductivity and pH were taken immediately after the supernatants were obtained. Treatments were the combination of particle size and solvent, therefore there was nine combinations plus the control (only solvent), summing up 12 treatments, and five extractions. Each treatment had 4 replications. Group analysis were calculated using the results of pH and CE as response variables by the Ward method and the Euclidean distance, considering the average of the response variables for the combinations of factors: particle size (CS, FS, FL), solvent (W,C,O) and extraction (E1 to E5). The three sets generated grouped the results exactly according to the solvents, disregarding the other factors. The two first components of the principal components analysis represent 98.07% of the total variability. The results suggest that the performance of a RM may be strongly influenced by the type and concentration of organic acids produced by the local plant and soil microbe communities.

(9835 - 2697) Land recover and soil management by Agroforestry system

Marques, Maria Aparecida[1,2][1]; Delgado, Angel Ramon Sanchez[1][2]; Dunay Anna[2][3]
[1]Federal Rural University of Rio de Janeiro, Rodovia BR 465, Km 07 - Zona Rural, Seropédica - RJ, 23890-000, Brazil (mariamarquesadm@gmail.com)[1]; [1]Federal Rural University of Rio de Janeiro, Rodovia BR 465, Km 07 - Zona Rural, Seropédica - RJ, 23890-000, Brazil[2]; [2]Szent István University, Gödöllő, Páter Károly u. 1, 2100, Hungary[3]

Besides the many environmental functions and ecosystem service, the soil is the base resource to food production. Currently is pointed by FAO that approximately one-third of arable lands have degradation process. Most part of the degradation factors in the soil are erosion, low soil nutrition, soil salinization, soil compaction and soil contamination. Brazil is not different, soil degradation is present, mostly by inappropriate land management. Strategic policies are in developed aiming to mitigate this problem. The sustainable agriculture, as Agroforestry, is pointed as a possible path to mitigate and even recovery degraded areas. Beyond the technics, the knowledge must reach the farmers, due to the complexity of the systems. The aim of this study was to analyze the experiences with Agroforestry, applied in Australia and Africa, and to compare with Brazilian cases, to find the similarities in the application of the methods in these complex systems. By the compilation of the Agroforestry system methods, each degradation factor presented a specificity in the method that promotes a decreasing in the environmental degradation, such desertification, also the recovering the soil physical and chemical quality, restoration the water cycle, among others.

(2599 - 2902) Leguminous mulch and nitrogen influences on soil penetration resistance and mayze growth in Arenic Hapludult soil

Lorena Silva Campos[1]; Jessica de Freitas Nunes[1]; Vinicius Ribamar Alencar Macedo[1]; Emanoel Gomes de Moura[1]
UEMA[1]

In tropical sandy loam soils, both available water capacity and nutrient availability are often limited. Furthermore the small content of free iron, organic carbon jointly with a large amounts of sandy particles tend to harden during drying which adversely affects root development. One of the feasible alternatives for increasing productivity is the use of mulch on the soil surface with leaves and branches of leguminous trees in order to increase crops productivity. This work is based on the hypothesis that the use of legume biomass in cohesion-prone soils may decrease water stress days, increase nitrogen efficiency. Therefore, the objective was to evaluate the effects of leguminous biomass on soil penetration resistance (SPR) and mayze growth. The experiment was conducted on State University of Maranhão field which had a hot, semi-humid, equatorial climate with two well-defined seasons and soil classified as Arenic Hapludults. The experiment was conducted under no-tillage conditions, with eight different treatments: 6-day irrigation intervals in bare soil (6S) or covered (6C), 6-day irrigation intervals with soil covered and nitrogen (6CN) or nitrogen in bare soil (6N), 9-day irrigation intervals in bare soil (9S) or covered (9C), 9-day irrigation intervals with soil covered and nitrogen (9CN), or bare soil and nitrogen (9N). The SPR was measured with 5-cm gradations until 20 cm using a digital penetrometer. In the 0- to 5-cm treatment, comparing the the 9C and 9S measurements, there was no significant difference in SPR. In the layer of 6-10 cm, mulching decreased the resistance only when added nitrogen. In the range of 11-15 cm the SPR was lower in all treatments with coverage. From 16 to 20 cm the resistance was lower in 9CN than 9N. The results show that mulching can reduce three days of water stress in the presence of nitrogen. The use of the 9-day irrigation interval with plant cover (9 CN) compared to 6 days without mulch (6 N), both in the presence of N, developed the same rate of growth for the crop, which means greater efficiency in use of nitrogen and water. Therefore, the usage of mulch with nitrogen have demonstrated to be a good solution in order to increase maize productivity.

Keywords: Mulching; nitrogen; mayze.

(4378 - 1486) Long-term application of liquid dairy manure in no-tillage: effects on water, soil, and phosphorus loss by runoff under natural rainfall

Nerilde Favaretto[1]; Verediana F. Cherobim[1]; Gabriel Barth[2]; Volnei Pauletti[1]; Jeferson Dieckow[1]; Fabiane M. Vezzani[1]
Department of Soil Science and Agricultural Engineering - Federal University of Paraná, Curitiba, Paraná, Brazil[1]; Foundation for Agricultural Assistance and Technical Divulgation, Curitiba, Paraná Brazil[2]

Milk production generates a large amount of waste, which is disposed on agricultural fields, improving soil quality and crop yields. On the other hand, manure application without criteria can cause environmental problems. The objective of this study was to report the effects of long-term (10 years) application of liquid dairy manure (LDM) on runoff, soil and phosphorus losses in no-tillage under natural rainfall. The study was conducted at two research sites of the ABC Foundation, Paraná state, Brazil: 1) located in Ponta Grossa, started in November 2005 in a dystrophic red-yellow oxisol (sandy clay loam texture with 13% slope); 2) located in Castro, started in May 2006 in a dystrophic oxisol (clayey texture with 10% slope). Treatments consisted of four LDM (0, 60, 120, 180 m^3 ha^{-1} $year^{-1}$) displayed in a randomized complete block design with four replications. The manure was applied on soil surface in the winter and summer crops in 29.75

m² plot bounded by metal strip. The no-tillage had been practiced at the two research sites prior to the first application of LDM for more than 15 years, then, no-tillage practices continued to be applied along with annual applications of liquid dairy manure for the next 10 years in a crop rotation with black oat and wheat in the winter and soybean and maize in the summer. The surface runoff was sampled and analysed after each rainfall event for 10 years. Application of LDM reduced losses of water, soil and dissolved reactive phosphorus with lowest values, in general, at 120 m^3 ha^{-1} $year^{-1}$, in both oxisols (sandy clay loam and clayey soil textures). However, the weighted mean concentration of dissolved reactive phosphorus increased with LDM application. Overall, the losses of water, soil and phosphorus were low compared to intensive agricultural system, even in the treatment with no LDM application, indicating the efficiency of no-tillage on soil and water conservation. In practical terms, considering the potential risk of water pollution, it is recommended best management practices to avoid the surface runoff to reach the aquatic system providing agronomic benefits and minimizing environmental problems

(2995 - 2031) Mechanical resistance to the penetration of a Red Oxisol under different forest systems in the Cerrado.

Diego dos Santos Pereira[1]; Christtiane Fernandes Oliveira[1]; Rafael Montanari[1]; Alan Rodrigo Panosso[1]; Leandro Alves Freitas[2]; Eduardo de Lima Felix[1]; Joel Francisco dos Santos[1]; Jaqueline Bonfim de Carvalho[1]; Jean Carlos de Almeida Ramos[1]

São Paulo State University (UNESP)[1]; Federal University of Technology Paraná (UTFPR)[2]

The expansion of pine and eucalyptus forests has occupied large areas in the Brazilian Cerrado. However, there are few studies on the impacts these forests can have on the soil. The mechanical resistance to penetration (RP) has been used as an indicator of soil compaction, as it is a parameter of easy determination and is directly related to the root growth of the plants. Monitoring and periodically evaluating this attribute becomes important as a subsidy for the adoption of rational soil management systems. In this sense, the objective of the work was to evaluate the RP of a dystrophic Red Oxisol, reforested with Pinus, Eucalyptus and a Ciliary forest. The experiment was conducted in three areas of the Teaching and Research Treasury, Faculty of Engineering of Ilha Solteira (UNESP), located in the municipality of Selvíria-MS, the soil is classified as a dystrophic Red Oxisol, and is being used as a reforestation with Pinus (*Pinus caribeae* var. *Hondurensis*), Eucalyptus (*Eucalyptus camaldulensis*) and a Ciliary forest reforested with native species over 30 years old. The RP was evaluated in 25 points per area, obtained by means of an impact penetrometer, in the 0.00-0.10 layers; 0.10-0.20; 0.20-0.30 and 0.30-0.40 m. The values obtained in each area were compared using the Tukey test at 5% probability. The values of RP in the area under Ciliary forest, RP1 (2.575 MPa) and RP2 (4.377 MPa), and in the area under Pinus, RP1 (2,020 MPa) and RP2 (4,349 MPa), were statistically the same, and both treatments presented the same values, lower values of RP1 and RP2, when compared to the Eucalyptus area, with RP1 (4,694 MPa) and RP2 (6,200 MPa). The soil of the Ciliary forest presented higher values of soil moisture due to shading and the accumulation of organic matter from litter from the trees, contributing to the lower values of RP1 and RP2. The RP4 (5.264 MPa) area was statistically equal to the values obtained in the areas of Pinus RP4 (6,010 MPa) and Eucalyptus (4,323 MPa), and the area under Pinus culture presented the highest value of RP4. It is probable that the low water content in the deepest layer evaluated in the Pinus area has caused an increase of the cohesion between the mineral particles of the soil, making them more difficult to be separated by external forces, resulting in the increase of RP4. The values of RP1 and RP2 were higher in the Eucalyptus area, while RP4 was higher in the Pinus area.

Keywords: Eucalyptus, Pinus, Ciliary forest, mechanical resistance to penetration.

(4501 - 1614) Microbiological attributes as indicators of soil quality in agricultural management

Elaine Araújo[1]; Luiz Gustavo Garbelini[1]; Gislaine Silva Pereira[2]; Igor Matheus Oliveira dos Santos[1]; Lucas Augusto de Assis Moraes[1]; Paula Pinheiro Sanches[1]; Laura Feuser Acco[1]; César Yoshio Muraoka[1]; Amanda Letícia Pit Nunes[1]; Adriana Pereira da Silva[1]

Universidade Estadual de Londrina[1]; Universidade Estadual e Londrina[2]

Microorganisms have gained prominence due to their role in the operation and soil quality, being considered critical components agro ecosystems, regulate the decomposition of the organic material and biogeochemical cycles, with effect on fertility and nutrition of plants. The aim of this study was to evaluate microbial attributes, in a dystroferric Red Latosol, with 24 years under no-tillage (NT) and conventional tillage (CT), in succession of cultures. The experimental area consisted of plots with 7.5 m wide by 30.0 m in length, with four repetitions (four servings) per treatment, distributed with experimental design in randomized blocks, with two systems of soil management (NT and CT) in succession soybean (summer)/ corn (winter). The soil samples were collected in the winter of 2017, at the depth of 0-10 cm. Carbon and nitrogen of microbial biomass were evaluated (MB-C and MB-N), by fumigation-extraction method, basal respiration (BR), total organic carbon (TOC), metabolic (*q*Met) and microbial (*q*MIC) quotients. The contents of MB-C and MB-N were significantly higher in the NT compared to CT. For the MB-C, the contents found in the NT (136.97 mg kg^{-1} of dry soil) were 45% higher than that obtained in the CT (75.19 mg kg^{-1} of dry soil). In the case of the MB-N, the CT presented only 41% of the biomass observed in NT. The NT system benefits the formation and stabilization of macro-aggregates, which combined with ongoing coverage maintenance, provides an environment with greater availability of organic matter, moisture retention and lower thermal oscillations and hydropower. These factors improve the structural quality of the soil, protect the habitat of the microorganisms, leading to higher levels of microbial biomass in that system. For the BR there was no significant difference, possibly due to soil sampling have been carried out in the winter. The 50% higher qCO_2 was on CT (1.09 mg CO_2-C g^{-1} h^{-1} CBM) compared to the NT (0.55 mg CO_2-C g^{-1} h^{-1} CBM), indicating less efficiency in nutrient mineralization and immobilization by soil microorganisms. The TOC was 32% higher in NT (34.32 mg kg^{-1}) compared to the CT (23.40 mg kg^{-1}). The increment of TOC in the NT surface is due to the continuous supply of organic matter added to the soil via cultural waste. For the *q*MIC, there wasn't observed difference between treatments, however variation in this attribute suggest changes in the conversation efficiency from organic-C to microbial-C, C losses and stabilization.

Keywords: microbial biomass, basal respiration, metabolic quotient (qCO_2), microbial quotient (*q*MIC).

(5148 - 222) Nutrient activation of different coverage plants in sugarcane areas

Euriana Maria Guimarães[1]; Camila Viana Vieira Farhate[1]; Zigomar

Menezes de Souza[1]; José Luiz Rodrigues Torres[2]; Lenon Herique Lovera[1]; Ingrid Nehmi de Oliveira[1]
State University of Campinas (Unicamp), Agricultural Engineering (Feagri)[1]; Federal Institute of Triângulo Mineiro Campus Uberaba[2]

Significant increase in planted areas for sugarcane production has been supported on new technologies and high crop mechanization index. Such scenario has led to mechanized harvesting of most of the cultivated areas in the country, which is considered a world-class technology with recognized environmental and economic benefits. However, intensive sugarcane cultivation characterized by monoculture, intense soil revolt and machine traffic are all factors which caused an accelerated process of soil degradation. Therefore, more comprehensive research on the optimum use for cover crops along the sugarcane off-season planting is required. In this context, our aim was to quantify the accumulation of macro and micronutrients in different hedge plants used as green fertilizers in sugarcane areas production. We carried out our study under field conditions at Santa Fe Mill, an experimental area in the municipality of Ibitinga, São Paulo, Brazil. Our experimental design was a randomized block with three replications and four crops as cover plants: i) sum hemp (IAC KR1), ii) Millet (BRS 1501), iii) Peanut (Runner IAC 886), and iv) High biomass sorghum (BD 7607). Each experimental unit was 90 m long and 10 m wide, covering an area of 900 m^2. At the point of maximum flowering, the plants were sampled for analysis of dry biomass as well as accumulation of macro and micronutrients. The use of high biomass sorghum provided the highest values of dry biomass, having reached a production of 21 Mg ha^{-1}, followed by sum hemp and millet, which produced 11 and 10 Mg ha^{-1}, respectively. Peanut was the cover plant which provided the lowest biomass production, only 5 Mg ha^{-1}. Regarding the accumulation of macronutrients, we observed that sum hemp and sorghum provided higher accumulations of nitrogen (N), potassium (K), and calcium (Ca). However, sorghum is highlighted with higher accumulations of magnesium (Mg) and sulfur (S). As for the accumulation of micronutrients, in general, sum hemp and sorghum presented higher values than the remaining treatments. Therefore, the use of high biomass sorghum provides good soil cover and allows higher accumulation of both macro and micronutrients, with the cover plant with the highest potential to supply the nutritional need of the sugarcane crop.

Keywords: High biomass sorghum, macronutrients, micronutrients

(1015 - 1406) Participative Quality Index for the No-Till System (IQP) and Soil Structure Rapid Diagnosis (DRES)

Amanda Letícia Pit Nunes[1]; Ana Carolina Polinarski Coqueiro[1]; Adriana Pereira da Silva[1]; Jeankleber Bortoluzzi[2]; Cassio Wandscheer[3]; Hudson Carlos Lissoni Leonardo[2]; George Gardner Brown[4]; Marie Luise Caroline Bartz[5]; Ricardo Ralisch[1]
Universidade Estadual de Londrina[1]; Federação Brasileira de Plantio Direto e Irrigação[2]; Itaipu Binacional[3]; Embrapa Floresta[4]; Universidade Positivo[5]

The Participative Quality Index for the No-Till System (IQP) is a management tool that qualifies and monitors the quality of the No Till-System (NTS) in Brazilian conditions, by a participative methodology, which involved farmers to decide about the 8 indicators used to give a note between 0 to 10. The Brazilian Federation of No-Till System and Irrigation (FEBRAPDP) developed the tool in partnership with Itaipu Binacional based in scientific data, to promote the best ways to adopt the NTS. The soil structure is a fundamental characteristic of its fertility, being directly altered by the management, mainly its topsoil. Therefore, soil quality and management can be evaluated and monitored by the quality of topsoil structure. A new methodology for rapid assessment of topsoil structure (Soil Structure Rapid Diagnosis – DRES) was proposed by Londrina State University (UEL), FEBRAPDP, Embrapa Soils, Embrapa Soybean, Embrapa Wheat and Embrapa Western Agriculture, with the support of Itaipu Binational. The sample, taken as a monolith from 0 to 0.25 m, is separated into layers (when visually differentiated) and identified as to size of clods, signs of compaction and presence of roots. The aim of this study was to correlate the IQP data and the history of the management with soil structure quality. Samples were collected in the Paraná Watershed 3; located in the western region of Paraná State, Brazil. It was assessed 40 areas cultivated under different systems, including NTS and Conventional System, and six native forests to compare as their references. In each of these areas were sampled five points, in a transect. The structural quality of soil was evaluated by DRES methodology, from 0 to 0.25 m. The IQP information, which results in one note per area, qualifying the NTS, allowed the separation of the areas into distinct groups of management quality. Based on the effects resulting management observed in the topsoil structure, associated with the IQP score, it was possible to establish recommendations for the farmers to obtain improvements in the management adopted. Crop rotation and the non-disturbance of the soil allowed the maintenance of soil organic matter contents, as well as better topsoil structure quality. The soil quality evaluated by DRES methodology agreed with the IQP methodology and allowed the understanding of the quality of the management adopted.

(7388 - 1562) Physical and Chemical Attributes of Red Oxisols in Southern Minas Gerais, Brazil

André Silva Tavares[1]; Augusto César Ferreira Guiçardi[1]; Natanael Rodolfo Ribeiro Sakuno[1]; Lucas Emanuel Servidoni[1]; Joaquim Ernesto Bernardes Ayer[2]; Ronaldo Luiz Mincato[1]
University of Alfenas[1]; University of Campinas[2]

Inadequate agricultural management reduces environmental services and changes the ecological balance. Thus, soil conservation is essential for agricultural production. This study evaluated the soil management from the spatial variation of the physical and chemical attributes of a watershed, in the South of Minas Gerais, Brazil. On average, the precipitation is 1,500 mm $year^{-1}$ and the temperature is 22 ° C. The region belongs to the Proterozoic metamorphic polydeformates Varginha - Guaxupé Unit. Soil uses are coffee in level, maize/bean in succession with direct planting, native forest, eucalyptus with planting slope downhill, exposed soil, constructions and alluvial areas. Deformed and undeformed soils were collected at 0-20 and 20-60 cm, considering the relief and land use. Red Oxisols were classified in relief plan to wavy, wavy and strong wavy. The values of pH, base saturation (V%), cation exchange capacity (CEC) effective and potential, silt-clay ratio, geometric mean diameter (GMD), soil density (Ds), soil penetration resistance and soil permeability to water, that were obtained by impact penetrometer and by mini infiltrometer, respectively. Geoprocessing techniques allowed to interpolate points in each attribute, generating linear regression indices. The pH ranged from 4.68 in native forest, to 6.92 in coffee, which illustrates the natural acidity of the soils, which require correction for agricultural production, which is confirmed in the coffee cultivation with higher values of V% (<50%) and CEC, which illustrate the importance of the fertility improvement. The permeability was 0.63 and 87.03 mm h-1,

with lower values of infiltration in the exposed soils in steep reliefs, which has greater soil mechanical resistance to penetration due to compaction and reduction of macro porosity by agricultural machines, which resulted in higher Ds (1.24 g cm^{-3}). DMG and silt-clay ratio showed higher values in coffee plantations and lower in native forest, with a texture varying from clayey to very clayey, which reflects the loss of fine grains in coffee plantations. Thus, definition of areas for the adoption of conservation management techniques that combat erosion, based on spatial assessment of soil attributes, is an efficient method for the planning and management of sustainable agricultural production. Geoprocessing techniques are effective in identifying priority areas for improvement of management practices.

(1193 - 2868) Physiological responses of *Theobroma cacao* L. genotypes to drought stress

Paúl Lama Isminio[1]; Jose Olimpio de Sousa Junior[2]; Julio Lima Neves[3]; Raphael Bragança Alves Fernandes[3]
National University Toribio Rodriguez of Mendoza[1]; State University of Santa Cruz[2]; Federal University of Viçosa[3]

Irregular rainfall and soil-water stress in the cocoa producing regions affect the growth and development of the plants, especially in the first years of cultivation. The objective of this study was to evaluate the physiological alterations and tolerance to soil water deficit of four cocoa genotypes (CCN-51, PS-13.19, CEPEC-2002, and PH-16). After a period of acclimatization, seedlings of cocoa genotypes were subjected to two soil water regimes (control and drought) during a period of 12 days under greenhouse conditions. In the control, soil moisture was maintained near field capacity with the leaf water potential of -0.1 to -0.3 MPa. During and after the cultivation period were evaluated leaf water potential (Ψw), stomatal conductance (gs), rate of assimilation of CO_2 (A), and transpiration (E). The values of Ψw recorded after 12 days after the suspension of the irrigation were -2.30 MPa (CEPEC-2002), -2.09 MPa (PS-13.19), -1.86 MPa (PH-16), and -1.45 MPa (CCN-51), providing a reduction of the total leaf area and total dry mass of CCN-51 and PH-16 genotypes. Reductions of *gs* and *E* values were verified in all the genotypes starting from -0.5 MPa, whereas reduction of A values started close to -1.0 MPa. The results indicate that the genotypes CCN-51 and PH-16 present mechanisms that allow them to maintain high values of Ψw during more days in soil water depletion conditions, in relation to the PS-13.19 and CEPEC-2002 genotypes.

(6980 - 1041) Soil aggregate stability in an Ultisol under increasing cattle trampling pressure

Mastrangello Enivar Lanzanova[1]; Rodrigo Da Silveira Nicoloso[2]; Thomé Lovato[3]; Vitor Girardello[4]; Jardes Bragagnolo[4]
UERGS[1]; EMBRAPA[2]; UFSM[3]; URI[4]

One of the main problems found in crop-livestock integration systems is soil compaction due to both machinery traffic and animal trampling. Among the soil attributes used to evaluate soil compaction, the aggregate stability is usually considered a good indicator of soil physical quality. The present work was conducted in an Ultisol from Southern Brazil. The climate of the region is classified as Cfa. The experiment was established in random blocks with four replications of increasing intensities of winter forage grazing: 14 days (G14); 28 days (G28) and no grazing (NG). The winter forage consisted of a forage consortium of black oats (*Avena strigosa* L.) and ryegrass (*Lolium multiflorum* L.) under no-tillage. Cattle with 350 kg live weight were used for grazing. In the G14 treatment, grazing occurred at 50, 64, 78, 92 and 106 days after forage emergence, while for G28 grazing occurred at days 50, 78 and 106. Thus, a total of three and five grazing events occurred during one winter forage cycle. Soil was sampled and winter forages were then terminated at day 131 with the application of glyphosate for establishment of summer crops. The analysis of the distribution of water-stable aggregates followed Kemper & Chepil (1965). Briefly, soil was passed through a 8 mm sieve and the soil retained on the top of 4.76 mm sieve were air dried. Samples were placed on a set of sieves of 4.76, 2.00, 1.00 and 0.21 mm, and wet-sieved with vertical oscillation (3.8 cm) during 10 minutes at 0.5 Hz. The mean geometric diameter (MGD) of soil aggregates did not differed among treatments for the 0-5 cm depth. The MGD of soil aggregates from the 5-10 cm layer were slightly lower than the surface layer. The MGD of soil aggregates (5-15 cm) were 4.41, 4.83 and 4.56 mm, for NG, G28 and G14, respectively. Thus, no significant effect of cattle trampling on soil structure was noticed. Nonetheless, soil bulk density was higher in the soil with increased cattle trampling intensity (G14). Higher root density and aboveground biomass production by winter forages under no-tillage was shown to increase SOC stocks, thus alleviating the negative impacts of animal trampling and soil compaction on soil structure.

(4327 - 2723) Soil chemical, physical and microbiological properties under Integrated Crop-Livestock System in Araguaia Valley Region, Mato Grosso State, Brazil

Silvio Yoshiharu Ushiwata[1]; Cesar Crispim Vilar[1]; Ândria Alves de Souza[1]; Luis Paulo Leme dos Santos[1]; Franciele Kelly Mendes Soares[1]; Kálita Souza Silva[1]; Potiguara Marques Pizarro[1]; Vandoir Holtz[1]; Marcelo Alessandro Araújo[2]
Universidade do Estado de Mato Grosso[1]; Universidade Estadual de Maringá[2]

The Integrated Crop-Livestock System (ICLS) comes as option for the recovery of large areas with degraded pastures. However, information is missing to expand and consolidate the use of the system in the region. The aim of this work was to evaluate the influence of the ICLS on soil chemical, physical and microbiological properties. The study was fulfilled in the São Luiz Farm, in the Araguaia Valley region, Mato Grosso, Brazil, in the year 2017. Five areas were evaluated: two, three and four years of ICLS (ICLS2, ICLS3 and ICLS4), native vegetation (NV) and degraded pasture (DP). Each area was subdivided in five pseudo-repetitions. The soil was sampled in different depths: 1) 0 to 5; 5 to 10; 10 to 20 and 20 to 40 cm for analysis of soil organic matter (SOM), base saturation (%BS) and pH; 2) intervals of 10 in 10 cm to the depth of 60 cm to determine the soil penetration resistance (SPR); and 3) 0 to 5 and 5 to 10 cm to analyze the acid phosphatase activity (APA) and beta glycosidase activity (BGA). The data were analyzed by the confidence interval of averages to 95 % ($p<0,05$) of probability. Therefore, the SOM content in NV were higher in all depths, ranging from 12.6 (20 to 40 cm) to 32.8 (0 to 5 cm) g dm^3. Though in other areas there was no significant difference. On the other hand, the %BS and the pH were higher in ICLS in relation to DP and NV. While the SPR in the depths of 0 to 10 cm and 10 to 20 cm were lower in ICLS (ranging from 1.8 to 2.32 and from 2.6 to 3.2 MPa) when comparing to DP (7.9 and 5.7 MPa). To depths of 20 to 30 cm, the SPR ranged from 2.66 to 3.44 MPa in ICLS and the values decreased under 30 cm. In relation to APA, a higher value in ICLS4 (503 mg of p-nitrophenol kg^{-1} of soil h^{-1}) was found when compared to DP (265) and no significant difference was found to NV (588) in the depth of 0 to 5 cm. While at 5 to 10 cm the APA was higher in ICLS3 (44) in relation to DP (28), but lower in relation to NV (108). The values of BGA were higher in NV and there

were no differences among the other areas. The results show that the system of ICLS was not enough yet to raise the SOM, but the practices of soil correction favored the reduction of the soil acidity and raised the %BS. In ICLS, the higher values of SPR between 10 and 30 cm show a tendency of compaction by the traffic of agricultural machines. At the same time, the higher values of APA in ICLS indicate that the system is benefiting the soil microbial activity.

(5829 - 774) Soil density dynamics and physical fractions of organic matter in management systems in the Conesul´s region of Mato Grosso do Sul

Paulo Guilherme da Silva Farias[1]; Jean Sérgio Rosset[1]; Camila Beatriz da Silva Souza[1]; Elias Faria[1]; Luan Soares Bispo[1]; Thais Melissa Dias dos Santos[1]; Leandro Marciano Marra[1]; Selene Cristina de Pierri Castilho[1]; Jefferson Matheus Barros Ozório[1]

UEMS[1]

Physical fractionation of soil organic matter (SOM) is one of the techniques used to identify the dynamics of SOM in relation to different forms of soil use. The objective of this work was to evaluate the dynamics of soil density (SD), total organic carbon (TOC) and physical fractions of SOM in different management systems over time in the Conesul´s region of Mato Grosso do Sul. areas managed in addition to a reference area (native forest - NF) in the municipality of Mundo Novo, MS. The two areas managed included: permanent coast-cross pasture (*Cynodon dactylon*), with visible signs of degradation (pasture - PA) and an area that was under the same conditions as the PA area, but in March 2016 it was isolated , where native tree species were planted for recovery (area in recovery - AR), making three different systems analyzed as a function of driving time. Three samples of soil were taken in the 0-0.05, 0.05-0.1 and 0.1-0.2 m layers at zero month (March / 2016), after six months (September / 2016), and after 12 months (March / 2017) (time counted from the isolation and planting of native species in AR). For the three soil samples, the SD, TOC contents and the physical-granulometric fractions of SOM were evaluated: particulate organic matter - POM and mineral organic matter - MOM. For the SD, the AP area presented the highest value in the 0-0.05 m layer, 1.72 Mg m^{-3}, a value considered critical for crop development. In addition, there were no changes in SD in RA over 12 months. When the TOC dynamics were evaluated, the AR in the 0-0.05 m layer presented a 31% increase between time zero and after 1 year of evaluation, going from 17.31 to 22.67 g kg^{-1}, demonstrating potential for TOC accumulation after 12 months. The same dynamics observed in AR for TOC was also observed for the POP and MOM fractions, especially the POM, reaching 10.61 g kg^{-1} in the 0-0.05 m layer, the layer is more sensitive to changes caused by the management systems. The isolation and planting of native tree species in the recovering area was shown to be beneficial for the improvement of soil quality in this area, mainly in relation to the organic fraction of the soil, with increase in the total organic carbon, particulate organic matter associated with sand fraction and mineral organic matter, associated with silt and clay fractions.

(3972 - 3126) Soil losses in different soil management under pasture

Fabiano Oliveira Machado[1]; Marlete Littig[1]; Paulo Roberto da Rocha Junior[1]; Felipe Vaz Andrade[1]

Federal University of Espírito Santo[1]

Soil loss on pasture lands is caused by several biotic and abiotic factors, including inadequate management practices and, especially, failure during the pasture formation. The objective of this work was to evaluate soil loss on pasture lands under different soil management and natural rainfall during the dry and rainy season and indicate, focused on soil conservation view, sustainable management practices. The experiment was carried out in the city of Alegre, ES, on the Federal University of Espírito Santo Research Farm. Control pasture (CP), scarified pasture (SP), fertilized pasture (FP), burned pasture (BP), crop, livestock, and forest integration pasture (CLFI) and plowed and harrowed pasture (PHP). The plots were set up in the direction of the slope, with dimensions of 11 x 3.5 m. A collecting system was installed on the lower part of the plot to direct the surface runoff soil to sediment collection boxes for later further analysis. Soil loss data were evaluated during the dry and rainy period, starting in April 2015 until March 2017. Soil losses were quantified after each rain event, and data were grouped for each month. Coarse sediment was obtained was retained in the 0,250mm mesh sieve installed at the water box entrance of each plot, and then dried using an oven at 40º C for 72 h for subsequent mass quantification of the bulk sediment. The fine sediment was obtained from the total volume of the suspension (water + fine sediment) that passed through the 0,250mm mesh sieve of the collection boxes. Summarizing, BP was the management that presented the highest loss of soil in the dry (107 kg ha^{-1} per year) and rainy period (3,600kg ha^{-1} per year). For the dry period, the lowest values of soil loss were found in PHP (2 kg ha^{-1} per year) and FP (11 kg ha^{-1} per year), and CLFI (83.57 kg ha^{-1} per year), PHP (4.77 kg ha^{-1} per year) and FP (80.83 kg ha^{-1} per year) for the rainy season. The management that showed highest coarse sediment loss was BP in the rainy season (5724.58 kg ha^{-1} per year) and the lowest was PHP for the dry period (1,573 kg ha^{-1} per year). The results proved that using edaphic practices to manage soil erosion contributes to increase water infiltration into the soil, and consequently, reduce soil loss by erosion, however, there was a soil mass displacement in the treatment, reducing coarse and fine sediment compared to the other treatments.

(8813 - 1898) Soil mechanical resistance to penetration of maize no-tillage system in succession with cover crops and chiseling systems

Márcia Luciane Kochem[1]; Paulo Cesar Conceição[1]; Lizete Stumpf[1]; Vitor Cauduro Girardello[2]; Maiara Karini Haskel[1]; Weslei Sbalcheiro[1]

UTFPR[1]; URI[2]

The adoption the non-soil turnover combined with machine traffic has promoted the compaction of subsurface layers in the no-till areas, becoming the main problem to the sustainability of this system, between four and six years of establishment. In this sense, many farmers have adopted chiseling as an additional cultural treatment before planting, aiming at increasing the physical soil quality and guaranteeing the productivity of crops. Therefore, the objective of the study was to evaluate the soil mechanical resistance to penetration of an Oxisol under maize no-tillage in succession with winter cover crops and two chiseling systems. The five soil prepare systems evaluated were: a) No-tillage; b) No-tillage chiseling only in the start of experiment (2015) with Jumbo equipment; c) No-tillage chiseling only in the start of experiment (2015) with Terrus equipment; d) No-tillage chiseling annually (2015 and 2016) with Jumbo equipment; e) No-tillage chiseling annually (2015 and 2016) with Terrus equipment. The winter cover crops evaluated were: a) vetch; b) radish; c) Oats. In April 2017, after the maize harvest, the soil mechanical resistance to penetration was evaluated in the different treatments and the data presentation of 0.00-0.05 m, 0.05-0.10 m, 0.10-0.20 m and 0.20-0.40

m layers. The maize no-tillage in succession with different cover plants did not present mechanical resistance to penetration restrictive to root development, providing the same grain yield in relation to chiseling treatments. The succession maize/oat and maize/radish promoted the permanence of the chiseling soil effect for 24 months, therefore there is no need to carry out the scarification annually

(9179 - 1726) Soil organic matter and macronutrients dynamics of a long-term conservation tillage experiment in a brazilian Ultisol

Fernanda Cristina Caparelli de Oliveira[1]; Alceu Pedrotti[1]; Sara Julliane Ribeiro Assunção[1]; João Lucas Souza Santos[1]; Matheus Emmanuel Oliveira Vieira[1]
Universidade Federal de Sergipe[1]

Low natural fertility and sandy texture in the shallow depth of Ultisols, and climatic conditions of Northeast Brazil stimulate soil degradation in case of inappropriate agricultural management adoption. Conservation tillage (CT) usually has positive impact in soil chemical attributes (SCA), however there is a lack of dataset to support CT establishment in Northeast Brazil. Thus, the overarching goal of this work is to evaluate the dynamics of soil organic matter (SOM) and macronutrients in a long-term maize experiment. The experiment was established in 2001 at UFS Campus Rural (10°55'24"S; 37°11'57"W) and repeated annually throughout 16 yr. Soil is classified as Ultisols and the climate described as tropical with dry summer. Treatments consisted of three tillage operations (conventional, minimum and no-tillage) and four cover crops (sunn hemp, Pigeous bean, millet, cowpea). Tillage operations were laid out as whole plot (830 m²), and the cover crops randomly distributed through three plots (60 cm² each). Soil sampling (0-10 cm) occurred after maize harvesting at 5, 9, 11, and 14 yr of the experiment beginning. A principal component analysis (PCA) was performed to investigate the soil chemical attributes dynamics throughout agricultural management. The first two principal components (PC) accounted for 74.9 % of the dataset variation. The PCA shows that SCA were first separated by the duration of the management adoption: the SCA at 5 and 9 yr were more similar than at 11 and 14 yr. Phosphorus (P) and potassium contents increased with time of management adoption, conversely to Ca and Mg content. SOM content tend to stabilize after 9 yr and presented lower values in conventional tillage. P and SOM contents separated minimum tillage and no-tillage from conventional tillage. There was no clear pattern of cover crops effects on SCA. Our results indicate that either minimum or no-tillage have great potential of increasing natural fertility of maize cultivated Ultisols in Northeast Brazil.

(1411 - 2300) Soil physical attributes under integrated agricultural production systems at Agreste mesoregion of Paraiba State, Brazil

Pedro Luan Ferreira da Silva[1]; Flávio Pereira de Oliveira[1]; Danillo Dutra Tavares[1]; Mylena Costa Da Silva[1]; Alisson José Da Silva[1]; André Julio Do Amaral[2]; Camila Costa da Nóbrega[1]; Victor Ferreira Brandão[1]
Universidade Federal da Paraíba[1]; Embrapa Solos[2]

The objective of this study was to evaluate the soil quality by means of physical attributes under a crop-livestock-forest integration system with two years of implantation. The experiment was conducted at the experimental station of the EMEPA, in Alagoinha City (PB) in a Eutric Planosol. A randomized complete block design (DBC) was used, with five treatments and three repetitions, as: 1) *Brachiaria decumbens* + *Gliricidia sepium* (ILFG); 2) *Brachiaria decumbens* + *Mimosa caesalpiniifolia* (ILFS); 3) *Brachiaria decumbens* + *Tabebuia alba* (ILFI); 4) *Brachiaria decumbens* + *Zea mays* (ILCm); 5) *Brachiaria decumbens* (P), in plots with dimensions of 38 x 20 m. Forest species were planted in triple rows, at spacing 3 x 2 m, with 20 m between triple row and another. Undisturbed samples were collected at depths of 0.0 - 0.10 m and 0.10 - 0.20 m, totalizing 120 samples. Granulometry, flocculation degree (GF), soil density (Ds), total porosity (Pt), macroporosity (Ma), microporosity (Mi), saturated hydraulic conductivity (Kθ), resistance to penetration (Rp), aggregate stability index (IEA), total organic carbon (TOC), field capacity (θCC), permanent wilting point (θPMP) and available water (θAD) had the variances evaluated. The analyzes were carried out at the Soil Physics Laboratory of the Agricultural Sciences Center of the Federal University of Paraíba. The analysis of variance and its medias were compared by the Tukey test at the 5% probability level. The soil was classified as sandy-loam and the sand contents ranged from 650 to 703 g kg^{-1}. At depth of 0 - 0.10 m the soil Ds was lower in T3 - 1.24 kg dm^{-3} and higher in T5 - 1.27 kg dm^{-3}. There was an increase of Ds in depth and the soil Pt ranged from 0.45 to 0.49 m^3 m^{-3}. The Kθ was larger on the surface, with 13.37 cm h^{-1} at T2 and 4.32 cm h^{-1} at the control treatment. The Rp was below the critical limit in all evaluated treatments, and the highest average was 0.30 MPa in T1 in the 0.10 - 0.20 m layer. The COT content decreased in depth, as did the IEA values. The content of θAD did not differ between treatments and depths evaluated. The highest volume of θAD (0.463 m^3 m^{-3}) was verified in T4 at a depth of 0.10 - 0.20 m. Soil density was the attribute that presented the greatest variation between the collection distances and the evaluated treatments. The adoption of ICLF contributed to the improvement of the physical attributes of the soil in comparison to the areas occupied with isolated cultivation.

(7979 - 1577) soil physical quality of an ultisol under crop-livestock-forest integration system in Amazonia, Brazil

Diego Lima de Souza Cruz[1]; José Frutuoso do Vale Júnior[2]; Edmilson Evangelista da Silva[3]; Anna Bárbara de Souza Cruz[4]
Instituto Federal de Roraima - IFRR[1]; Universidade Federal de Roraima - UFRR[2]; Embrapa RR[3]; Universidade de São Paulo - USP[4]

The Crop-Livestock-Forest Integration System (ILPF) is considered one of the most suitable conservationist systems for the recovery of degraded pastures, because it increases the efficiency of the area utilization. In Brazil, this system have a wide use, mostly because of governamental incentive. In this context, the present work was elaborated with the objective of comparing the management systems with a natural forest with the physical and chemical characteristics of Ultisol in the state of Roraima. The study was carried out in a private property with ILPF experiment installed in partnership with Embrapa-RR. There were 4 main treatments (Areas): T1 = Rotated Pasture; T2 = Natural Forest (NF); T3 = Crop-Livestock Integration (CLI); T4 = Livestock-Forest Integration (LFI); The secondary treatments were 6 depths: P1 = 0 to 10 cm; P2 = 10 to 20 cm; P3 = 20 to 40 cm; P4 = 40 to 60 cm; P5 = 60 to 80 cm; P6 = 80 to 100 cm in a completely randomized design in the spli-plot scheme. The evaluated properties were: Soil Penetration Resistance (PR), Texture, Soil Density (SD) and Soil Particle Density (PD), Total Porosity (TOP), Dispersed Clay in Water (DCW), Clay Flocculation Degree (CFD) , Soil Organic Matter (SOM), Soil Carbon Stock (SCS) and Soil Physic Quality Index (SPQI). Analyzing the set of all the properties and comparing the managed environments with the natural forest, considered as a parameter of physical soil quality, it was verified that there is no physical degradation of the soil in the management systems studied, being able to be indicated to be used as a recovery system for degraded areas. Some properties showed values that indicate soil low quality (SD, TOP and PR), but the natural áreas had the same characteristics.

Therefore, comparing the crop area with the natural area, there where no loss of soil phisical quality, even though that values where considered critical by the literature. The higher SD values in the CLI and LFI was a signal to the importance of implementing a physical soil quality monitoring program in the property, besides the control in the activities of machines and animals in those systems.

(5623 - 266) Soil quality indicators of a Planosol under integrated Crop/livestock/Forest system at Agreste Mesoregion of Paraiba State, Brazil

André Julio do Amaral[1]; José Carlos Pereira dos Santos[1]; Luís de França da Silva Neto[1]; Roberto da Boa Viagem Parahyba[1]; Giliane Aparecida da Silva Souza[2]; Flávio Pereira de Oliveira[2]; Djail Santos[2]; Valdemir Ribeiro Cavalcanti[3]

Embrapa Solos[1]; Universidade Federal da Paraíba[2]; Empresa Estadual de Pesquisa Agropecuária da Paraíba[3]

Crop, livestock, and forestry integrated systems (CLFIS) are strategies that promote soil quality. This work aimed to determine some soil quality indicators attributes, after short time use of CLFI systems at Agreste of Paraiba State, Brazil. The soil is an Eutric Planosol, moderate A horizon, sandy loam texture, light towaved slope, sub-deciduous forest of semi-arid climate. Intercropping was implemented at June 2015: a) B*rachiaria decumbens sole pasture* (Livestock system); b) *B. decumbens* + Gliricidia (*Gliricidia sepium* (Jacq.) Steud.) (Livestock/Gliricidia Forest integration system LGFIS); c) *B. decumbens* + Sabiá (*Mimosa caesalpiniifolia*) (Livestock/Sabia Forest integration system LSFIS); d) B. decumbens+ Yellow Ipê (*Tabebuia alba* (chamiso) sandwith) (Livestock Ipê Forest integration system LIFIS); e) B. decumbens+ maize (*Zea mays* L.) (Crop/Livestock integration system CLIS) at last crop in april 2016, in no-tillage. The trial was carried out in a randomized block experimental design, with four replicates. Forest species were planted in triple rows, at regular spacing 3 m x 2 m, with 20 m between triple rows. Plots (rectangular format) have 20 m x 38 m. In April 2016, 15 days after maize seeding, soil samples (5 subsamples) was collected, inside the plots (triple rows) at center plots, at 0-0.10m; 0.10-0.20 m and 0.20-0.40 m depths. Physical attributes of: gravimetric soil moisture (Ug), soil bulk density (Ds) and index cone by electronic device (RP) and chemical attributes of: soil reaction (pH-H_2O); potassium (K^+), phosphorus (P) and organic matter (OM) were evaluated. In general, no significant difference was found in both physical (without indicating additional soil compaction) and chemical attributes. Probably the short time of systems was the reason. The pH-H_2O mean values ranged from 4.7 to 5.2 ($p > 0.05$). From the results it was concluded that it is necessary to raise pH-H_2O to increase availability of the replacement of nutrients, mainly Ca^{2+}, Mg^{2+} and P and K^+. OM levels increased at 0-0.10 m depth this shown important role of CLFI systems for the recovering of degraded pastures by higher soil cover, increasing nutrient cycling, promoting income diversification and increasing productivity in farmlands at the local of this study.

(8315 - 2270) Soil temperature measurements by newly developed soil probes in Hungary

Zsófia Dobó[1]; Csaba Centeri[1]; Izabella Oláh[1]

Szent István University[1]

According to the state of science today, we have different ways available to measure soil paramteres, including in situ and remote sensing methods. In agricultural production the effect of soil temperature on germination is well known. Besides that soil temperature has impact on other biology, chemical and physical processes. This research was carried out on measuring soil temperature by newly developed soil probes in Hungary. The soil puffer capacity and its temperature dinamics does not belong to the main research themes. We have selected a few arable land throughout Hungary which have characterized by different soil type. The common point is the cultivated plant grown on them. By the examination we get answer about puffer capacity, resistance of each soil types againt athomosperic effects. Each type of soil has different characters, whereupon each soil type has different response againts external influences. We would like to use the results to help developing landscape management.

(5563 - 2978) Soil water dynamics in a Cerrado fragment and clonal *Eucalyptus* plantation fertilized with K sources

Fábio Henrique Silva Floriano de Toledo[1]; Eric Victor de Oliveira Ferreira[2]; Alexandre de Vicente Ferraz[3]; Yesid Alejandro Mariño Macana[4]; Gabriela Gonçalves Moreira[5]; José Leonardo de Moraes Gonçalves[4]

Universidade Federal de Lavras[1]; Universidade Federal Rural da Amazônia[2]; Instituto de Pesquisas e Estudos Florestais[3]; Universidade de São Paulo[4]; International Paper[5]

Among the Brazilian tropical soils most used for *Eucalyptus* plantation are oxisols (48%) and ultisols (26%). Often these soils present low natural chemical fertility and, those with lower clay content, low water retention capacity. Considering that potassium (K) presents physiological functions related to plant water regulation and frequently provides positive responses in tree growth, the objective of this research was to evaluate the potassium fertilization effect in a clonal *Eucalyptus* plantation in a Red Yellow Oxisol with low clay content (185 g kg^{-1}; 0-60 cm soil layer) and exchangeable K (0.3 $mmol_c\ dm^{-3}$), and compare the soil water content dynamics under *Eucalyptus* plantation, using a Cerrado fragment as reference, original phytophysiognomy of the study area. The experiment was carried out in the municipality of Luiz Antônio, SP, Brazil, between April 2014 and December 2016. Three treatments were evaluated: (CER) Cerrado fragment; (POT) *Eucalyptus* plantation fertilized with 180 kg ha^{-1} K_2O, using KCl; and (FO) *Eucalyptus* plantation fertilized with 180 kg ha^{-1} K_2O, using phonolite rock powder. Soil water content was measured monthly at 1.6 m depth with a capacitive probe (Diviner model) between the 16th and 41st months after *Eucalyptus* planting. The measurements were performed in a 120 m² plot using three probe access tubes, which were considered repetitions. To assess tree growth, the circumference at the breast height (CBH; 1.3 m above ground level) of the trees of the two treatments with *Eucalyptus* at the 13th and 42nd months after planting were measured. CBH averages were generated from the measurement of four plots with 16 trees/treatment. During the 16 months of evaluation, the CER treatment presented the highest soil water content (154 mm), followed by FO treatment (131 mm) and POT treatment (111 mm). The growth in CBH of the FO treatment was 5 and 0.7% higher than POT at the 13th and 42nd months after planting, respectively. The substitution of KCl fertilizer by phonolite rock powder decrease soil water consumption, maintaining the same CBH growth in eucalyptus trees.

(7994 - 1896) Sources, manners application and translocation of sulfur in the initial development of corn.

Rafael de Paiva Andrade[1]; Moniki Campos Janegitz[1]
Faculdades Gammon[1]

Due to the low concentration of S in the soil, corn can present a high probability of response to this nutrient, visa that this is an essential element and participates in the synthesis of various proteins. The objective of this study is to evaluate different sources and methods of sulfur in the initial development of the corn in soil with low content of this nutrient. The experiment was conducted in a greenhouse conditions with three sources of sulfur: 2,5 l ha^{-1} do Sulformax 50% S, 30 kg ha^{-1} of granular elementary sulfur (99% S) and 530 kg ha^{-1} of gypsum (17%SO_4) and different modes of application, being composed of six treatments with five replicates each one. The treatments was: Control without addition of sulfur; Sulfur via leaf; Elementary sulfur via soil; Gypsum; Elemental sulfur via soil + Sulfur via leaf and Gypsum + Sulfur via leaf. Thirty-two days after plant emergence height of plants, shoot dry matter, root dry matter and S content in shoot and root was determined. There was statistical difference for all variables, except for the S content in the shoot and plants height. The highest sulfur concentration independent of the application form was in the root when compared to the shoot. Elementary sulfur application in the soil was statistically equal to the control treatment. The treatments that received soil + foliar and / or gypsum fertilizer increased the S content in plants. However the gypsum and leaf application of sulfur increased the S content in root of corn plants.

Keywords: Sulfate; sulfur efficiency use; foliar fertilizer.

(4800 - 365) Soybean yield and physical soil properties in succession to cover crops.

Katiely Aline Anschau[1]; Edleusa Pereira Seidel[1]; Jean Sérgio Rosset[2]; Marcos Cesar Motin[1]; João Henrique Silva Caetano[3]
West Paraná State University, 1170 Pernambuco St., Marechal Cândido Rondon - PR, 85960-000, Brazil[1]; State University of Mato Grosso do Sul - UEMS, Unidade Universitária de Mundo Novo, BR 163, km 20,2, 79980000 - Mundo Novo, MS - Brazil[2]; West Paraná State University, 1170 Pernambuco St., Marechal Cândido Rondon - PR, 85960-000, Brazil (jhscaetano@bol.com.br)[3]

The soybean (Glycine max (L.) Merrill) is the main crop growing in Brazilian commercial fields and its production is mainly focused on exporting. However, in the last years, the economic pressures and the farmers' lack of care had lead to the loss of quality of the soils. It includes problems in soil physical properties, leading increase erosion, compaction and consequently crop yield loss. The crop coverage use, in No-Tillage system, is an useful tool to increase ambiental quality and avoid physical problems in the fields, enhancing biological diversity, the carbon and nitrogen input and, by this way, leading to the production sustainability. The aim of this work was to evaluate the physical properties (macroporosity, microporosity, total porosity, bulk density) and aggregates stability (aggregates stability index, weighted average diameter and geometric mean diameter) after soybean crop cultivation. The experimental design was a completely randomized block design, with six treatments and four replications. The treatments consisted of the soybean crop sown on different coverage plants straw (No-Tillage): black oats, black oats + forage turnip, forage turnip, black oat + forage pea, forage pea and control (fallow). Among the evaluations carried out , the use of cover plants did not alter the total porosity and microporosity. On the other hand, the use of coverage crops enhanced qualities, showing significant positive differences in macroporosity and bulk density in almost all observations. For the depth of 0.10 m, only treatments of soybean seeded on turnip and oat + pea did not obtain macroporosity higher than control; for the other depths all treatments were superior to the control's. Regarding the aggregates stability, only the weighted average diameter, in the peas covered treatment (0,10 m layer) was different of the control, reflecting the small time frame on the evaluations carried out.

(3956 - 1758) Spatio-temporal heterogeneity of water table level under cranberry production

Jonathan A. Lafond[1]; Silvio José Gumiere[1]; Guillaume Létourneau[1]; Jacques Gallichand[1]
Laval University[1]

In North America, cranberry production is rising. Since 2005, land area dedicated to cranberry doubled, principally in Canada. Recent studies have shown that subirrigation could lead to improvements in yield, water use efficiency and pumping energy requirements compared to conventional sprinkler irrigation. Knowledge of spatiotemporal structure and evolution of the water table and soil properties is primordial to establish new and more intelligent water management methodology in cranberry production. The objective of this work is to characterise the spatiotemporal heterogeneity at the farm scale. Water table level measurements over more than 60 observation wells, including weekly and automatic at 15-minutes time step, during the 2016 and 2017 growing seasons were used to performed multi-frequential periodogram analyses and coregionalization analyses with a drift (CRAD). Preliminary results will be presented showing distribution patterns of water table maintained in time and over years. The structure revealed by this spatio-temporal analysis will be integrated to an irrigation app developed for integrated irrigation management.

Keywords: irrigation, geostatistics, frequency analysis

(7392 - 2162) Stability of soil aggregates on over crop cultivation in *Piper nigrum* in northern Espírito Santo state

Ivoney Gontijo[1]; Juan Ricardo Rocha[1]; Ivne Franco Pires[1]; João Vitor Furlan[1]; Alan Mendes de Araújo Lima[1]; Yan Vinturini Vieira Dantas[1]; João Victor Fioroti Cescon[1]; Hugo Calegari Bonini[1]
UFES[1]

In the north of Espírito Santo state, conditions of exposed soil are frequently observed, which predisposes them to water erosion and decrease of the organic matter content, being influenced by the stability of soil surface aggregates. One of the most used conservation practices is the green manuring in the line of perennial crops, and has proved to be efficient in achieving sustainability in the agricultural system. The organic matter is one of the conditioners of soil that has greater influence under the structure and aggregation, due to its cementing action, giving the soil greater stability. The objective of this work was to study the potential of different species used as cover crops in *Piper nigrum*, under soil and climate conditions in the northern region of Espírito Santo state. The study was carried out in a commercial crop, with localized irrigation, on a dystrophic Yellow Latosol of franco-clayey texture and particle density of 2.65 g cm^{-3}. The experimental design was a randomized complete block design with four species of cover plants (*Crotalaria spectabilis, Cajanus cajan,*

Pennisetum glaucum and *Brachiaria*) and one control, with four replicates, the samples being taken at two depths, 0.0-0.10 and 0.10-0.20 meters. Cover plants were harvested during the flowering period, and after 45 days soil samples were collected. In each experimental plot, a deformed sample was collected for determination of the stability analysis of aggregates, in the interweaving of *Piper nigrum* planting, in the line of traffic of implements. The aggregate analysis was performed by the wet screening method according to the methodology recommended by Embrapa (1997), using a Yoder apparatus (1936). Analysis of variance was performed by the GENES software. Under the conditions under which the experiment was conducted, no significant statistical differences were observed between the species of plants used, as well as between the depths studied, since there was not sufficient accumulation of organic matter in the soil surface in the studied time, being insufficient for the physical improvements of the soil.

Keywords: conservation practices, stability of aggregates, organic matter

(1281 - 892) Stability of soil aggregates under distinct management systems of cauliflower at hillslope areas

Nivaldo Schultz[1]; Carlos Roberto Pinheiro Junior[1]; Gustavo Candido da Silva Rodrigues[1]; Luiz Alberto da Silva Rodrigues Pinto[1]

UFRRJ[1]

Adequate maintenance of the mineral, organic and porous on soil is a basic principle to meet the nutritional demands of plants, providing infiltration and reducing the runoff of rainwater and irrigation. The objective of this study was to evaluate the stability of soil aggregates before and after three crop cycles (2 years) of cauliflower (*Brassica oleraceae var. botrytis*) in different management systems. The experiment was developed in a Cambisol, under hillslope relief, located in Barracão dos Mendes, Nova Friburgo, Rio de Janeiro State. The design was randomized blocks, with 3 treatments and 4 replications and two evaluation periods - March 2015 and April 2017. The treatments were: conventional tillage with the soil preparation using rotating hoe without presence of cover plants - CT; conventional planting with incorporation of hedge plants using rotary spindle - CPIHP; and no-till (NT). The straw was formed by black oats (*Avena strigosa*) and weeds, in the proportion of approximately 50% of black oats and 50% of weeds. The accumulation of straw was 8.1, 10.3 and 5.1 Mg ha^{-1} for the first, second and third cycle, respectively. Soil samples were collected between the lines of cauliflower, at 0.0-0.10 m and 0.10-0.20 m depth. A sample per plot was collected to evaluate the stability of aggregates, through the index weighted mean diameter (WMD). Data were analyzed for variance and the means were compared by *T* test at 5% probability, using the Sisvar 4.3 software. The stability of the aggregates was altered in function of management. In March of 2015 the soil WMD values of the plots under CT, CPIHP and NT treatments were still to be implanted were 4.68, 4.85 and 4.63 mm in the 0.0-0.10 m and 4.81, 4.78 and 4.73 mm in the 0.10-0.20 m layer, respectively. No differences were observed in the values, as expected to the initial analysis. In April 2017, after the third cycle of cauliflower production, the WMD values of CT, CPIHP and NT were 3.52, 4.04 and 3.94 mm in the 0.0-0.10 m, respectively, and 3.43, 4.13 and 4.00 mm in the 0.10-0.20 m layer, respectively, with CT differing from CPIHP, and NT with the lowest value. This result shows the beneficial effect of no-tillage system on soil physical attributes. Based on these results, it can be inferred that soil management in no-tillage system provide the infiltration of water into the soil and reduces the runoff minimizing problems from water erosion.

(5994 - 2860) Subsurface erosion formation and triggering: pedological controlling factors

Renata Cristina Bovi[1]; Gabriela Pereira da Silva Souza[1]; Matheus Ortega Gomes[2]; Miguel Cooper[1]

Luiz de Queiroz School of Agriculture, University of São Paulo[1]; University of São Carlos[2]

Soil erosion studies are mainly focused on the soil particles release and their subsequent transport into surface flows, while subsurface flows are considered as a process of importance limited only to certain materials. Piping is an erosive process that involves the removal of particles from the subsurface of the soil, causing the formation of underground tunnels. The study area is located in the county of Piracicaba (state of São Paulo, Brazil), which presents several erosive features, among them the piping, object of the present study. Six pits were opened and described, in which the soil was classified as Hapludults (Argissolo Amarelo distrófico típico). The occurrence level of the pipes lies between the horizons E and Bt. With the objective of detecting contrasts between these horizons that could trigger the subsurface erosive process, based on the stagnation of water at the top of the Bt horizon, disturbed and undisturbed samples were collected in the E and Bt horizon and the following analyzes were performed: morphological, particle size distribution, bulk density (Ds), particles density and mapping of the Bt horizon microtopography (performed in successive points with an auger). In general, a gradient of pedological factors between the E and Bt horizon was observed. They are: a) textural gradient with increment of clay in subsurface, changing from sandy texture to medium texture, b) low flocculation degree in surface and high in subsurface, c) simple grains structure in the superficial horizons, in contrast to the subsurface horizons, which presented a better structuring, with medium to large subangular blocks, moderate degree, d) higher Ds in the subsurface horizons, together with a lower total porosity, in contrast to the superficial horizons with low Ds and higher total porosity. Also, it was observed that the top of the Bt horizon presented a slight inclination and a non-homogeneous microtopography. It was concluded that the contrasts in the pedological factors between horizons E and Bt may favor the accumulation of water at the top of the Bt horizon due to changes in the hydraulic conductivity between the two horizons, altering the fluxes in subsurface, in order to favor lateral flow instead of vertical. On the other hand, the microrelief and slope of the top of the Bt horizon may be responsible for inducing sufficient erosive velocity to the water flow.

(5863 - 1285) ***Theoretical and methodological contributions of the Integrated Management of Watersheds and Coastal Areas (IWCAM), for the improvement of the Sustainable Land Management (SLM) in the province of Cienfuegos.***

Yamila Vigo Cuza[1]; Yodani López Fonseca[2]; Clara Elisa Miranda Vega[3]

Provincial Department of Soils.Ministry of Agriculture[1]; Provincial Department of Soils. Ministry of Agriculture[2]; Center for Environmental Studies of Cienfuegos[3]

With the aim of demonstrating how from the approach of Integrated Management of Watersheds and Coastal Areas (IWCAM) approach contributes to the improvement of the Sustainable Land Management (SLM), a review is made of the studies carried out on sustainable land management in the province of Cienfuegos. 15 of the 98 studies were taken for the analysis, as they are the most representative of the subject in question. The analysis of the results obtained in these studies allowed identifying the need to incorporate the IWCAM approach to the SLM studies. The points of convergence that allowed establishing the complementation relationship between SLM and

IWCAM are also identified. It is concluded that the SLM and the IWCAM, pursue common objectives so promoting the SLM with IWCAM approach is to approach the response of a search for a solution to the environmental problems caused by agricultural activity in the basins. The points of convergence found in the theoretical review of the object of study allow establishing the articulation between SLM and the IWCAM. The analysis of the Environmental Totality, contributed to the theoretical foundation of the relationship that coexists between both approaches. The contributions of the previous studies in the basin constitute a strong contribution in the elaboration of the current proposal. The articulation of the SLM and the IWCAM in the province will contribute to the improvement of the management plans of their tributary basins.

(8693 - 3082) Variation of water storage in mobilized soil by deep tilling equipment in the Northwest of Paraná

Gislaine Silva Pereira[1]; Rayane Vendrame da Silva[1]; Emily Carolina Bacon[1]; Caroline Honorato[2]
UEM[1]; UNOESTE[2]

It is essential knowledge to relation between the water-soil-plant system for the proper management of soil parameters and irrigation. The objective of the present work is to evaluate the variation of the water storage in a dystrophic red Oxisol managed with the use of deep tilling in the northwest of Paraná. The study was conducted at the State University of Maringá, Campus do Arenito, in Cidade Gaúcha, Paraná. According to Koppen, the region has subtropical climate, with minimum annual temperature of 18 ° C and maximum of 22 ° C. The evaluation was execute in the year 2015 in a dystrophic red Oxisol with sandy texture, under area cultivated with cassava, evaluations at intervals of three days between the period from 20 to 30 July 2015. The soil mobilization was execute using equipment of deep tilling, denominated "penta". Deformed and undisturbed sample were collected with the use of auger and equipment called “castelo” in the layers between 0.00-0.20 m; 0.20-0.40 m and 0.40-0.60 m. Soil density and gravimetric moisture were obtained according to Embrapa (1997). Volume moisture was measured through the relationship between gravimetric moisture and soil density. Soil water storage was estimated according to Libardi (2012). There was an increase in water storage (120 to 207 mm) in the period between 20 and 23/07, under the influence of rainfall occurred on July 21. In the other periods, the values obtained from water storage were lower. The variation of water storage decreased over time and may be related to the type of soil management execute in the area. The deep tilling equipment made the mobilization of the soil layer to the depth of 0.60 m, causing the breakage of the same, and the rotary hoe coupled to the penta, broke the superficial layers of the soil until the layer of 0.30 m. The decrease in water storage was related to the management adopted and due to soil texture. Sandy soils have a greater amount of macropores, which favors water storage, however, they have a low retention capacity of stored water, which causes this water to be lost rapidly by infiltration to the deeper layers. The use of deep tilling equipment favored the loss of water from the system.

(5509 - 1429) Water and sediment losses in paired zero-order catchments under no-till with and without terraces.

Ana Lúcia Londero[1],[1]; Jean Paolo Gomes Minella[1],[2]; Fabio José Andres Schneider[1][3]; Dinis Deuschle[2]; Tiago de Andrade Neves Hörbe[3]
Federal University of Santa Maria, Roraima Avenida n.1000, Santa Maria, RS Postal Code 97105-900, Brazil.E-mail: londeroanalucia@gmail.com[1]; Federal University of Santa Maria, Roraima Avenida n.1000, Santa Maria, RS Postal Code 97105-900, Brazil.[2]; Federal University of Santa Maria, Roraima Avenida n.1000, Santa Maria, RS Postal Code 97105-900, Brazil[3]

The no-till system is a conservation technique for soil management whose principles are little or no soil disturbance, maintenance of surface straw and crop rotation. Currently, negligence in its use leads to situations of soil degradation. Despite this, little is known about the hydrological and erosive dynamics in hillslopes and zero-order catchments under this kind of land use and soil management. The present study monitored water and soil losses in these mishandled tillage systems in the scope of paired catchment of zero order with and without mechanical practices for runoff control. The areas are located within the Seed Research Center, which is located in the County of Julio de Castilhos in central Rio Grande do Sul State, Brazil. The catchments have an area of approximately 2.4 hectares. The main variables measured in each event rain/flow were: rainfall, water flow, surface runoff volume, peak flow, surface runoff coefficient, suspended sediment concentration and sediment yield in the period of 2015/2017 in different soil cover conditions, rainfall magnitude and antecedent moisture. The events were compared in terms of total water and sediment losses, and the comparison of the hydrograph and sedimentograph was performed in order to better comprehend the dynamics of runoff formation and erosive processes. The results demonstrate that the catchments are highly responsive to precipitation and that runoff is highly significant in the catchment without terraces. The no-till system without mechanical practice was unable to contain the superficial runoff whereas in the catchment where mechanical practices were used such losses were greatly reduced. For rainfall of larger magnitudes, flow rates were heightened, which indicates high sediment yield capacity. Soil losses were significant for larger events in areas with little ground cover. For a better parameterization of the WaterSed model, used in this work to simulate catchment scale, input data of the parameters of the simulated events were obtained from hydrological and sediment monitoring variables in this scale. On grounds of the above, the no-till system cannot contain runoff, and adoption of complementary practices, such as terracing, are necessary to reduce soil and water losses.

(3589 - 1428) Wood ashes as an alternative source of potassium in the biomass production of *Pennisetum purpureum* cv. Cameroon, for energy purposes.

Gabriel Barros Pinto[1]; Jean Felix Loubak[1]; Márcio dos Reis Martins[1]; Bruno Jose Rodrigues Alves[2]; Robert Michael Boddey[2]; Cláudia Pozzi Jantalia[2]; Segundo Urquiaga[2]
UFRRJ[1]; Embrapa Agrobiologia[2]

In the same manner as sugar cane, energy cane (*Saccharum* spp.), *Miscanthus* spp. and switch grass (*Panicum virgatum)*, elephant grass (*Pennisetum purpureum*) accumulates very large quantities of potassium, a fertilizer nutrient with severely limited world resources. The use of ash derived from the combustion of plant biomass, may help to minimize the necessity for K fertilizer and act as an alternative source of K for biomass production. The objective of this study was to evaluate the response of elephant grass to the application of ash as an alternative source of potassium fertilization in a long-term study planted in a Planosol on the field station of Embrapa Agrobiologia - RJ. The research was carried out from September 2013 to July 2017, in which the treatments were evaluated, T1, control, without potassium, T2 that received KCl, and T3 where applied vegetable ash as a source of potassium. The ash was derived from plant biomass burnt at 900 °C in the ovens of a brick factory. The potassium dose applied was 100 to 150 kg $K_2O.ha^{-1}$. The elephant grass genotype studied was cv.

Cameroon Piracicaba planted in plots of 5 rows of 5 m length with 0.8 m between rows, with 4 replications, in an experimental arrangement of randomized complete blocks. A total of seven cuts were performed every six months between the years of 2013 and 2017. The experimental results of biomass production demonstrated that the ash was only as effective as the KCl fertilizer from the second year onwards. Subsequently biomass production was approximately 26 $Mg.ha^{-1}$ with yields being very similar to those receiving K fertilizer, a much higher yield than that of the control treatment (10.3 $Mg.ha^{-1}.year^{-1}$), which each year decreased its production. Similar behavior was observed in the accumulation of K by plants. According to the results presented, the use of plant ash as an alternative source of potassium for elephant grass fertilization proved to be a promising long-term alternative to the same rate of K applies as KCl.

(5186 - 2647) Pig slurry application methods: Implications for soil quality parameters and productivity of maize and soybean crops (Córdoba, Argentina)

Pegoraro, Vanesa Romina[1]; Cazorla, Cristian Román[1]; Bachmeier, Omar Antonio[2]; Hang, Susana[2]; Ortiz, Jimena[1]; Briacchi, Martina Betiana[3]; Maury, Mariana[1]; Baigorria, Tomás[1]; Boccolini, Mónica Fabiola[1]; Zubillaga, Marta Susana[4]
Instituto Nacional de Tecnología Agropecuaria, Marcos Juárez, Córdoba, Argentina[1]; Universidad Nacional de Córdoba, Córdoba Capital, Argentina[2]; Universidad Nacional de Rosario, Zavalla, Santa Fé, Argentina[3]; Universidad Nacional de Buenos Aires, Buenos Aires Capital, Argentina[4]

Surface application of pig slurry (PS) is characterized by a high risk of ammonia losses. Different methods to decrease these emissions are available, but there is poor information about its impacts on the soil-plant system. The aim of this investigation was to evaluate PS application methods on indicators of soil quality and grain production, in maize-soybean crop sequence. Field testing was carried out for two years and five treatments were evaluated: acidified PS (AS), incorporated PS (IS), surface PS (SS), mineral N fertilization (MF) and control (C). Chemical parameters (0-20 cm depth) were determined during crops growth, and microbiological parameters (0-10 cm depth) were determined at physiological maturity, as soil quality indicators. Organic C, organic N, ammonium, nitrate (NO_3^-), extractable P (Pe), pH, electrical conductivity (EC), anaerobic N (AN), particulate organic matter, microbial biomass C, microbial respiration (MR), metabolic coefficient and acid phosphatase were evaluated. Also, grain yields were measured. Incorporate slurry inputs caused increases in AN and MR after two successive applications of PS on soybean crop. Treatments with PS and/or FM showed significant lower values in pH than C in both crops, and higher EC only in maize crop. PS treatments showed higher Pe on soybean crop, with respect to MF and C, due P contribution of PS. The concentration of NO_3^- increased with MF in both crops. In maize, MF presented similar concentrations to AS and SS, while the applications methods did not differ among them. For other soil quality indicators were not observed differences between treatments. Grain yields were affected by application method, depending of the crop evaluated. IS increased yields of maize crop by 16 %, whereas SS and AS increased yields of soybean crop by 112% and 79%, respectively, compared to C. Therefore, the different methods of application of PS produced changes in soil quality and modified the crops response. The surface application could indicate lower efficiency in retention of N within the system, being more evident in cereal crops. On the other hand, the soybean crop yield could be more related to the P contribution of PS.

(5902 - 742) ^{15}N recovery in depth by flooded rice in Southern Brazil

Gerson Laerson Drescher[1]; Qamar Sarfaraz[1]; Cesar Cella[1]; Allan Kokkonen[1]; Natalia Tobin Aita[1]; Gustavo Dal Molin[1]; Leandro Souza da Silva[1]
Federal University of Santa Maria, 1000 Roraima Ave, Santa Maria-RS, 97105-900, Brazil[1]

Nitrogen (N) fertilization for rice in Southern Brazil is based on soil organic matter (SOM) content (analyzed on a 0-0.2m layer) as a soil index. Recent studies have shown alkaline hydrolysable nitrogen (AH-N) as a better N availability index than SOM. SOM content is higher at soil surface and decreases with depth, while some soils have large amount of AH-N in depths bellow 0.2m, which can contribute to rice nutrition and affect AH-N calibration. This study aims to investigate the soil depth that rice plants are actively using N in Southern Brazil paddies. Stratified soil samples were collected up to 0.6m depth in three rice paddies (PSM, GSM, and GA) and selected chemical and physical properties were analyzed. The study was carried out in greenhouse, and rice was grown in undisturbed soil samples collected with a polyvinyl chloride tube (0.2 x 0.65m). ^{15}N-labeled $(NH_4)_2SO_4$ was injected at 0, 0.1, 0.2, 0.3 and 0.45m deep. Rice shoot part was collected at flowering, and dry mass, total N, and ^{15}N content and recovery was evaluated. Anova was conducted in factorial arrangement, and means were compared with Fisher`s LSD ($\alpha \leq 0.05$). Highest ^{15}N recovery was observed when fertilizer was injected at 0.1, 0.2, and 0.3m deep for all soils, which can be related to ammonium (NH_4^+) adsorption to cation exchange sites, and protection against loss. Thus, NH_4^+ was protected and available when rice roots reached deeper layers, which apparently occurred when plants where in a phenological stage of higher N demand, resulting in high ^{15}N recovery even when fertilizer was applied at 0.45m. The GA soil had higher ^{15}N recovery (52%) when ^{15}N was applied at 0.1m, with constant decrease with depth. PSM and GSM soils kept similar recovery when ^{15}N was applied at 0.2 (54% and 61%, respectively) and 0.3m (54% and 59%, respectively), and only decreased ^{15}N recovery at 0.45m (22% and 36%, respectively). Overall, GSM had the highest ^{15}N recovery, while also presented highest hydraulic conductivity (HC), which indicates HC is an important soil property that dictates N absorption, considering that N is predominantly absorbed through mass flux. These findings indicate rice plants are actively using N from depths up to 0.45m, and the intensity of N recovery is also related to soil physical properties. N located bellow 0.2m contributes to plant nutrition, therefore it should be considered in future studies with calibration of soil-based N tests such as AH-N for rice in Southern Brazil.

(7964 - 1960) Addition of gypsum with leguminous residue to reduce cohesion and increase maize grain yield.

Stéfanny Barros Portela[1]; Virley Sena[2]; Vinícius Macedo[1]; Francielle Silva[3]; Luis Adriano Almeida[1]; Carlos César Sousa[1]

Universidade Estadual do Maranhão[1]; Universidade Estadual de São Paulo[2]; Universidade Estadual do Norte Fluminense[3]

In the humid tropics region, the accumulation of humified organic matter, which could attenuate the negative effects of cohesion and reduced soil rootability, is prevented by the availability of water, oxygen and high temperatures favoring the rapid biomass decomposition. We hypothesized that the use of gypsum with the leguminous biomass applied to the soil surface can contribute to the permanence of Ca and organic matter in profile, increase the thickness of rooting layer and increase the water and nitrogen use efficiency in cohesive soils. This work began in January 2016 and ended in June 2017, following a randomized block design with four replications of the following treatments: control (C); 4 Mg ha^{-1} of gypsum (G); 200 kg ha^{-1} of N from urea (U); 12 Mg ha^{-1} of dry matter legumes residue (L); 12 Mg ha^{-1} of dry matter legumes residue + 4 Mg ha^{-1} of gypsum (LG); 200 kg ha^{-1} of N from urea + 4 Mg ha^{-1} of gypsum (UG); 12 Mg ha^{-1} of dry matter legumes residue, 200 kg ha^{-1} of N from urea + 4 Mg ha^{-1} of gypsum (LUG). In 2016 gypsum application decreased maize grain yield and the N use efficiency due to Ca excess in the surface layer and leaching of K and Mg to depths not intercepted by the root zone. P deficiency was also observed. Ca has a preference in the lyophilic sequence of the soil, competing for the same active site as K and Mg, which decreases the availability of these nutrients in the superficial layer. In 2017, the levels of Ca in the soil reduced due to leaching and export through the crop. This year, it was noticed an improvement in soil ephemeral structure, which increased the absorption of water and nutrients by the maize crop due to the direct and indirect improvements provided by Ca. Directly because Ca contribution stimulating maize root development and indirectly because Ca in soil does strong binding with c-organic. These factors improved maize rooting, which reflected higher N uptake, 75 kg ha^{-1} in the control treatment and 195 kg ha^{-1} in GLU treatment, and higher maize grain yield, 3.10 Mg ha^{-1} in Control and 6.17 Mg ha^{-1} in GLU. In humid tropics the contribution of organic matter and gypsum application are alternatives that allow to improve the soil ephemeral structure, to increase c-organic levels and base saturation in the rooting layer from the second year of cultivation.

(4436 - 3115) Agronomic characteristics of sunflower cultivars (*Helianthus annuus* L.) BRS 122 and BRS 324 under nitrogen fertilization in the brazilian semiarid region.

Amanda Michele Santos de Lima[1]; Francisca Maria da Silva Correia[1]; Emídio Cantídio Almeida de Oliveira[1]; Abraão Cícero da Silva[1]; Magda Aline da Silva[1]

Universidade Federal Rural de Pernambuco[1]

The Brazilian semiarid is a region that shows peculiar and limiting conditions of soil and climate to the majority of plant species. The restrictions imposed by these peculiarities, especially the local irregular rainfall distribution, give to the soil some specific characteristics such as low organic matter content, the main source of Nitrogen to the soil. Therefore, the nitrogen requirement of the agricultural crops at this location is almost exclusively supplied by the nitrogen fertilization. That being said, identifying crops that present high efficiency in the use of nitrogen fertilizers has become crucial in the management of the crops cultivated in this region. In this perspective, this paper aims to evaluate the growth and yield of two sunflower cultivars under different levels of nitrogen grown in the semiarid region. The experiment occured in a field with two sunflower cultivars (BRS 122 and BRS 324) and four levels of nitrogen (0, 40, 80 e 120 kg ha^{-1}) distributed in randomized blocks with six repetitions in a 2x4 factorial design. Growth parameters (height, diameter, amount of leaves, diameter of the capitulum, and dry biomass produced) were evaluated at 45, 53, 60, 67, 70, 81, 90 and 104 days after sowing (DAS). Production parameters were also evaluated (aerial dry mass, root dry mass, mass of 1000 achenes, achene yield, yield, and oil content) at the end of the cycle. There was a significant interaction between the level of nitrogen applied and the cultivar regarding height, diameter of the capitulum, and amount of leaves. The achene yield, oil content, and the total dry mass differed according to the level of nitrogen applied, presenting better results with the amount of 100kg ha^{-1}. At the end of cycle, the BRS 122 cultivar presented higher efficiency of nitrogen fertilizer use and higher increases in growth variables, while the BRS 324 cultivar showed to be more demanding in nitrogen, and presented better performance in the amount of achenes and oil content in response to nitrogen fertilization. For both cultivars, with the increase of the nitrogen level, there was an increase in oil productivity and reduction in oil contents.

(9360 - 1357) Agronomic variables and silage production of maize plant intercropped with forage plants under different nitrogen topdressing rates.

Clarice Backes[1]; Stephanie Vicente de Bessa[1]; Lucas Matheus Rodrigues[1]; Arthur Gabriel Teodoro[1]; Alessandro José Marques Santos[1]; Lorrayne Lais Ferreira Leite[1]

State University of Goiás[1]

The maize silage is an important food in dairy and cattle production during dry season thus is fundamental improve productivity. To improve yield and silage production it can be use intercropping maize with forage plants and nitrogen fertilization. The objective of this study was to evaluate the effect of nitrogen topdressing rates applied to an intercrop of maize (M) with paiaguás grass (G) and pigeonpea (P) on silage production and on agronomic variables of shoots of maize plant. Treatments consisted of two intercropping systems (M+G; and M+G+P) and four N topdressing rates (0, 80, 160, and 240 kg ha^{-1}). In the maize dent reproduction stage, the plants were harvested for silage production. On that occasion, was measured agronomic traits of maize such as plant height, height of ear insertion, stem diameter, final stand, and ear index. The growth of maize plants was not influenced by the introduction of pigeonpea into the system, although the legume was sown simultaneously in the maize inter-row. The N rates influenced only the stem diameter and the estimated N rate of 198 kg ha^{-1} provided maximum value. Silage dry matter yield was affected by the interaction between intercrops and N rates. The highest yields were obtained when the pigeonpea was introduced in the system, with increase of 43% based on the means of the M+G+P intercrop in relation to M+G. With respect to the N rates, for the M+G intercrop, yields increased linearly, reaching 13.9 t ha^{-1} at the N rate of 240 kg ha^{-1}. For the M+G+P intercrop, the response was quadratic, with maximum yield (18.1 t ha^{-1}) obtained at the estimated N rate of 120 kg ha^{-1}. The introduction of pigeonpea contributed to increase the silage dry matter and reducing the N rate in the system as a function of the produced mass.

Keywords: maize morphology; crop-livestock integration system; legumes.

(7308 - 2973) Ammonia volatilization from liquid nitrogen fertilizers

treated with urease and nitrification inhibitors

Mateus de Paula Gomes[1]; Chaenzy Specimille Hamer[1]; Ariana Mota Pereira[1]; Reinaldo Bertola Cantarutti[1]

Universidade Federal de Viçosa[1]

UAN is a liquid fertilizer composed of urea and ammonium nitrate, with 32% N. It can have its efficiency compromised through N losses by ammonia volatilization and nitrate leaching. The objective of this study was to evaluate the efficiency of the urease inhibitor N-(n-butyl) thiophosphoric triamide (NBPT) and the nitrification inhibitor dicyanodiamide (DCD) to control UAN volatilization. The experiment was carried out on a soil cultivated with maize (Red Latosol, clay-sandy loam) collected in Patos de Minas and a soil under pasture (Cambic Red-Yellow Argisol, very clayey) collected in Viçosa, Minas Gerais, Brazil. The fertilizers evaluated were UAN+NBPT+DCD (UANnbpt.dcd), UAN+NBPT (UANnbpt), UAN+DCD (UANdcd), UAN and Urea (U). NH_3 volatilization were measured 20 times. Thus, the treatments consisted of a factorial design (2 × (5 + 1)) × 20. The experiment was arranged in a completely randomized design with measurements repeated over time, with three replicates. The soils previously received limestone application sufficient to raise the base saturation to 70%. The experiment was conducted in a system of an incubator containing 200 g of soil connected to a NH_3 collector containing H_3BO_3 solution (20 g L^{-1}). Fertilizer amounts equivalent to 100 mg of N were applied on the soils. The system was closed and immediately subjected to a flow of NH_3-free air to carry the NH_3 produced. The 20 measurements of volatilized NH_3 were performed between 3 and 312 h from the fertilizer applications. At each measurement, the collecting units were changed and the NH_3 captured by the H_3BO_3 solution was determined by potentiometric titration. The fertilizer urea showed the highest ammonia volatilization, with losses of 291 and 286 mg/g of N for the soils with the maize crop and the pasture area, respectively. The peak of volatilization occurred after 48 h and 24 h for the soils with maize and pasture, respectively. The application of DCD to UAN had no influence on the N loss by ammonia volatilization in both soils. However, the application of NBPT to UAN reduced the ammonia volatilization accumulated in the soil from the maize area by 55% at UANnbpt.dcd and 50% at UANnbpt. While in the pasture soil, the NBPT delayed the volatilization peak, which occurred after 60 hours for UAN and after 120 hours for UANnbpt and UANnbpt.dcd.

Keywords: NBPT; DCD; UAN

(3176 - 959) Ammonia volatilization from nitrogen fertilizer formulated with biochar

Aline Peregrina Puga[1]; Cristina Silva Carvalho[2]; Marcos Antônio Vieira Ligo[1]; Adriana Marlene Moreno Pires[1]; Braulio Garcia Pereira Neto[3]; Cristiano Alberto de Andrade[1]

Embrapa Meio Ambiente[1]; UEMA[2]; Carbosolo Desenvolvimento Agrícola[3]

Ammonia (NH_3) volatilization results in low N use efficiency by crops. The aim of this study were to evaluate NH_3 volatilization from nitrogen fertilizer formulated (F) with biochar (BC). In a incubation experiment the fertilizers were applied to soil surface. NH_3 volatilized was captured by H_2SO_4 solution. BC used in the production of fertilizers is from eucalyptus (charcoal fines). Two types of formulated fertilizers were tested: granulated (F6 and F8; mixture of BC, urea and additives) and coated granulated fertilizers (F17 and F19; coating of urea granule with BC, acidified or not, and additives). Treatments tested were: 1) blank; 2) control; 3) soil + urea; 4) soil + F6 (10% N, 51% BC); 5) soil + F8 (20% N, 29% BC); 6) soil + F17 (20% N, 29% BC) and 7) soil + F19 (32% N, 20% BC). Granulated fertilizers (F6 and F8) and F17 coated fertilizer volatilized lower amounts of NH_3 than urea, indicating greater efficiency when applied to the surface. In the case of F17, where the BC was previously acidified prior covering urea granule, acidification must have influenced the reduction of NH_3 losses. In total urea volatilized 71% of N applied while F6 and F8 showed losses of 60% and 66%, respectively. F8 was produced with 20% N and 29% BC, while F6 with the lowest NH_3 loss had 10% N and 51% BC. Proportion of BC in the fertilizer and the BC/N ratio appear as important in reducing N loss by NH3 volatilization. F19 showed worse performance than urea, volatilizing 80% of the applied N. However, F17 which was coated with previously acidified BC, presented lower volatilization (64%) compared to F19 and urea. In the equations of first-order chemical kinetics model describing the urea NH_3 volatilization process of BC granulated and BC-coated fertilizers, it was found that the lowest N_0 values (indicates the stabilization value of the volatilization process) belong to F6 and F8 (@64%), 12% lower than urea (N_0=73%). It was observed that the highest value of N_0 was of F19 (84%), confirming the BC alkalinity effect (pH@ 7.7) favoring N losses when fertilizer production technology was the coating of urea granule with BC without prior acidification. F6 and F8 tested in this study demonstrated potential to be applied in top dressing fertilization, due to lower volatilization rates, providing lower risk of N losses due to volatilization of NH_3. Granulated F6 and coated F17 provided reductions between 10 and 15% for NH_3 losses compared to urea.

(2061 - 1197) Ammonia volatilization in oxisol cultivated with maize and irrigated with swine wastewater treated anaerobically

Sarah Mello Leite Moretti[1]; Edna Ivani Bertoncini[2]; André Cesar Vitti[2]; Cassio Hamilton Abreu-Junior[1]

University of São Paulo, Center for Nuclear Energy in Agriculture[1]; São Paulo's Agency for Agribusiness Technology, Secretariat of Agriculture and Food Supply of São Paulo[2]

Swine effluent presents significant nitrogen (N) amounts in forms easily available by crops and its agricultural use can represent mineral fertilizers savings and nutrient cycling. However, its potential fertilizer can be reduced due to N atmospheric losses, which is preferably in ammoniacal form in effluent. Under tropical and subtropical conditions, there is little information about N volatilization from organic wastes applied to soils. This study was carried out in field conditions, in randomized blocks with three replicates. Summer and winter corn crops were cultivated in a clayey Oxisol, evaluating the following treatments: T1- control, without fertilizer and irrigation; T2- mineral fertilization without irrigation, T3- irrigation with swine wastewater SWB, T4-irrigation with SWBD, T5-mineral fertilization with irrigation with water. Irrigation needs were controlled by crop water requirement and soil matric potential measured by tensiometers installed in each plot. Next to maize central line of each plot, it was installed semi-open chambers containing foams soaked in 0.01 mol L^{-1} phosphoric acid and glycerin to capture volatilized N-NH_3. Periodically, the saturated foams were exchanged, washed with deionized water, and N-NH_4^+ contents were determined in extracts, quantifying the N losses. The average N-NH_4^+content in treated effluents was 1423.2 mg L^{-1}, representing 80% of N-total. The pH value at the soil surface was 4.7, which could facilitate N losses by

volatilization. Higher N losses occurred 2 and 3 days after first application of SWB (33.3 mm) in T3 and T4 treatments, equals to 4 kg ha^{-1} and 3.8 kg ha^{-1} of N, respectively for winter and summer cultivation. However, highest lost nitrogen percentage was obtained for soil irrigated with SWBD during winter cultivation, equal to 6.4% of total N applied when compared to SWB irrigation, in which the losses were equal to 3.3% of total N. Higher rainfall indices observed during summer cultivation promoted the incorporation of effluents and nitrogen fertilizer to soil, reducing the N atmospheric losses. Despite a small increase in losses observed at 22^{nd} day of evaluation in treatments with mineral fertilizer application, as function to temperature (29ºC). Thus, N volatilization was influenced by amount and characteristics of swine effluents, application time and soil characteristics. These factors should be considered for predict nitrogen losses by volatilization in soils treated with swine wastes.

(3055 - 1326) Ammonia volatilization of nitrogen sources applied in maize in no tillage

Bruno Paulo Moschini[1]; Nicole Colombari Cheng[1]; Pedro Lopes Garcia[2]; Paulo Cesar Ocheuze Trivelin[2]

ESALQ/USP[1]; CENA/USP[2]

The maize (*Zea mays* L.) is one of the most studied crops due to its economic importance. Despite the high yield potential in maize, what can be observed in practice is a low and irregular grain yield due to management problems such as the incorrect use of nitrogen fertilizers which provide nitrogen (N) losses in the soil-plant-atmosphere system. A manner to increase fertilizers use efficiency can be using enhanced efficiency fertilizers. The objective of this study was to evaluate the effect of N rates and sources on volatilization of ammonia (NH_3-N). The experimental area was located in Iracemápolis, São Paulo, Brazil, in a Rhodic Eutrustox site with clayey texture. The treatments were arranged in randomized blocks with four replications and consisted of the application of urea, ammonium nitrate, and blends of NBPT-treated urea with polymer-sulfur coated urea with the following rates: 75, 150, 225 and 300 kg N ha^{-1}. The treatments were applied at maize sowing at top dressing in no tillage. A control treatment (without urea-N) was also included. A static open collector (14 x 14 x 7 cm) manufactured with PVC with an exchangeable circular foam (diameter: 15 cm; thickness: 2 cm; density: 0.02 g cm^{-3}) soaked in 25 mL of phosphoric acid solution (5 mol L^{-1} with 5% of glycerin (v/v)) was used to quantify the ammonia losses. The flow injection analysis (FIA) was utilized to determine NH_3-N retained in the foam after extraction by deionized water. The results were submitted to analysis of variance, the means were compared by the Fischer test, both at 0.1 of probability, using the R statistical software. The ammonia losses were measured during 61 days, having low losses until the fourth day of evaluation, maximum losses in the fifth day after fertilization, and decreasing losses until the last evaluation. The maximum volatilization losses was similar in the treatments. The urea (225 and 300 kg de N ha-1) had higher total volatilization losses than other treatments.

(8413 - 2369) Analysis of initial growth of pepper pout submitted at nitrogen levels

Jéssica Patrícia Paula Lima[1]; Márcio Koetz[1]; Edna Maria Bonfim-Silva[1]; Juliane de Souza Beltrão[1]; Francielly Gonçalves Barbosa-Oliveira[1]

Universidade Federal do Mato Grosso[1]

The production of peppers in Brazil has shown growth in the last years, being worth mentioning the pepper pout of the genus Capsicum chinense, considered the most domesticated Brazilian species. Its cultivation in Brazil is maintained by the small and medium farmers, mainly of the Southeast region. Because it is a crop that does not require excessive labor, especially when it comes to its harvest, its cultivation is a good option for obtaining income. However, research is still necessary for its efficient cultivation in the Cerrado. The objective of this study was to evaluate the diameter of the stem of the pepper pout in protected crop under nitrogen doses. The experiment was conducted in a greenhouse in pots of 5 dm^{-3} with Oxisol from native Cerrado. The experimental design was completely randomized, with 5 nitrogen doses (0, 60, 120, 180 and 240 mg dm^{-3}) and 5 replicates, totaling 25 experimental units. According to the soil chemical analysis, the base saturation was corrected to 80% and fertilized with 600 mg dm^{-3} of phosphorus, 180 mg dm^{-3} of potassium and nitrogen, divided in 3 times according to the treatments. It was fertilized with micronutrients via solution, applying 5,72 mg dm^{-3} of boron, 3,93 mg dm^{-3} of copper, 10,95 mg dm^{-3} of manganese and 13,51 mg dm^{-3} of zinc. The cultivar BRS Moema was used to seed the seeds in expanded polystyrene bile and later transplanted to the pots, when the seedlings reached an average of 7 cm in height, 37 days after sowing. Irrigation was performed by monitoring soil moisture with tensiometers, installed at 10 cm depth in the pots, so that the soil returned to the field capacity condition whenever the read tension reached 15 kPa. The stem diameters were analyzed at 15, 30, 45 and 60 days after transplanting (DAT). A significant difference was found in the F-test at 5% probability at 30, 45 and 60 DAT, where it was fitted to the linear regression model, using the statistical software SISVAR. The stem diameters of the pepper pout cultivated with Oxisol, under protected environment were influenced by the nitrogen doses.

Keywords: Capsicum chinense, irrigation, family farming, fertilization.

(7690 - 3128) Biological nitrogen fixation in legume crops grown in a consortium with grasses

Jéssica Rafaella de Sousa Oliveira[1]; Sueide Karina da Silva[1]; Ana Dolores Santiago de Freitas[1]; Carolina Etienne de Rosália e Silva Santos[1]; Vinicius Santos Gomes da Silva[1]; Leandro Reis Costa Santos[1]

Universidade Federal Rural de Pernambuco[1]

Biological nitrogen fixation (BNF), performed by diazotrophic microorganisms, is extremely important for agriculture, since it has the potential to reduce the indiscriminate use of nitrogen fertilizers, resulting in savings for the producer and reduction of impacts on the environment. The objective of this study was to estimate the BNF of jack bean (*Canavalia ensiformis*) and cowpea (*Vigna unguiculata*) grown in a consortium with C4 grasses (maize (*Zea mays*), sorghum (*Sorghum bicolor*) and millet (*Pennisetum glaucum*)) or sunflower (*Helianthus annus*). Samples of the superficial layer of a Planosol (0-30cm) were collected in agricultural area of the municipality of Belo Jardim, semiarid region of Pernambuco state. This soil was used for potting (6.5L). The study was conducted in a greenhouse using a randomized block design. The harvest was done 50 days after planting, cutting the aerial part, which was dried in an oven, ground and submitted to analysis of N concentrations and its isotopes. The nodules were counted and packed in silica gel to determine the biomass of dry nodules. FBN was estimated using the ^{15}N natural abundance methodology. For the biomasses, concentrations and accumulations of N, nodulation, % Ndda and N fixed in the legumes, comparisons were made considering a 2 * 4 factorial experiment (8

treatments: 2 legume species and 4 intercalary species situations) and the means were compared to the Tukey test at 5% probability. The presence of compatible rhizobial populations in the soil was demonstrated by the natural nodulation of legumes. It was verified that the grass species does not alter the nodulation, demonstrated by the similarities in the number of nodules, dry biomass and average size of legume nodules when cultivated together with maize, sorghum or millet. On average, the plants had 118 and 56 nodules, with a dry biomass of 0.84 and 0.45 g plant^{-1} and mean nodule size of 7.81 and 8.63 mg for jack bean and cowpea , respectively. For jack bean, the percentage of nitrogen derived from the atmosphere (% Ndda) varied between 67 % and 86 %, showing that in intercropped or single crops, the legume has considerable fixation capacity, which corresponds to a mean of 461 mg of nitrogen obtained by FBN. The same occurred with the cowpea, which had values between 70 and 85% and 366 mg plant^{-1} of fixed N. The sampled soil harbors a naturally established rhizobial population with the ability to nodulate the legumes, not being altered by the consortium.

(1729 - 1709) Components of the efficiency of nitrogen use in culture of the inoculated corn with *Azospirillum brasilense*

Karen Alessandra Sousa Castro[1]; Marcelo Marinho Viana[1]; Lincon Matheus Araujo Silva[1]; Danilo Nunes Sodre[1]; Assistone Costa de Jesus[1]; Ester de Paiva Alves[1]; Werlen Araújo Barbosa[1]; Erivaldo Plinio da Costa Borges[1]; Cristina Silva Carvalho[1]; Heder Braun[1]
State University of Maranhão[1]

The association of nitrogen with diazotrophic bacteria of the genus Azospirilum brasilense can guarantee a greater productive capacity and efficiency of the use of N for the corn crop. The objective of this study was to evaluate the association between inoculation of Azospirillum brasilense and N rates on grain yield and efficiency of N using corn. The experiment was installed in the field at the State University of Maranhão in the year 2015 (2° 35'S and 44° 12' W). A randomized complete block design with four replications in a factorial scheme was used, the treatments consisted of the combination of four doses of N (0, 45, 90 and 180 kg ha-1) applied as a cover in the form of urea (45% of N) with three forms of inoculation of the bacteria of the genus A. brasilense (seeds, foliar and control). The seed corn was the hybrid AG-1051, with plots of four rows spaced 0.80 m and 0.20 m between plants. The relationship between the N content and the plant matter mass and the dry grains determined the content of N. With these data the following components of the NUE were calculated: N utilization efficiency (NUtE, kg kg-1), N uptake efficiency (NUpE, kg kg-1) and nitrogen use efficiency (NUE, kg kg-1). The ANOVA was performed adopting p≤0,25 for the interaction and p≤0,05 for the Tukey test. The R software was used with the RStudio interface to perform the analysis. The interaction rates of N x inoculation forms of A. brasilense influenced grain yield (p = 0.0381). The mean grain yield (GY) with seed inoculation was 8.0% higher than the GY average with foliar inoculation and 50% higher than the GY mean where it was not inoculated with A. brasilense. The interaction between the doses of N and the forms of inoculation with A. brasilense was significant on NUpE (p <0.0001) and NUE (p <0.0001). There was a 50% increase in NUE where inoculation with A. brasilense by way of seed was received in relation to treatment that was not inoculated. NUpE increased 62% when inoculated with A. brasilense by way of seed in relation to treatment that was not inoculated. There was no significant interaction for NUtE (p = 0.6683). With these results we can conclude that there was a 50% increase in GY and NUE in treatment of seed inoculant when compared to the control. In this way, the inoculation of A. brasilense in the seeds provides an increase in the productivity and greater efficiency of the use of N and its components, which proves the efficiency for the humid tropic of Maranhão.

(9636 - 1303) Cultivation of pout pepper under nitrogen in a greenhouse

Juliane de Souza Beltrão[1]; Márcio Koetz[1]; Edna Maria Bonfim-Silva[1]; Jéssica Patricia Paula Lima[1]; Francielly Gonçalves Barbosa-Oliveira[1]
Universidade Federal de Mato Grosso[1]

The cultivation and processing of peppers is an important economic activity for small producers. The pepper pout (*Capsicum chinense*) stands out due to its main characteristic which is the absence of pungency in the fruits, allowing its use in several product lines. However, studies are still necessary, in order to have the knowledge of the ideal techniques of its cultivation in the Cerrado. The objective of this study was to evaluate a plant height of the pepper pout submitted to different doses of nitrogen. The experiment was conducted in a greenhouse, located at the Federal University of Mato Grosso, Campus Rondonópolis. The experimental units were composed of pots of 5 dm^{-3}, filled with Red Latosol, from the Cerrado. The experimental design was completely randomized, with 5 nitrogen doses (0, 60, 120, 180 and 240 mg dm^{-3}) and 5 replicates, making 25 experimental units. From the chemical analysis, dolomitic limestone was applied to soil to raise the saturation by bases to 80% and was fertilized with macro and micronutrients, applying 600 mg dm^{-3} of phosphorus, 180 mg dm^{-3} of potassium and nitrogen, divided in 3 times according to the treatments. The micronutrients were via aqueous solution with 5.72 mg dm^{-3} of boron, 3.93 mg dm^{-3} of copper, 10.95 mg dm^{-3} of manganese and 13.51 mg dm^{-3} of zinc. The seeds of the cultivar BRS Moema were seeded in expanded polystyrene trays to be transplanted to the experimental units 37 days after sowing, when the seedlings reached an average of 7 cm in height. By means of a previous study with the soil, the water retention curve was obtained, where it was verified that the soil in the tension of 5 kPa was in the capacity condition of the field. Thus, irrigation was performed whenever the average reading of tensiometers installed at 10 cm depth in the experimental units, indicated the tension of 15 kPa, applying the volume of water required for the soil to return the field capacity. Plant height at 15, 30, 45 and 60 days after transplanting (DAT) was evaluated. A significant difference was found at 15, 30 and 45 DAT, by the F test at 5% probability, adjusting to the linear regression model at 30 DAT and quadratic at 15 and 45 DAT, using the statistical software SISVAR. The height of pepper pout plants cultivated with Red Latosol under greenhouse conditions are influenced by the nitrogen doses.

Keywords: *Capsicum chinense,* BRS Moema, family farming, irrigation, fertility.

(9193 - 2724) Differential response of maize hybrids to inoculation with Azospirillum brasilense

Denise Pacheco Dos Reis[1]; Rafael Augusto Lima Rodrigues[1]; Christiane Abreu De Oliveira Paiva[2]; Lauro José Moreira Guimarães[2]; Ivanildo Evódio Marriel[2]
Universidade Federal De São João Del Rei[1]; Embrapa Milho E Sorgo[2]

High costs of nitrogen fertilizers from an energy and economic point of view make it important to develop technologies that increase the

nitrogen use efficiency by crops. The objective of this work was to evaluate the genetic variability and to identify maize genotypes responsive to the inoculation with diazotrophic bacteria of the genus Azospirillum, in an environment with low nitrogen availability. The study was conducted in dystrophic Red Latosol (Oxisol) soil, Cerrado phase, poor in nitrogen (<20 ppm of mineral N), in experimental area of EMBRAPA Maize and Sorghum, Sete Lagoas - MG. Seven hybrids of maize (HB1, HB3, HB3, HB4, HB5, HB6 and HB7) were evaluated in the presence and absence of an inoculant composed of three different strains of Azospirillum brasiliense, in a randomized complete block design with four replicates. At planting a uniform basal dose of 300 kg ha^{-1} of formulation 8-28-16 was applied. Coverage was not applied. For the preparation of the inoculant, cultures of bacteria enriched in defined medium for 5 days under stirring at room temperature, were centrifuged, washed and resuspended in saline. The cell suspensions were adjusted to approximately 10^8 CFU mL^{-1}, incorporated into ground charcoal (60% w/ v) as carrier and added to the seeds moistened with cassava starch gum 5%. In addition to the agronomic characteristics, grain yield (GY) at 13% moisture was evaluated. There results revealed that there were significant difference between maize genotypes ($p<0.05$), with GY ranging from 2.764 to 5.561 kg ha^{-1}, with differential response to inoculation ranging from -7(HB6) to + 82% (HB1) in uninoculated treatment. It is concluded that the technology of inoculation with Azospirillum brasilense can contribute to the gain of maize yield depending on the cultivar used.

(3609 - 2156) Does the way of lime application change nitrogen amidic sources efficiency in mitigating N-NH_3 loses?

Marcos Renan Besen[1]; Evandro Antonio Minato[1]; Carolina Fedrigo Coneglian[1]; Éder Junior De Oliveira Zampar[1]; Bruno Maia Abdo Rahmen Cassim[1]; Lucas Simas De Oliveira Moreira[2]; Tadeu Takeyoshi Inoue[1]; Marcelo Augusto Batista[1]
UEM[1]; COAMO[2]

Higher nitrogen (N) loses in N-NH3 form can occur when urea is applied on surface, and can be enhanced by liming, due to soil pH increase changing the equilibrium between NH_3 e NH_4^+ in soil (NH_4^+ + OH↔ NH_3 + H_2O). in this way the use of enhanced efficiency fertilizers (EEF) can be an alternative in mitigation of N-NH_3 loses. The objective of this work was to evaluate the effect of lime application way in N amidic sources performance. O experimental design was a factorial randomized blocks (2x4x3 +2), where two ways of liming application: surface (SL) and incorporated (IL) application; four levels of base saturation (V%): 44, 60, 70 and 90%, which were combined to make the main plot; three N sources: conventional urea (CU); urea + N-butil tiofosfórico triamida (Ur-Nbpt); and commercial urea coated with boron and copper (Ur-CuB), which were the subplots. The additional treatments were with no N and lime in each soil management. N was applied in a rate of 80 kg N ha^{-1} in a Red Oxisoil, cultivated with wheat. The volatilization was measured to 2, 4, 7, 10, 14 e 17 days after N application. The volatilized NH3 evaluationg was carried out by semi open static chamber method with a filter paper tape submerged in a H_2SO_4 0,05 mol L^{-1} + 2% v/v de glycerin solution and determined by UV/VIS spectrophotometry. There was interaction only between N sources and ways of lime application and there was no effect from V%, possibly due the short term between lime reapplication and N application. Related to factorial versus additional treatments, only Ur-Nbpt in IL did not differ from the controls, showing higher mitigation potential. There was no effect from the Ur+CuB (20.15 kg N-NH_3 ha^{-1}) and UC (20.48 N-NH_3 ha^{-1}) in SL, however there was effect from Ur-Nbpt (15,33 kg N-NH_3), reducing in 25% the N loses compared to the others sources. When IL was used, mitigation occurred to both EEF. Emissions of 18.52, 13.60 e 8.30 kg N-NH_3 ha^{-1} were verified, resulting in N loses of 25, 17 and 10 % of the total amount of N applied from UC, Ur-CuB e Ur-Nbpt respectively. When we consider that in no-till system the urease activity is higher, we can presume that EEF efficiency in mitigate N loses is higher in less favorable conditions to volatilization, such as IL, being Ur-Nbpt source efficient in reduce N-NH3 volatilization in both soil managements.

(5736 - 2752) Effect of natural zeolite on the nitrogen fertilizer efficiency in coffee crop, in Aserrí, Costa Rica

Karla Montero Jara[1]; Patricia Oreamuno Fonseca[1]; Wagner Peña[1]
Universidad Estatal a Distancia[1]

The objective of this work was to evaluate the effect of natural zeolite on the efficiency of nitrogen fertilizer in coffee crop. In search for sustainable alternatives to the nitrogen fertilizer of coffee crops, the proportional addition of clinoptilolite-type natural zeolite contributes to enhance the use of urea. The experiment was conducted in Vueltas de Jorco-Aserrí (Central Valley of Costa Rica). This study was established during the first vegetative stage of the coffee plants, replacing with different percentages of natural zeolite (0, 15, 25 and 35%) combined with urea. Physical, biological and chemical variables were analyzed. Most of the results were positive, but the variables related to microbial activity stand out in the treatment of 25% of natural zeolite.

Keywords: Fertilization, urea, isotope, coffee.

(3608 - 750) Effect of the use of nitrification inhibitors in the reduction of nitrogen losses of nitrogenous fluid fertilizer

Ronaldo Batista Pinheiro[1]; Mauro Pinheiro Marra[1]; Karla Vilaça Martins[2]; Klaus Reichardt[3]; Adenir Antônio Martins Júnior[1]
Terrena Agronegócios Ltda[1]; University of Patos de Minas[2]; University of São Paulo[3]

Nitrogen (N) is the most used nutrient in agriculture, however, the main sources of nitrogen fertilizers present limitations due to N losses by volatilization, leaching or denitrification. One of the strategies to reduce the N losses of the nitrogen fertilizers applied to the soil is the use of urease and nitrification inhibitors. The objective of this research was to evaluate the ammonia volatilization of nitrogen fertilizers mixed with nitrification inhibitors. The study was carried out from December of 2017 to January of 2018, in a greenhouse located in the municipality of Patos de Minas, MG, Brazil. The experimental design consisted of a randomized complete block design with four treatments [T1 - Urea, T2 - Uan, T3 - Uan + DCD (dicyandiamide), T4 - Uan + DMPP (dimethylphenylpiperazinium), T5 - Uan + Nitrapirine and T6 - Uan + TA (ammonium thiosulfate)] all in 5 replicates. The experimental units consisted of plastic trays 50 cm long by 50 cm wide and 9 cm high. At the time of installation, a soil classified as Red Latosol of clay texture was sieved in each tray, sieved through 2 mm, and irrigated with 5 mm of water with the aid of a watering can. The ammonia collecting chamber was made from a transparent plastic bottle of polyethylene terephthalate (PET), with a capacity of 2 L. The ammonia losses were evaluated at 3, 7, 14 and 21 days after the application of the fertilizers (DAA). Ammonia losses were determined by titration with standardized solution of 0.005 mol L^{-1} H_2SO_4. Statistical analysis of the results was performed with the aid of the SAS® program. At 21 days after application of the fertilizers, the total

losses of N were, on average, in the T1 52% (a), T4 26% (b), T2 24% (b), T3 24% (b), T6 20% (b) and in T5 19% (b). The highest loss of N by volatilization was in the treatment with Urea application. And the smaller N losses were from treatments of uan only or mixed with nitrification inhibitors, so that we can conclude that the nitrification inhibitors do not affect ammonia volatilization when added to uan.
Keywords: Ammonia; Nitrogen; Volatilization.

(3848 - 752) Effect of urease inhibitor on a nitrogen fertilizer

Mauro Pinheiro Marra[1]; Ronaldo Batista Pinheiro[1]; Karla Vilaça Martins[2]; Klaus Reichardt[3]; Gustavo Borges Lima[1]
Terrena Agronegócios Ltda[1]; University of Patos de Minas[2]; University of São Paulo[3]

Nitrogen (N) is the most widely used nutrient in agriculture, however 20-50% of the N applied to the soil surface is lost by volatilization. Technologies have been developed to reduce losses of N by volatilization by inhibiting urease activity. The objective of this research was to evaluate the efficiency of urease inhibitors for a better use of nitrogen fertilizers. The study was carried out from October to November of 2017, in a greenhouse located in the municipality of Patos de Minas, MG, Brazil. The experimental design consisted of randomized complete blocks with 9 treatments including the inhibitors: NBPT [N- (n-butyl) thiophosphoricotriamide], AT (ammonium thiosulfate), HA (humic acid) and DCD (dicyandiamide), Treatments were: [T1 - Control, T2 - Urea, T3 - Ammonium nitrate, T4 - Uan, T5 - Uan + NBPT, T6 - Uan + TA, T7 - Uan + AH, T8 - Uan + NBPT + DCD and T9 - Uan + DCD], all with 5 replicates. The experimental units consisted of plastic trays 50 cm long by 50 cm wide and 9 cm high. At the time of installation, a soil classified as Red Latosol of clayey texture was sieved through 2 mm, placed into trays and irrigated with 5 mm of water with the aid of a watering can. The ammonia collecting chamber was made from a transparent plastic bottle of polyethylene terephthalate (PET), with a capacity of 2 L. Ammonia losses were evaluated 3, 7, 14, 21 and 28 days after fertilizer application (DAA). Ammonia was determined by titration with standardized solution of 0.005 mol L^{-1} H_2SO_4. The statistical analysis of the results was carried out with the aid of the SAS® program. At 28 DAA the total N losses were, on average, in T2 42% (a), T7 23% (b), T4, T6 and T9 20% (bc), T8 and T5 11% and, T3 6% (d). The greatest loss of N by volatilization was in the treatment with Urea application (T2). The lowest losses were observed in the treatment with Ammonium Nitrate (T3), followed by the treatment with the Uan fertilizer when the NBPT urease inhibitor was applied (T5 and T8). The DCD nitrification inhibitor did not affect ammonia volatilization when added to uan together with NPBT.

(1684 - 1514) Efficiency of nitrogen fertilization and association with rhizobia in Vigna unguiculata in Latosol of the cerrado of Tocantins

Weslany Silva Rocha[1]; Mauro Gomes dos Santos[1]; Valéria França Brito[1]; Gilberto Coutinho Machado Filho[1]; Manoel Mota dos Santos[1]
Universidade Federal do Tocantins[1]

High doses of nitrogen can increase production costs and damage to the environment, but through symbiosis with bacteria of the genus *Bradyrhizobium*, cowpea, can obtain N by the biological fixation process of N_2 (BNF), reducing costs with nitrogen fertilizers and also environmental contamination. However, nitrogen, deficient in most cerrado soils, affects nitrogenase activity and may interfere with BNF. The objective of this study was to evaluate the efficiency of nitrogen doses with and without the use of rhizobium inoculation in *Vigna unguiculata* in the Latosol of the cerrado of Tocantins. The experiment was conducted in a greenhouse on the campus of Gurupi belonging to the Federal University of Tocantins, with the variety BRS Novaera. For the inoculation a standard strain already recommended for the cowpea culture was used. The experimental design was completely randomized, in factorial (2x5) with two variables (with and without inoculation) and five nitrogen doses, totaling 10 treatments, with three replications. To determine the aerial part dry mass (MSPA); dry mass of roots (MSR); number of nodules (NN); dry mass of the nodules (MSN) and accumulation of nitrogen in the aerial part (ANPA). There was no efficiency of both the doses and the inoculation for the dry mass of the aerial part of the cowpea. Nitrogen doses that allowed maximum root dry mass production were 60 kg ha^{-1} of N without inoculation of rhizobium and 120 kg ha^{-1} of N with inoculation of rhizobium. The application of nitrogen with or without inoculation negatively influenced the number and mass of nodules of BRS Novaera cowpea. The accumulation of nitrogen in the aerial part was only influenced by the doses of nitrogen, presenting greater accumulation in the dose of 120 kg ha^{-1} of N.
Keywords: Cowpea; Symbiosis; Urea.

(6511 - 2480) Efficiency of nitrogen use due to the application of phosphorus and nitrogen doses inoculated with N_2-fixing bacteria in cowpea bean

Ester de Paiva Alves Barbosa[1]; Werlen Araújo Barbosa[1]; Marcelo Marinho Viana[1]; Assistone Costa de Jesus[1]; Danilo Nunes Sodré[1]; Erivaldo Plínio Borges da Costa Junior[1]; Karen Alessandra Sousa Castro[1]; Lincon Matheus Araujo Silva[1]; Márcia Masson Mendes[1]; Cristina Silva Carvalho[1]; Heder Braun[1]
Universidade Estadual do Maranhão[1]

In Brazil, nutrient deficiency in soils, especially nitrogen (N), has been considered a preponderant factor to obtain low yields by the beans. The cowpea has the capacity to symbiosis with bacteria of the genus *Bradyrhizobium*, to perform the biological fixation process of N_2 (BNF). Phosphate fertilizer (P) added to the soil, besides the immediate effect on the crop following fertilization, may have a residual effect on the subsequent crops. The objective of this study was to quantify the efficiency components of the use of N due to the form of application of phosphorus and nitrogen doses associated to the use of inoculated N2 fixing bacteria. The experiment was carried in the field, located in São Luis, MA, Brazil (2°30'S and 44°18'W). The treatments were a factorial arrangement (4x3) + 2 of four doses of N (0, 20, 60 and 120 kg ha^{-1}) and three ways of applying P (in the total area - TA, planting furrow - PF and split in the furrow - SF), plus two additional treatments (N_2-fixing bacteria and control without N, P, and bacteria) in total 56 plots. Treatments were replicated four times and randomized complete block design was used. The cultivar used was "BRS Guariba", with plots of four rows spaced 0.50 m and 0.25 m between plants. As sources of N and P, urea (45% N) and simple superphosphate (20% P_2O_5) were used. The content of dry matter in the grains, N harvest index, crude protein and yield were determined. The ANOVA for the qualitative factor (forms of P application) were compared by the Turkey's test ($p \leq 0.05$) and for regression analysis the quantitative factor (N doses) was applied. There was a significant interaction between the treatments on the average dry matter content in the grains ($p=0.05$) and productivity ($p=0.01$). There was no significant interaction between treatments for crude protein averages ($p>0.05$) and harvest index of N ($p>0.05$). There was a significant difference between the two treatments (bacteria and control) on all variables studied. The plots that received only the bacteria showed higher means in relation to the control treatment. The application of P_2O_5 (SF) presented higher averages for the crude protein, harvest

index of N for wet tropic conditions. Thus, our results suggest that the dose of 60 kg ha^{-1} of N when associated with the application of P (SF) and inoculated with *Bradyrhizobium* in the seeds provides an increase in yield and dry matter content in the grains for cowpea bean cultivation.

(8039 - 441) Influence of N source on nutrient uptake and cabbage growth.

Ivan Carlos Carreiro Almeida[1]; Talita Gabriela Gentil[2]; Leonardo Angelo De Aquino[2]
IFNMG - TEÓFILO OTONI[1]; UFV - RIO PARANAÍBA[2]

The cabbage has a high potential for nutrient extraction. High fertilization is required to allow the achievement of high yields and crop quality. Among the nutrients, nitrogen (N) is the second most accumulated and exported by the crop. The objective of this study was to evaluate the influence of sources and rates of N on the cabbage yield. The experiment was carried out at UFV - Rio Paranaíba, Brasil. Pots with a capacity of 250 dm^3 were used, filled with sifted soil, which is classified as Red-Yellow Latosol very clayey texture with the following chemical characteristics: pH (H_2O) = 5.7; Ca^{2+} = 5.8; Mg^{2+} = 1.2; Al^{3+} = 0, expressed in $cmol_c$ dm^{-3}, P = 13.4; Prem = 14.1; S = 14.7; K = 46.2 expressed as mg dm^{-3}, organic matter = 3.1 kg kg^{-1} and V = 63%. The treatments consisted of four sources: urea (U), ammonium nitrate (AN), ammonium sulfate (AS) and calcium nitrate (CN) and four doses (50, 100, 150 and 300 mg dm^{-3}) of N and a further control treatment, without application of N. Doses of 50 and 100 mg dm^{-3} of N were applied incorporated before transplanting the seedlings. The doses of 150 and 300 mg dm^{-3} were split-fertigated two and three times, respectively. The first on the day of transplanting the seedlings, the second at 15 days after transplant (DAT), and the last at 40 DAT. At 40 DAT, 50 mg dm^{-3} of K was applied to all treatments. The cultivar used was Astrus Plus, F1 hybrid, and cultivated four plants per pot. The seedlings were transplanted 35 days after sowing. In the transplantation, 5.4 g of P (SSP), 0.4 of Cu, 0.5 of B and 100 mg dm^{-3} of K was applied. The dry matter of cabbage-head and accumulations of N were determined in each part of the plant. The best doses were defined as those that allowed the reach of 95% of the maximum productivity estimated by the adjusted models. N sources did not influence productivity. The accumulation of dry matter in the whole plant (head, outer leaves, stem and root) with an application of the N dose to obtain 95% of the maximum estimated cabbage-head production was 242.1; 255.1; 240.0 and 257.2 g/plant with a N uptake of 4.72; 4.40; 4.10 and 4.23 g/cabbage-head, and in the whole plant was 7.40; 7.80; 6.90 and 7.21 g/plant in the sources U, AS, AN and CN, respectively. The uptake and partition of N were similar between N sources. Urea is generally the lowest cost source and in its use measures to avoid N volatilization should be employed, making it the best option for nitrogen fertilization in cabbage.

[1]Programa de Pós-Graduação em Agronomia/UFG – e-mail: amanda.mabu@gmail.com. alineandrade418@gmail.com. fredlimaufg@yahoo.com.br; [2]Departamento de solos/UFG – e-mail: rilner1@hotmail.com. Universidade Federal de Goiás; [3]Departamento de Microbiologia do Solo, Embrapa Arroz e Feijão – e-mail: enderson.ferreira@embrapa.com.br.

Common bean (*Phaseolus vulgaris* L.) is able to benefit from the biological nitrogen fixation when associated with rhizobacteria. The addition of nitrogen fertilizers in bean cultivation may help increase grain yield. Despite the beneficial effect of nitrogen fertilization, the addition of fertilizer may disrupt the association and nodules formation by diazotrophic bacteria. The objective of this work was to evaluate the effect of nitrogen fertilization on the number and weight of nodules formed by symbiotic association of rhizobacteria in common bean. The study was performed in the EA / UFG with the BRS Pérola cultivar using a randomized block design, 2x2 factorial scheme, with four replications. The first factor was the presence or absence of seed inoculation. The second factor used was nitrogen fertilization (120 kg of N ha^{-1}), 80 kg ha^{-1} at 20 days after germination (DAG) and 40 kg ha^{-1} at 40 DAG or 60 and 60 kg ha^{-1} of N at 20 and 40 DAG. The inoculation was carried out using peaty inoculant, containing the strains SEMIA 4077 and SEMIA 4080 of *Rhizobium tropici* and the strain SEMIA 4088 of R. *freirei*, using 10% sugar solution as an adhesive agent. The sowing occurred in the winter cropping season, under no-tillage system, under a central pivot irrigation system. The number of nodules per plant was obtained by extracting 3 plants with their conserved roots. Nodules were removed from the roots, counted and, subsequently dried (65 ºC; 72 h) to determine the nodules dry weight (NDW). Plants not inoculated with the highest N supply in the first days showed an average of 36.64 nodules per plant and the ones with less supply had 20.39 nodules. Beans inoculated with 60 kg of N ha^{-1} at 20 DAG obtained an average of 30.84 nodules and those with 80 and 40 kg of N ha^{-1} in the 20 DAG presented an average of 42.94 nodules per plant. Also, plants fertilized with 80 kg ha^{-1} of N at 20 DAG showed higher NDW, for which inoculated plants presented NDW of 24 g and for the non-inoculated plants the NDW was 0.9 g. No significant differences were found for the weight of nodules of the bean fertilized with the 60 and 60 kg N ha^{-1} plots at 20 and 40 DAG.

(1897 - 1683) Maize crop inoculed with *Azospirillum brasilense* and nitrogen top-dressing increase grain yield and nitrogen use efficiency

Marcelo Marinho Viana[1]; Lincon Matheus Araujo Silva[1]; Karen Alessandra Sousa Castro[1]; Ester de Paiva Alves[1]; Danilo Nunes Sodre[1]; Assistone Costa de Jesus[1]; Werlen Araújo Barbosa[1]; Erivaldo Plinio da Costa Borges[1]; Cristina Silva Carvalho[1]; Heder Braun[1]
State University of Maranhão[1]

Nitrogen (N) management is essential to maximize nitrogen use efficiency (NUE) and sustain agricultural production as well as reduce environmental impacts. We hypothesized that the combination of N and inoculants containing plant growth promoting bacteria (*Azospirilum brasilense*) can increase grain yield and NUE for the maize crop. The present study aimed evaluate the relationship between inoculation way of application of *A. brasilense* and N fertilization rates on grain yield and NUE on maize crop. The experiment carried out in the field at 2016 (2°35' S and 44°12' W), in a randomized complete block design, with four replications. The treatments were performed in factorial arrangement 4 x 3: four N fertilization rates (0, 45, 90 and 180 kg ha^{-1}), applied as top-dressing with three inoculation way

(seeds, leaf and control). Urea (45% of N) was N source. Nitro 1000 Gramíneas® was the inoculant used in the treatments. It was performed with 100 mL ha^{-1} of the commercial product in seed-inoculant before planting and 200 mL ha^{-1} in leaf-inoculant spraying application. The N fertilization rates and *A. brasilense* leaf-inoculant spray were applied at the corn growth stage V4. The variable evaluated were: grain yield (GY, Mg ha^{-1}), N utilization efficiency (NUtE, kg kg^{-1}), N uptake efficiency (NUpE, kg kg^{-1}) and nitrogen use efficiency (NUE, kg kg^{-1}). The ANOVA was performed adopting p≤0,25 for the interaction and p≤0,05 for the Tukey test. The R software was used with the RStudio interface to perform the analyzes. There was no significant interaction between the doses of N x forms of inoculation of *A. brasilense* (p=0,5444) for grain yield (GY). The interaction between the doses of N x forms of inoculation with A. brasilense significantly influenced NUE (p=0,0003), but did not significantly influence NUtE (p=0,7955) and NUpE (p=0,6396). With these results, we can conclude that there was increase of 20% in GY and 42% in NUE in seed-inoculant treatment when compared with control. N fertilization rates affect positively the GY and reduce NUE and its components. In view of the results, there should not be a total substitution of nitrogen fertilization by inoculation with *A. brasilense,* but it is necessary to perfect the N partition, which can result in increased productivity, even at low levels of N. Responses depend on the concentrations of bacteria, soil, climate of each ecosystem and inoculation technology.

(7582 - 1963) Mulching of leguminous trees to improve nitrogen use efficiency in tropical cohesive soil

Virley Gardeny Lima Sena[1]; Vinicius Ribamar Alencar Macedo[2]; Stéfanny Barros Portela[2]; Ivana de Sousa Diniz[2]; Juliano Carlos Calonego[1]

UNESP[1]; UEMA[2]

The reduced efficiency of nitrogen use (EUN) is one of the problems that weaken the productivity and profitability of crops under the conditions of family agriculture. Mainly, in soils that present very low levels of organic matter, as occurs in the humid tropic region. Under these circumstances, reduced availability and low efficiency of applied nitrogen can make agricultural crops unviable and decrease farmers interest in making continuous use of the same area every year. This process ends up forcing farmers to constantly change the area of planting, a disadvantage for agriculture and the environment that ends up losing natural reserve area. In order to increase the efficiency of nitrogen use, the legume *Gliricidia sepium* (4% N) was used as a cover crop in cohesive soils with low natural fertility. This study started in January 2016, after a randomized block design with four replicates of the following treatments: T1: gliricidia + nitrogen, T2: gliricidia + potassium, T3: gliricidia, T4: gliricidia + potassium + nitrogen, T5: soil exposed + nitrogen T6: uncovered soil + potassium, T7: uncovered soil, T8: uncovered soil + potassium + nitrogen. The corn cultivar AG 7088 (*Zea mays* L.) was sown between the legume lines, spaced 80 cm apart. In 2016, the area received P fertilization of 120 kg ha^{-1} P in the form of triple superphosphate, 60 kg ha^{-1} K as KCl, 60 kg ha^{-1} N as urea and 200 kg N organic / ha in the form of *Gliricidia Sepium* gliricidia for certain treatments to be received. It could be observed in two years of cultivation of maize that this legume gave rise to considered increases in the efficiency of N use compared to treatment that received only chemical fertilization (T4> EUN T8). In addition, when it was associated with chemical nitrogen fertilization (T1), it was more advantageous when confronted with an area that received only mineral fertilization (T5). These results evidenced the possibility of using gliricidia to increase the EUN in cohesive soils. In addition to contributing to a decrease in the pressure for natural resources, once higher productivity is achieved even with the continuous use of the area.

(2850 - 1315) Nitrogen (^{15}N) use efficiency in maize as affected by urea treated with boric acid and copper sulfate

Nicole Colombari Cheng[1]; Bruno Paulo Moschini[1]; Pedro Lopes Garcia[2]; Beatriz Nastaro Boschiero[3]; Eduardo Mariano[4]; Paulo Cesar Ocheuze Trivelin[2]

ESALQ/USP[1]; CENA/USP[2]; CNPEM[3]; UNESP/Botucatu[4]

Urea (U) is the most used nitrogen fertilizer in maize (*Zea mays* L.). It is highly prone to ammonia (NH_3) volatilization losses when applied on soil surface. The use of urease inhibitors is one of the most promising and least expensive technologies on the market among the strategies that aim to circumvent the environmental impact and increase the nitrogen use efficiency (NUE). In this context, the objective of this study was to evaluate the NUE in maize at VT growth stage applying ^{15}N-urea treated with boric acid (H_3BO_3) and copper sulfate ($CuSO_4$) under controlled conditions. The study was conducted in greenhouse conditions in a randomized block design with three replications. The treatments consisted of a single rate of 180 mg N kg^{-1} soil applied in a band on soil surface with the following nitrogen fertilizers (N-fertilizers): (a) Conventional urea (U); (b) Urea treated with 0.40% boric acid (U+0.40% B); (c) Urea treated with 0.52% boric acid (U+0.52% B); (d) Urea treated with 0.64% boric acid (U+0.64% B); (e) Urea treated with 0.88% boric acid (U+0.88% B); (f) Urea treated with 0.40% boric acid and 0.15% copper sulfate (U + CuB); (g) Urea treated with thiophosphoric N-(n-butyl) triamide (U + NBPT). N-fertilizers were ^{15}N enriched (0.85 atom % of ^{15}N excess) and applied at V4 growth stage in granular form. Total N and isotopic abundance (^{15}N) analysis was performed in a mass spectrometer coupled with an automatic N analyzer. ^{15}N in the plant derived from fertilizer (NPDF), ^{15}N fertilizer use efficiency (NUE-F) and ^{15}N balance in the soil-plant system were calculated and then submitted to mean comparisons adopting the LSD test ($p \leq 0.05$). As the concentration of H_3BO_3 in the urea treatment increased, the NUE-F increased (10% on average). U+NBPT had higher NUE-F than untreated U (almost 20%) and did not differ from U+0.88% B. There were low ^{15}N recovered in the soil that suggests the occurrence of high N losses from the system. The treatments with urease inhibitors (H_3BO_3 and NBPT) increased the recovery of ^{15}N-urea in the soil-plant system from 7 to 10%. U+0.40% B did not differ from U+CuB for NUE-F and ^{15}N balance, it shows that there isn't effect for the addition of $CuSO_4$ in the coating of U granules. Therefore, the $CuSO_4$ is a component that can be reduced or dispensed from the U coating when in association with H_3BO_3 once it didn't influence the NUE-F.

Universidade Federal de Mato Grosso[1]

Wheat (Triticum aestivum L.) is one of the most cultivated crops around the world, standing out as the base of many food products for its nutritional value. Thus, the objective was to evaluate the productive characteristics of wheat irrigated in the Cerrado of Mato Grosso, fertilized with nitrogen and potassium. The experiment was carried out in the experimental area of the Federal University of Mato Grosso, in the municipality of Rondonópolis-MT, Brazil, located an altitude of 284 meters. The soil was classified as Oxisol. The experimental design was a randomized complete block design, with factorial scheme 5², fractionated with four replicates. Nitrogen doses were: 0, 70, 140, 210 and 280 kg ha^{-1} and potassium 0, 50, 100, 150 and 200 kg ha^{-1}. Nitrogen fertilization was applied in two periods, the first one in the seeding using 30% of the doses of each treatment and the remaining 70% at the beginning of the tillering, which occurred 15 days after the emergence of the plants using urea as source. The fertilization with potassium was applied at the time of seeding and the source used was potassium chloride. The irrigation of the experiment was performed by a system of irrigation bars coupled to a self-propelled roll system. The variables analyzed were number of spike per m² and dry mass of spikes. The analyzed variables did not present interaction between the nutrients, only isolated effect for the nitrogen. The number of spikes set to the quadratic regression model with the highest value of 408 spikes per m² in the nitrogen dose of 243.53 kg ha^{-1}. The dry mass of the spikes set to the linear regression model, with an increase of 34.92% when compared to the higher dose with the absence of fertilization. Nitrogen fertilization increases the number and dry mass of wheat spikes. Potassium does not influence the number and mass of wheat spikes.

(4489 - 949) Nitrogen and potassium in the production of braquiaria grass and organic matter of soil in the western Amazon

Edinelia Roos[1]; Andressa Gregolin Moreira[1]; Bianca Souza Selhorst[1]; Adriele Laurindo Sobreira[2]; Vanessa Rodrigues de Brito[2]; Fábio Régis de Souza[1]; Jairo André Schlindwein[1]; Elaine Cosma Fiorelli-Pereira[1]
Federal University of Rondonia, Av. Norte Sul, 7300, Nova Morada, Rolim de Moura - RO, CEP 76940-000, Brasil[1]; Federal University of Rondonia, Av. Pres. Dutra, 2965 - Centro, Porto Velho - RO, CEP 76801-974, Brasil[2]

The low fertility of the soil in the Amazon region associated with the poor pasture formation, with low adoption of technical management, in addition to the higher rates of capacity and a continuous grazing system, have contribute for the fast and rising degradation process, compromising the productive process. Reconstruction the fertility of the soil it is one of the ways to recuperate the productive capacity of the degraded pasture. The experimental design was in randomized blocks, in a factorial scheme 5x5, corresponding of five doses of nitrogen 0, 50, 100, 200 e 400 kg ha^{-1} de N) and five doses of potassium (0, 100, 200, 400 e 800 kg ha^{-1} de K2O) with four repetitions totaling 200 parcels, in a established pasture more than 10 years, in process of degradation, at a property in the municipally of Rolim de Moura, Rondonia, Brasil. Was evaluated the production of fodder dry mass, index of green color in leaves (SPAD) and organic matter of the soil. The nitrogen fertilization changed the production of dry mass on a quadratic form, being the major production observed in 41 kg ha^{-1} of N doses with 5212,9 kg ha^{-1} of dry mass. There was only influence in nitrogen doses in index of green color in leaves of brachiaria, where the major dose (400 kg ha^{-1} of N) provide the greater concentrations (47,57), so that, the index of green color is straightly related with the fertilization that the plant receive. The nitrogen influenced on the organic matter of the soil in a linearly way, being that at the dose of 0 kg ha -1 of N, had the major production of organic matter of the soil, with 33,18 mg kg^{-1}, fertilization with potassium do not have any effect in the variables studied.

(2613 - 459) Nitrogen and sulphur fertilization in the tillering of BRS 394 wheat cultivar irrigated in Brazilian Cerrado

Thiago Henrique Ferreira Matos Castañon[1]; Edna Maria Bonfim-Silva[2]; Tonny José Araújo da Silva[2]; William Fenner[3]
Federal University of Mato Grosso, Cuiabá – Mato Grosso, Zip-code 78070-900, Brazil (thiagocastanon@live.com)[1]; Federal University of Mato Grosso, Rondonópolis – Mato Grosso, Zip-code 78735-001, Brazil[2]; Federal University of Mato Grosso, Cuiabá – Mato Grosso, Zip-code 78070-900, Brazil[3]

Wheat has the characteristic of forming tillers and this structure is much important to occupy empty spaces between plants, improving soil cover and increasing the number of spikes, thus increasing grain yield. Many factors may influence wheat tillering, such as genotype, luminosity, soil moisture, temperature and nutritional status. Thus, the aim of this study was to evaluate the tillering of wheat submitted to combinations of nitrogen and sulphur in the Brazilian Cerrado. The research was carried out in the field in 2017, in the experimental area of the Federal University of Mato Grosso, Campus of Rondonópolis-MT, Brazil. The soil was classified as Oxisol. The geographical coordinates are 16º27'54.98"south latitude and 54º34'41.75" longitude west, altitude of 284 m. The experimental design was randomized block in factorial scheme 5², fractionated with four replicates. The treatments were five nitrogen doses (0, 70, 140, 210 and 280 kg ha^{-1}) combined with five doses of sulphur (0, 25, 50, 75 and 100 kg ha^{-1}). It was sown to wheat cultivar BRS 394, classified as an early cycle and indicated for irrigated systems. The irrigation was by sprinkling, with an adapted irrigation bar. The number of tillers + main stem was evaluated at 15, 30 and 45 days after emergence of the plants. It was quantified in 1m linear, divided into three samples of 0.33m in the useful area of each experimental unit, counting together tillers and main stems. The significant variables were number of tillers at 30 and 45 days after emergence (DAE) for nitrogen only. At 30 days the number of tillers was adjusted to the linear regression model, with a 19.47% increase when compared to the higher nitrogen dose with the absence of fertilization with this nutrient. However, at 45 days the number of tillers was adjusted to the quadratic regression model, with the highest number (104 tiller m^{-1}) at the nitrogen dose of 199 kg ha^{-1}. Nitrogen fertilization increases the number of tillers in wheat plants. Sulphur does not influence tiller formation of wheat plants when cultivated in Cerrado Oxisol.

(2816 - 1362) Nitrogen concentration in signal grass fertilized with nitrogen doses and sources

Guilherme Constantino Meirelles[1]; Reges Heinrichs[1]; Maikon Vinicius da Silva Lira[1]; Igor Virgílio Ribeiro[1]; Thiago Bergamini Ibañez[1]
São Paulo State University, FCAT/UNESP[1]

The amount and quality of forage produced is directly related to the nitrogen amount that is associated with the production system. For

sustainable agricultural production, techniques that minimize losses and support the use of nutrients during the crop cycle are necessary. The experiment was conducted in the experimental field of the College of Agricultural and Technological Sciences, Campus Dracena, SP, Brazil. The objective of this study was to evaluate the conventional nitrogen fertilizer and the nitrogen sources with increased efficiency in the nitrogen concentration in aerial part of the signal grass pasture (*Urochloa decumbens*; syn. *Brachiaria decumbens*). The soil of the area was classified as Ultisol. The experimental design was in ranged blocks with four replicates, in a factorial scheme 4x2+1. The plots were composed of 4 nitrogen sources (urea, ammonium nitrate, urea with NBPT inhibitor and urea coated with B and Cu), with two doses of nitrogen (100 and 200 kg ha^{-1}), plus a treatment without nitrogen fertilization (control). The nitrogen doses were divided in 5 equal applications (20 e 40 kg ha^{-1}), the first one after the cut of uniformization and the others after the immediately subsequent cuts. The N concentration in the aerial part of the forage varied as a function of the doses in the summer (water period) and winter (dry period), but did not present a difference between the nitrogen sources. The response in the nitrogen concentration in the forage in the winter season cut evidences the residual effect of the nitrogen fertilization performed during the period of the waters, providing the production of animal feed of better quality. The amplitude of response in nitrogen utilization due to the use of sources with increased efficiency can vary greatly with climatic conditions during the study. According to the interpretation ranges for plant nutrition, the levels of nitrogen in signal grass produced during the water period, in the treatments without nitrogen fertilization and in the dose of 100 kg ha^{-1} of nitrogen are slightly below the critical level, while at the dose of 200 kg ha^{-1} of N, the contents are within the range considered adequate.

(4469 - 1344) Nitrogen fertilization and crop management in the agricultural production system in sandy soil

Ana Carolina Mônico Moreira[1]; Carlos Henrique dos Santos[1]; Luciana Boulhosa Fabris[1]; Juliano Carlos Calonego[2]; Pedro Francisco da Silveira Reis[1]

Universidade do Oeste Paulista[1]; Universidade Estadual Paulista Júlio de Mesquita Filho[2]

Nitrogen is an essential element for the growth of plants, being constituent of molecules important for its development as proteins, nucleic acids, hormones and chlorophyll. The no-tillage system has as main objective the production of straw on the soil surface, and in this same system the use of legumes helps in this production besides performing the green fertilization providing N to the system. The aim of this research was to evaluate the N content made available by the soybean crop in a no tillage system. The experiment was carried out at the College of Agricultural Sciences, at University of Western São Paulo, in Presidente Prudente, São Paulo State, in soil classified as Ultisol. Soil samples were collected in the representative layers of the depths of 0-5, 5-10, 10-20, 20-40 and 40-60 cm for characterization of the granulometry and chemical parameters of the soil and, later, the experiment was installed following the randomized block design, with four replications, in a subdivided plot scheme. The plots were constituted by three crop rotations in no-tillage system: 1) Maize (Ma) / Lupine (Lu) / Fallow field (Fa) / Soybean (So); 2) Maize (Ma) + *Urochloa brizantha* cv. MG-5 (Uro) / *Urochloa brizantha* cv. MG-5 (Uro) / Soybean (So); 3) *Urochloa brizantha* cv. MG-5 (Uro) / Soybean (So) and the subplots were formed by four rates of N applied annually (50, 100, 150 and 200 kg ha^{-1}). The determination of the total N contents present in the straw collected from the soil surface was performed 30 days before the soybean harvest and the day after the harvest (residual straw). The results were submitted to analysis of variance and the effects compared by the Tukey test at the 5% probability level. There was a significant difference in the total N contents of the straw before soybean harvest as a function of the rotations and N rates applied, while in the residual straw after harvest there was no significant difference. The available N in this biomass returns to the soil after its decomposition, being able to be used by the successor culture. Crop management with the presence of both lupine legumes and soybean provided higher N contents, and after soybean cultivation these were even higher. In a no-tillage system, and especially in sandy soils, rotation of legume crops brings benefits to successor crops as well as improvement in soil biological quality.

(9004 - 2773) Nitrogen Fertilization at Different Stages in Soybean Culture

Felipe de Abreu Soldatelli[1]; Elaine Damiani Conte[2]; Taísa Dal Magro[1]; Joséli Schwambach[1]

University of Caxias do Sul, Vacaria, RS 95200-000, Brazil.[1]; University of Caxias do Sul, Vacaria, RS 95200-000, Brazil. E-mail: edconte@ucs.br[2]

Nitrogen fertilization in soybean crop (sowing and cover) is a subject that has been gaining importance among professionals and producers in Brazil in the search for increased productivity, being adopted as field practice by many of them. However, there is still no consensus regarding the efficiency of this practice, especially in soils with high levels of organic matter. This study sought to evaluate the efficiency of the use of top-dressing fertilization with nitrogen (N) at different stages of development of the soybean crop. The experiment was carried out in a no-tillage system during the 2016/17 crop with soybean cultivar BRASMAX Raio IPRO®, at Campus II of the University of Caxias do Sul, Vacaria, RS, Brazil (28º 30'S and 50º 56 'W). The soil at the experiment site is classified as typical Distroferric Bruno Latosol and presents 7.0% organic matter and 65% clay, with corrected acidity and fertility. A randomized blocks design with five treatments and five replicates was used. The treatments consisted of N application in different moments, being: a control (without external source of N) (T1); at sowing (T2); at complete development of the third tripartite leaf (T3); at flowering (T4); and, at grain filling (T5). The dose used was 120 kg / ha, with urea (45% N) as the source. The variables evaluated were: plant height; chlorophyll content in leaves; final plant stand / m²; number of vegetables and grains / vegetables; grain yield, expressed in kg / ha at 13% moisture; and, mass of 1000 grains, expressed in grams. The results of the evaluations were submitted to analysis of variance ($p \leq 0.05$); and, in case of significance, compared by Tukey test ($p \leq 0.05$). The results obtained showed only difference for the chlorophyll content, indicating a higher N uptake according to the period of application. However, this difference in chlorophyll content did not affect the other parameters evaluated, with an average yield of 4,123 kg / ha (Coefficient of Variation = 6.18%). Therefore, considering the edaphoclimatic conditions and the genetic potential of the cultivar evaluated, the application of N does not alter the productivity of the soybean crop.

(5560 - 1680) Nitrogen fertilization in *Brachiaria brizantha* cv. BRS Piatã in the end of the rainy season in the state of Rondônia

Cauandrey Deyverson Fagundes[1]; Fábio Régis de Souza[1]; Simone Assumpção De Almeida[1]; Iracy Soares de Aguia[1]; Anderson Cristian Bergamin[1]; Wesley Santana Ferreira[1]; Rodrigo Maciel Nunes[1]; Júnior

Antônio Rodrigues Mello[1]; Deisiane Lima Almeida[1]; Luciana Sônia da Silva[1]

Fundação Universidade Federal de Rondônia[1]

Currently almost 70% of formed pastures in Rondônia present in degradation state. The degradations process appears when the productivity of forage comes down in gradually, because of many factors. Like low natural fertility of the soil, inappropriate management of the pastures and no maintenance of fertility. The degradation reduces the index of organic matter and consequently the availability of nitrogen for the forages, being pointed such as low forage offer, this condition can be increased with nitrogen fertilizer with ammonium sulphate or urea. The objective was evaluate the agronomic characteristics of Piatã grass (*Brachiariabrizantha*cv. BRS Piatã) submitted to doses of nitrogen font in the end of the rainy season. The experiment was conducted in the experimental campus of Federal University of Rondônia Foundation, in the municipally of Rolim de Moura- Rondônia located at 11° 34' 57" south latitude and 61° 46' 21" of longitude. The design adopted was randomized blocks, in a factorial scheme, being the treatments nitrogen fonts (urea and ammonium sulphate) and the doses (0, 25, 50, 100, 150, kg of N ha^{-1}).Thework was conducted between April to December of 2016.The planting of Piatã grass was realized on April 5, 2016. The variables analyzed in the five cuts were: height of the plant; number of leafs, number of tiller, stem diameter, chlorophyll index, green matter and dry mass. Was obtained significates results for plant height in the third and fourth cut with the 80kg ha^{-1} (1,29 m) dose and 75 kg ha^{-1} (1,25 m) respectively. For the numbers of leaf was observed significance in relation to doses of nitrogen, presenting a linear behavior in the third and fourth cut. From the third cut has a linear increase of the tiller with the nitrogen increase. The chlorophyll index present larger values in the 75 kg ha^{-1} – dose in the third cut. Diameter and stem in the first cut and the green matter of the stem and leafs in the fourth cut, were observed higher results when the fertilizer font was urea.

(1522 - 2962) Nitrogen fertilization with urease inhibitor and nitrification in capim-tifton 85

Edimar Rodrigues Soares[1]; Esmeralda Ochoa Martínez[2]; Márcio Silveira Da Silva[3]; Fabio Tiraboschi Leal[3]; Edson Luiz Mendes Coutinho[3]

Faculdade de Educação e Meio Ambiente - FAEMA[1]; Instituto Nacional de Investigaciones Forestales, Agrícolas e Pecuarias - INIFAP[2]; Universidade Estadual Paulista - Faculdades de Ciências Agrárias e Veterinárias - UNESP/FCAV[3]

Nitrogen is a highly dynamic and mobile nutrient that may undergo losses through different processes, such as volatilization, leaching and denitrification. Urease or nitrification inhibitors are technologies that may improve nitrogen fertilization efficiency; however, usage of these products is little studied in tropical regions. The present essay evaluates growth and production of tifton 85 grass on field conditions according to nitrogen doses with urea containing urease and nitrification inhibitor for two agricultural years (2013/14 and 2014/15), from November through March, each year with four cycles of growth. Treatments in experiment were build up on a 3 x 5 factorial scheme with urea; urea + urease inhibitor [NBPT: N-(N-Butyl) thiophosphoric triamide] and urea + nitrification inhibitor (DMPP: 3,4-dimethyl pyrazole phosphate) and doses of N (0, 40, 80, 120 and 160 kg ha^{-1}, in each growth). N doses increased leaf area, leaf area indexes and height, but there was no effect due to the type of fertilizer in this scenario. On the tenth day of the first growth, it was verified that nitrogen fertilization increased tillers linearly. On the 20th day, there was tiller death due to greater doses of N applied, with linear reduction of tiller on the 30th day. The usage of urea + NBPT and urea + DMPP did not influence the production of tifton 85 grass in the two agricultural years. On the first year, an actual effect from doses of N was not observed, neither from the type of fertilizer on the apparent N recovering. The usage of urea with urease or nitrification inhibitor does not interfere in the production and growth of tifton 85 grass.

(7457 - 2265) Nitrogen fertilization in wheat

Gleize Leviski de Brito[1]; Dirceu Maximino Fernandes[1]; Aline Cássia da Fonseca[1]

Universidade Estadual Paulista "Júlio de Mesquita Filho"[1]

The nitrogen is one of the nutrients most required by the wheat crop, and the moment of application of this nutrient can directly influence its utilization by the plants The objective of this study was to evaluate the influence of the application of different nitrogen sources on sowing and tillering of wheat in medium texture soil. The experiment was conducted in Botucatu-SP, in a randomized blocks design with 4 replications, in a 3 x 2 factorial. The treatments consisted of 3 nitrogen sources (ammonium nitrate, ammonium sulfate and urea) applied at two times, the total dose incorporated in the soil in the week prior to sowing and 25% at sowing and the remainder in the tillering phase of wheat. The N dose was 80 Mg ha^{-1} and the spacing was 0.2 m. There wasn't interaction between the sources and the N application times. The N sources differed only when the number of tillers was evaluated, with the ammonium nitrate being responsible for the largest number of tillers, as for the yield components, all sources under study were similar. Although the application in cover provided a greater number of tillers in relation to the nitrogen applied at the time of sowing, the weight of 1000 grains, the number of spikes per spikelet and the number of grains per spike was higher when applied the total N at sowing.

Keywords: Tillering, nitrogen, Triticum aestivum

(7415 - 711) Nitrogen on dry biomass production and calorific power of elephant grass grown in Cerrado biome

Rilner Alves Flores[1]; Silas Ferreira de Queirós[1]; Virgínia Damin[1]; Mellissa Ananias Soler da Silva[2]; Gustavo Castoldi[3]; Carlos Ribeiro Rodrigues[3]

UFG[1]; Embrapa[2]; IF Goiano[3]

The Brazilian energy matrix has sought new alternatives for the gradual replacement of oil and its derivatives. In the last decade, studies with alternative sources of energy from biomass have gained prominence, since these represent 31.1% of the energy matrix in force in the country. In this scenario, elephant grass (*Pennisetum purpureum*) presents great potential for biomass production per unit of time, due to a short growth cycle (between 5 and 7 months), with rapid leaf expansion, high percentage of fibers, lignin, in addition to high calorific value. The objective of this work was to evaluate the effect of nitrogen fertilization on leaf contents and dry biomass production of elephant grass grown under the edaphoclimatic conditions of the Cerrado biome. The study was carried out in the 2016/17 harvest, in a clayey dystrophic Red Latosol, with the genotype 'Roxo'. The experimental design was in randomized blocks with five doses of nitrogen fertilizer (0, 50, 100, 150 and 200 kg ha^{-1}, applied in the planting furrow as urea). Forage cutting was performed 180 days after regrowth of the first ratoon. Leaf nitrogen levels, relative

chlorophyll index, biomass production and the upper calorific value of elephant grass biomass were evaluated. The results were submitted to analysis of variance by F-test, and when significant, polynomial regression analysis was performed to determine the maximum points of the variables evaluated. Nitrogen application did not affect leaf nitrogen content, which presented a mean value of 19.95 g kg^{-1}. Regarding stem production, there was a quadratic adjustment by F-test at 10% probability, with the maximum yield of 47.4 t ha^{-1} obtained with the use of 105 kg ha^{-1} N. The upper calorific value of elephant grass biomass was not altered due to nitrogen fertilization, presenting a mean value of 3952 kcal kg^{-1}. The results observed in this study are promising, since the crop is very responsive to nitrogen fertilization, with significant gains in biomass production. The results obtained for the calorific value of elephant grass biomass are very close to those observed in eucalyptus (~ 4500 kcal kg^{-1}), one of the main crops used for direct burning. Thus, nitrogen fertilization of elephant grass for the production of briquettes should aim at the maximum gain in biomass production when grown under the same conditions of the present study.

(4238 - 1296) Nitrogen use efficiency in maize-forage rotations

Letusa Momesso[1]; Carlos Antonio Costa do Nascimento[1]; Katiuça Sueko Tanaka[1]; Isabela Garcia Cocatto[1]; Ciro Antonio Rosolem[1]; Carlos Alexandre Costa Crusciol[1]

São Paulo State University (UNESP)[1]

Forage grasses of *Urochloa* genus are adapted to low fertility soils due to its vigorous and deep root system and its ability in taking up poorly available nutrients. *Urochloa* species introduced in a cropping system as cover crops can maintain or increase maize yields, but it depends on nitrogen (N) supply and management. Thus, an alternative for N fertilization in this cropping system would be to apply N to the cover crop, before desiccation, which can avoid N loss by leaching or NH_3 volatilization, improving N use efficiency. The objective of this study was to assess the feasibility of N application to forage grasses to supply N to maize. Palisade grass (*Urochloa brizantha*) and ruzigrass (*Urochloa ruziziensis*) were grown in the maize of-season, and 160 kg ha^{-1} of N was applied 5 days before grass desiccation and at maize planting + sidedressing), plus one control for each forage grass (no N added). Both dry matter and N accumulation by forage grasses were about 63% higher in palisade grass than in ruzigras. Nitrogen applied before desiccation increased forage dry matter and N accumulation by 17 and 30% , respectively. There was no difference between forage grasses on soil mineral N content. At desiccation, the soil mineral N was higher where fertilizer was applied to forage grasses. Palisade grass straw had released 222 kg ha^{-1} of N whilst 167 kg ha^{-1} of N were washed out from ruzigrass 90 days after disiccation, however, all treatments resulted in similar amounts of soil mineral N at this time. Nitrogen application at planting + sidedressing increased N in maize leaves and grain yield, and eventualy resulted in higher NUE than when N was applied to the forages. Maize yield was higher after palisade gras than ruzigrass, reaching 70% in the absence of N fertilization. Our results suggest that while both palisade grass and ruzigrass produce high biomass and N release N, applying all N to forage grasses is not a feasible alternative, probably because there is no synchrony between N release and maize demand. Thus, applying N at seeding + sidedressing is still the best alternative for N management in maize, irrespective of the cropping system.

(9139 - 1407) Number of wheat leaves cultivar brs 394 irrigated and fertilized with nitrogen and sulfur combinations in Cerrado mato grossense

Kellyane Pereira dos Santos[1]; Edna Maria Bonfim-Silva[1]; Thiago Henrique Ferreira Matos Castañon[1]; Tonny José Araujo da Silva[1]

UFMT[1]

The leaves are plant structures that, with their tissues, assist mainly in photosynthesis, respiration and transpiration processes, functioning as a reserve structure, characteristics that are linked to the vegetative development promoted by nitrogen, and consequently improves crop productivity. The objective was to evaluate the number of leaves of wheat plants submitted to different combinations of nitrogen and sulfur. The experiment was carried out in the experimental area of the Federal University of Mato Grosso, in the municipality of Rondonópolis - MT, Brazil, in a Oxisol. The experimental design was a randomized complete block design with factorial scheme 5^2, fractionated with four replications. The nitrogen doses were: 0, 70, 140, 210 and 280 kg ha^{-1} and sulfur 0, 25, 50, 75 and 100 kg ha^{-1}. The wheat cultivar used was the BRS 394. The nitrogen source used was urea (45% N). The sulfur fertilization was carried out in the sowing line in single application with elemental sulfur powder (97% S). The irrigation of the experiment was carried out by means of a sprinkler irrigation system. The number of leaves at 15, 30 and 45 days after plant emergence were evaluated. It was considered in the linear 1 m evaluation divided into three samples of 0.33 m. The number of leaves was significant at 30 and 45 DAE, presenting an isolated effect only for nitrogen. At 30 days after plant emergence, the number of leaves was adjusted to the quadratic regression model, with the highest number (387.05 leaves m^{-1}) at the nitrogen dose of 198.67 kg ha^{-1}. At 45 days after plant emergence, the number of leaves was adjusted to the linear regression model, with an increase of 18.36% between the highest nitrogen dose and the absence of fertilization. Nitrogen fertilization increases the number of leaves of wheat plants. Sulfur fertilization does not influence the number of wheat leaves.

(8317 - 1637) Paiaguas grass yield in two crop-livestock integration system under nitrogen topdressing rates applied

Alessandro José Marques Santos[1]; Stephanie Vicente de Bessa[1]; Lucas Matheus Rodrigues[1]; Arthur Gabriel Teodoro[1]; Clarice Backes[1]; Danilo Augusto Tomazello[1]

State University of Goiás[1]

Integrated crops provide economic and environmental improvements in addition to increasing production efficiency. In the crop-livestock integration system after silage production the grass remains in the area it is that making possible to supply feed to grazing animals during the offseason in addition to serving as roughage material in the system. The objective of this study was to evaluate the effect of nitrogen topdressing rates applied to an intercrop of maize (M) with paiaguás grass (G) and pigeonpea (P) on yield and number of tillers of paiaguás grass after silage process. Treatments consisted of two simultaneous intercropping systems (M+G; and M+G+P) and four N topdressing rates (0, 80, 160, and 240 kg ha^{-1}). The collection times was at harvest of maize, after 72 and 245 days after the harvest of maize (DAH). The number of tillers and dry matter of the grass yield responded to the interactions at the three collection times. At the harvest of maize, the M+G intercrop provided the highest number of tillers only with zero N. After 72 days of harvest, at the N rate of 0 kg

ha^{-1}, the intercrops showed no significant differences; however, they did at the other rates, with the M+G intercrop resulting in the highest means. At 245 DAH, the intercrops differed from each other at all rates, with M+G providing higher means when compared with M+G+P. The N rates promoted increase on number of tillers in both intercrops at harvest of maize, at 72 DAG and at 245 DAH. On the dry matter yield at harvest, with the N rates of 0 and 80 kg ha^{-1}, M+G resulted in the highest dry matter yield of paiaguás grass, but the other rates did not lead to differences between the intercrops and at the other evaluated times, at 72 and days after harvest the highest means were obtained in the M+G intercrop as compared with M+G+P in all N rates and at 245 days after harvest with zero N the yield was similar, but in other rates the M+G intercrop provided the highest means. The N rates, at harvest and at 72 DAH, both intercropping systems tested here had a linear increase in grass dry matter. At 242 DAH, these variables responded quadratically, with 3,868 kg ha^{-1} for M+G and 3,086 kg ha^{-1} for M+G+P at the respective estimated N rates of 164 and 163 kg ha^{-1}. In these crop-livestock integrated systems M+G intercrop get highest means of number or tillers and dry matter yield of paiaguás grass comparing with M+G+P intercrop.

(7239 - 1347) Persistence and release of nitrogen from the straw of cover crops under no-till

Hugo Mota Ferreira Leite[1]; Juliano Carlos Calonego[2]; Ciro Antonio Rosolem[2]; Letícia Azal frare[2]; Carlos Antonio Costa do Nascimento[2]
UNESP/UFAC[1]; UNESP[2]

In crop rotation systems the amount, quality and persistence of straw depend on the types of cover crops. Moreover, the amount of N accumulated in the straw and its release rate during the following soybean cycle, are important factors in the crop rotation in tropical regions, due to the high straw decomposition rates. The objective of this study was to evaluate the persistence of millet, sorghum and sunn hemp straw and its nitrogen release under no-till, as well a and the rotations effect on soybean yield. The work was carried out under field conditions in Botucatu, state of São Paulo, Brazil. The crop rotations in a 15-years no-till system, with no nitrogen application. Triticale (*X Triticosecale* Wittmack) and sunflower (*Helianthus annuus*) were cultivated in plots through fall-winter; in subplots, millet (*Pennisetum glaucum*), sunn hemp (*Crotalaria juncea*), forage sorghum (*Sorghum bicolor*) and fallow were cultivated through spring: and soybean (*Glycine max*) was cultivated in the summer. Sunn hemp, sorghum and millet were desiccated 50 days after the emergence. The persistence, nitrogen release, and C/N ratio of the cover crop residues were evaluated at 0, 30, 60 and 90 days after desiccation. The dry matter accumulation was 6.3, 5.8, and 4.6 Mg ha^{-1} for sorghum, sunn hemp, and millet, respectively. Sunn hemp straw showed lower persistence among the studied species, it lost the most of its biomass within 30 days, while for millet and sorghum this occured within 60 days. After 90 days, only 24% of the sunn hemp dry matter remained, and it was approximately half of the values observed in millet and sorghum. The C/N ratio of the cover crops increased with time. The highest initial C/N ratio was found in sorghum (26/1) and lowest in sunn hemp (10/1). The amount of N released was higher for sunn hemp (0.14 Mg ha^{-1}) than for millet and sorghum (0.02 Mg ha^{-1}) until 30 days of desiccation. Lower yield of soybean was observed with sunn hemp, even with higher N input, while higher yield was observed after millet, where straw dry matter and N accumulation was lower, but the persistence was higher, protecting the soil and avoiding water losses, which probably resulted in a greater benefit to yield than the contribution of N input by sunn hemp.

Keywords: Sorghum, millet, sunn hemp, crop rotation, plant residue.

(7225 - 1693) Photosynthetic efficiency in the use of nitrogen in the culture of the inoculated corn with *Azospirillum brasilense*

Lincon Matheus Araujo Silva[1]; Marcelo Marinho Viana[1]; Karen Alessandra Sousa Castro[1]; Ester de Paiva Alves[1]; Danilo Nunes Sodre[1]; Assistone Costa de Jesus[1]; Werlen Araújo Barbosa[1]; Erivaldo Plinio da Costa Borges[1]; Cristina Silva Carvalho[1]; Heder Braun[1]
State University of Maranhão[1]

The nitrogen fertilization in maize culture assumes a potential effect on agricultural production, because nitrogen is considered to be one of the most important factors in increasing grain production. Therefore, measures should be taken to maximize the efficiency of the constant use of this nutrient. In this study, the aim to quantify the photosynthetic efficiency of nitrogen use (PNUE) in corn culture inoculated with *Azospirillum brasilense* and nitrogen applied in coverage. The experiment carried out in the field at 2016 (2°35' S and 44°12' W), in a randomized complete block design, with four replications. The treatments were performed in factorial arrangement 3 x 3: three N fertilization rates (45, 90 and 180 kg ha^{-1}), applied as top-dressing with three inoculation way (seeds, leaf and control). Nitro 1000 Gramíneas® was the inoculant used in the treatments. It was performed with 100 mL ha^{-1} of the commercial product in seed-inoculant before planting and 200 mL ha^{-1} in leaf-inoculant spraying application. The variable evaluated were: to 20, 40 and 60 days after the fertilization of the photosynthetic CO_2 assimilation (*A*) was obtained with the aid of infrared gas Analyzer (Li 6400XT, LiCor, Lincoln, USA). Was quantified specific leaf area (LA, cm^2/g) and the N content per unit leaf area (TNT_A, g/m^2). The photosynthetic efficiency of N use (PNUE) was obtained by the ratio A/TNT_A. The analysis of variance (ANOVA) was performed with the goal of deploying the sum of squares of treatments for each factor and to the interaction between the factors. Was adopted $p \leq 0.25$ for the interaction between the factors and $p \leq 0.05$ to the Tukey test. For statistical analysis we used the Software R with the interface RStudio. There was significant interaction for doses of N x forms of inoculation of *A. brasilense* just for photosynthetic assimilation of CO_2 (μmol m^{-2}, s^{-1}) ($p < 0.05$) to 20 days after fertilization (DAF), for other times and evaluated variables there was no interaction. The forms of inoculation did not make the necessary income to lift the photosynthetic efficiency of N use in evaluated. The doses of N influenced so backwards specific leaf area and photosynthetic efficiency of the use of the N. The doses of N increasingly influenced the content of N per unit leaf area and total N content.

(1037 - 1457) Plant height of herbaceous cotton drip fertigated under nitrogen fertilization and water depth

Daniele Job Alves[1]; Tonny Jose Araújo da Silva[1]; Paula Caroline Lima Silva[1]; Edna Maria Bonfim-Silva[1]; Thiago Franco Duarte[1]
Universidade Federal do Mato Grosso[1]

Cotton (*Gossypium hirsutum* L.) is of great importance in agriculture in Mato Grosso State, being the largest producer in Brazil. This great importance is due to the different forms of use of this culture, where both fibers and seeds are used. With the fibers are produced the fabrics, mattresses, among others. Already the seeds are used in the manufacture of oil, biodiesel and derivatives. The objective of this

study was to analyze the influence of drip fertigation on herbaceous cotton cultivated in Cerrado Oxisol, as a function of nitrogen doses and water depths. The study was carried out in the field at the Federal University of Mato Grosso, University Campus of Rondonópolis, from June to December 2017. The experiment utilized a 3 x 3 factorial arranged in a randomized complete block with four replications. The treatments consisted in three water depths of 50, 100 and 150% of ETc and three levels of nitrogen fertilization of 20, 110 and 200 kg ha^{-1} by drip fertigation, contemplating 40 experimental units. The total area of the experiment was 1,440 m², with each plot experimental area of 30 m² (6x5m). The plant height variable was obtained from 67 days after emergence with 15-day intervals, performed with the aid of a graduated scale measuring from the neck to the apex of the plant in nine plants per experimental unit. For the statistical analysis, the Sisvar software was used, at a level of 5% error probability. Nitrogen fertilization showed a significant difference at 97 days after emergence for plant height, showing an increasing linear behavior for the highest height of 74.04 cm at the dose of 200 kg ha^{-1}. Nitrogen fertilization positively interfered the plant height variable in all evaluations with an isolated effect. The plant height of cotton was influenced by nitrogen fertilization and water depth.

(1764 - 1257) Productive development of herbaceous cotton fertigated by dripping under nitrogen doses and water slides

Paula Caroline Lima Silva[1]; Tonny José Araújo da Silva[1]; Thiago Franco Duarte[1]

Universidade Federal de Mato Grosso[1]

Cotton is the most important natural fiber produced in the world. In Brazil, the Mato Grosso State has great representativity in the culture production. In the 2016/2017 harvest, the State produced 66.1% of the national amount. Due to the crop importance in the Brazilian and Mato Grosso production, it is necessary to invest in research and technologies to ensure sustainability in the cultivation of cotton. The objective of this study was to evaluate the performance of the herbaceous cotton cultivated in Dystrophic Oxisol fertigated by drip irrigation, as a function of nitrogen doses and water slides. The experiment was carried out in the field, at the Federal University of Mato Grosso, University Campus of Rondonópolis, from June to December 2017. The experimental design was a randomized complete block with four replications, in a factorial scheme, with nine treatments, three nitrogen doses (20, 90 and 200 kg ha-1) and three water slides (50, 100, 150% ETc), totalizing 40 experimental units. The experimental units had dimensions of 6 x 5 m (30 m²), with total área of 1440 m². Before the harvest, the number of beaks per plant was obtained by means of a general average, after manual counting of the beetles in nine plants per experimental unit. The data were submitted to statistical analysis on the response surface using the Sisvar software at the 5% probability level in all statistical tests. Nitrogen doses had an isolated effect with increasing linear behavior for the variable number of beaks per plant, reaching a maximum value of 4.67 beaks. The water depth was significant for the variable number of beaks per plant, where the water blade of 108.48% of ETc provided the maximum value of 3.77 beaks per plant. Nitrogen fertilization and water depth influenced the number of pods per herbaceous plant.

(5221 - 948) Reduction of nitrogen fertilization in corn crop due to combinations of plant growth promoting bacteria

Marcelo Carvalho Minhoto Teixeira Filho[1]; Jeferson Silva de Souza[1]; Rafaela Neris Gaspareto[1]; Fernando Shintate Galindo[1]; Íngrid Torres Pereira[1]; Salatiér Buzetti[1]; Laura Britto Garcia de Oliveira[1]; Antonio Leonardo Campos Biagini[1]

Universidade Estadual Paulista (UNESP), Ilha Solteira Câmpus[1]

Recent researches have shown that inoculation with plant growth promoting bacteria, such as *Azospirillum brasilense*, can increase the efficiency of nitrogen fertilization in grasses, such as corn. Other bacteria such as *Bacillus subtilis* and *Pseudomonas fluorescenses* have several plant benefits, such as phytohormonal effect and induction of resistance to pathogens. Therefore, as there are few studies with the interaction of these bacteria, the objective was to evaluate the influence of combinations of seed inoculations with plant growth promoting bacteria (*A. brasilense*, *B. subtilis* and *P. fluorescens*), associated to the reduction of N fertilization, in the N concentrations in leaf diagnosis, grains and straw, and corn grain yield. The experiment was conducted in second corn crop, under no-tillage system with supplementary irrigation, in Selvíria - MS, Brazilian Cerrado region. The experimental design was a randomized block, with four replications and eight treatments, being: 1) Control (without inoculation and without N fertilization); 2) Without inoculation and with 75% of the recommended N dose (112.5 kg ha^{-1} of N, in the form of urea applied in V4 stage); 3) Without inoculation and application of the recommended N dose (150 kg ha^{-1} of N); 4) Inoculation with *A. brasilense* + 75% of the N dose; 5) Inoculation with *A. brasilense* + *B. subtilis* + 75% of N dose; 6) Inoculation with *A. brasilense* + *P. fluorescens* + 75% of N dose; 7) Inoculation with *B. subtilis* + *P. fluorescens* + 75% of N dose; and 8) Inoculation with *A. brasilense* + *B. subtilis* + *P. fluorescens* + 75% of N dose. The results were analyzed by analysis of variance and Scott-Knott's test at 5% probability for comparison of treatments means. N concentrations in the diagnostic leaf, grains and straw of corn were higher with fertilization at the recommended N dose and when was used 75% of the N dose associated with inoculation with *A. brasilense*, *A. brasilense* + *B. subtilis*, and *A. brasilense* + *P. fluorescens*. However, the highest grain yields were obtained in the treatments with the inoculations + 75% of the N dose, all of which were significantly higher than the control and the application of 75 and 100% of the recommended N dose. This is due in part to the fact that these bacteria induce systemic resistance of the plant to pathogens, which caused less damage of the corn stunt. Therefore, with the inoculation of these bacteria, was possible to reduce in 25% the N dose applied in the corn crop.

(5670 - 2041) Response of Marandu grass (Brachiaria brizantha) to mineral and organic fertilization

Andréia Lopes de Morais[1]; Jéssica Rodrigues Dalazen[1]; Renan Garcia Malikouski[1]; Kamila Cabral Mielke[1]; Janderson Rodrigues Dalazen[2]; Karem Caroline V. do Nascimento[3]; Anderson Cristian Bergamin[3]

UFES[1]; EMATER - RO[2]; UNIR[3]

Marandu grass (Brachiaria brizantha), is considered one of the most used forages in Brazil, this preference is due to its high tolerance index in conditions of low soil fertility, resistance to pests, and high productivity in properly managed soils. Fertilization, along with other management strategies, is fundamental for pursuing economic, social and sustainable exploitation, without causing damage to the environment. The present study aimed to evaluate the behavior and productivity of Brachiaria Brizantha cv. Marandu under the use of mineral fertilization (MF) using Urea as source and organic fertilization (OF) using bovine manure as the source. The study was carried out in pots with a volume of 5 dm³, conducted in a greenhouse at the Experimental Campus of the Federal University of Rondônia (UNIR), from October to December 2014. With a completely randomized

experimental design, with five treatments and five replications, in the following combinations 0% OF / 100% MF; 25% OF / 75% MF; 75% OF / 25% MF; 100% OF / 0% MF and one control (0% of nitrogen fertilization and 0% of organic fertilization), totaling 25 experimental units. For the study of the morphogenic and structural variables, the dry mass weight (Air Part) was analyzed; leaf appearance rate; leaf elongation rate; leaf senescence rate; number of leaves per tiller during its establishment phase. For Marandu grass, no response was observed for leaf elongation rate and leaf appearance rate, with no difference between treatments. The treatment that obtained the best response for wet mass and dry mass was 0% OF and 100% MF better, the control obtained the worst yield. Treatment with a dose of 75% OF; 25% MF showed better results to the chlorophyll content and with the dose 100% OF and 0% MF the result was not satisfactory. For the best management of the plant, the use of mineral nitrogen and organic nitrogen is recommended, because of this, to an interaction with different times of nitrogen reaction in the plant, so that maximum production can be obtained.

(7947 - 2759) Root growth and expression *OsNRT2.4* gene in rice lines under low nitrate supply

Andressa Fabiane Faria de Souza[1]; Laura Carine Candido Diniz Cruz[1]; Leilson Novaes Arruda[1]; Carlos Alberto Bucher[1]; Sonia Regina de Souza[1]

Universidade Federal Rural do Rio de Janeiro[1]

Nitrogen (N) is one of the factors that most limits plant growth and productivity, being the nitrate (NO_3^-) a major source of N for most higher plants in cultivated (well aerated) soils (Glass, 2009). Nitrate uptake by plants is mediated by two different transport systems, a low (NPF) and other high-affinity (NTR2), in which the high-affinity transport system operates at low nitrate concentration in the external medium. Thus, the present study aimed to evaluate a relative expression of the OsNRT2.4 gene in transformed rice lines obtained by gene silencing technique using the artificial micro RNA (amiRNA), under low N supply. The experiment was performed in a growth chamber at $28^oC/24^oC$ day/night temperature with a 14/10 h light/dark regime, with a light intensity of 318 µmols $m^{-2}.s^{-1}$. The relative humidity was kept at 70%, at the Soil Department of the Federal Rural University of Rio de Janeiro (UFRRJ). The rice seeds (wild type (WT) and lines) of the variety Nipponbare (*Oryza sativa* L. subsp. Japonica) were surface-sterilized with sodium hypochlorite (2,5%) for 15 min and germinated in deionized water. Three days after germination (DAG), plants were transferred to modified Hoagland solution (Hoagland and Arnon, 1950) with different N regimes. The solutions were changed every 3 days, and the pH was maintained at 5.5. At 15 DAG the treatment was started, with the ½ ionic strength of 0.2mM N-NO_3^-. The plants were harvest at 21 DAG, four hours after the change of the nutrient solution. A fresh weight of the plants and root length were measured, and root samples were stored at -80°C for subsequent use. Total RNA was extracted, and gene expression was analyzed by real-time semi-quantitative RT-PCR through the comparative Ct method 2^(-delta delta Ct) using gene-specific primers. It was used as the housekeeping genes UBC, eEF-1α. The results indicated that the transformed lines used as study object had a reduction in the expression of the *OsNRT2.4* gene up to 80% compared to WT plants. And even under the effect of gene silencing, when growth in a solution containing 0.2mM N-NO_3^- (low N), the silencing lines the *OsNRT2.4* gene presented values of root length close to the wild type. It was also observed that the silencing lines the OsNRT2.4 gene showed a lower root dry matter compared to the WT plants. These results reinforce the performance of the OsNRT2.4 transporter in rice roots under low N supply.

(4944 - 1675) Secondary macronutrients concentration in signal grass (*Urochloa decumbens*) fertilized with nitrogen doses and sources

Guilherme Constantino Meirelles[1]; Reges Heinrichs[2]; Maikon Vinicius da Silva Lira[2]; Filipe Virgílio Ribeiro[2]; Luiz Felipe de Melo Santos[2]

São Paulo State University (UNESP), FCAT[1]; São Paulo State University, FCAT/UNESP[2]

The interaction between nutrients can substantially affect the mineral nutrition of plants. The effects of nitrogen fertilization on sulfur contents are well known, especially due to the joint action in the production of amino acids. However, with the use of nitrogen sources efficiently increases can also affect in a distinct way the use of other nutrients. The experiment was conducted in the experimental field of the College of Agricultural and Technological Sciences, UNESP, Campus de Dracena, SP, Brazil. The objective of this study was to evaluate the conventional nitrogen fertilizer and the nitrogen sources with increased efficiency in the secondary macronutrients concentration in aerial part of the signal grass pasture (*Urochloa decumbens*; syn. *Brachiaria decumbens*). The soil of the area was classified as Ultisol. The experimental design was in ranged blocks with four replicates, in a factorial scheme 4x2+1. The plots were composed of four nitrogen sources (urea, ammonium nitrate, urea with NBPT inhibitor and urea coated with B and Cu), with two doses of nitrogen (100 and 200 kg ha^{-1}), plus a treatment without nitrogen fertilization (control). The nitrogen doses were divided in five equal applications (20 e 40 kg ha^{-1}), the first one after the uniformization cut and the others after the immediately subsequent cuts. The results presented lower sulfur concentration with application of nitrogen doses in the summer (water period) and winter (dry period), but did not differ among the sources. These results can be attributed to the dilution effect, due to the higher production of dry mass with nitrogen fertilization. A similar result was verified with the Mg concentration in the winter period. The Ca concentration at the two season and the Mg during the water period were not affected by nitrogen fertilization. The Mg and S contents in the aerial part of the signal grass are within the range considered adequate. On the other hand, the Ca presented values below the critical level for the forage.

(5402 - 978) Soil Inorganic nitrogen content in a system of legume intercropping with pasture in the Brazilian Savannah

Carlos Henrique dos Santos[1]; Ana Carolina Mônico Moreira[2]; Amarildo Francisquini Júnior[2]; Juliano Carlos Calonego[3]; João Pedro de Pádua Dutra[2]; Jean Marcos Pereira da Silva[2]; Willian Lucas Mativi[2]; Lucas Rodrigues da Silva[2]

University of Western São Paulo, College of Agricultural Sciences, Campus II, 19067-175, Presidente Prudente, State of São Paulo, Brazil (chenrique@unoeste.br)[1]; University of Western São Paulo, College of Agricultural Sciences, Campus II, 19067-175, Presidente Prudente, State of São Paulo, Brazil[2]; São Paulo State University, College of Agricultural Sciences, PO Box 237, 18610-307, Botucatu, State of São Paulo, Brazil[3]

Nitrogen is an essential element for the development and growth of plants, but difficult to manage due to its high mobility in the soil, which leads to higher losses due to leaching, volatilization and denitrification. These losses may be more intense in sandy soils due to the low clay content and organic matter. The major challenge from this is to implement systems such as no-tillage, crop-livestock integration, crop rotation and intercropping to increase the accumulation of organic matter in soils and improve the conditions of the production system. The purpose of this research was to evaluate the levels of N-inorganic in soil (NH_4^+ and NO_3^-) in a system of crop-livestock integration, with N supply through composting or intercropping with legumes in pasture areas. The experiment was carried out at the experimental farm of University of Western São Paulo, in Presidente Bernardes, State of São Paulo, Brazil, in a soil classified as Ultisol. The experimental design was defined as a randomized complete block design with four replicates and de treatments were described as: 1) Single mombaça grass with N cover fertilization, 2) Mombaça grass intercropped with dwarf pigeon pea without N fertilization, 3) Single mombaça grass with absence of N fertilization, 4) Mombaça grass intercropped with *Macrotyloma axillare* cv. Java without N fertilization. Soil samples were collected at depths of 0-5, 5-10, 10-20, 20-40, 40-60 and 60-80 cm and the data were submitted to analysis of variance and compared by Tukey test ($p<0.05$). The legumes influenced positively the NH_4^+ and NO_3^- contents in the system, promoting a significant increase of inorganic N in the soil. The intercropping between mombaça and the legumes increased the contents of N-inorganic in the soil, with a predominance of NH_4^+ in relation to NO_3^-. There was a statistical difference for the NH_4^+ levels between the treatments only in the depth of 40-60 cm, whereas the NO_3^- contents were significantly different in the same ones in all the depths sampled. Legumes influenced positively the NH_4^+ and NO_3^- contents in the system, promoting a significant increase of inorganic N in the soil.

(1490 - 743) Urease inhibitor use in nitrogenous fluid fertilizers in mixture with vinasse

Karla Vilaça Martins[1]; Ronaldo Batista Pinheiro[2]; Mauro Pinheiro Marra[2]; Klaus Reichardt[3]; Maicon Henrique Martins[2]
University of Patos de Minas[1]; Terrena Agronegócios Ltda[2]; University of São Paulo[3]

The use of fluid nitrogen fertilizers mixed with vinasse is an alternative for fertilization of the sugar cane crop. However, there is a lack of information regarding nitrogen (N) losses that can occur by volatilization when the fertilizer is applied on the straw. The objective of this research was to evaluate N losses of nitrogenous fertilizers in mixture with vinasse applied on sugarcane straw. The study was carried out in a greenhouse situated in the municipality of Patos de Minas, MG, Brazil. The experimental design consited of randomized blocks with 8 treatments [T1 - Control, T2 - Uan, T3 - Liquid urea, T4 - Uan + inhibitor NBPT (N-(n-butil) tiofosfóricotriamida), T5 - Vinasse, T6 - Uan + Vinasse, T7 - Liquid urea + Vinasse and T8 - Uan + NBPT + Vinasse] and 5 replicates. The experimental units consisted of plastic trays 50 cm long by 50 cm wide and 9 cm high. At installation time, the soil classified as Red Latosol of clayey texture, was sieved through 2 mm, covered with 1 cm of sugar cane straw and irrigated with 5 mm of water on each tray using a watering can. An ammonia collecting chamber was used, made from a transparent polyethylene terephthalate (PET) plastic bottle with a capacity of 2 L. Ammonia losses were evaluated 3, 7, 10 and 14 days after fertilizer application (DAA). Ammonia was determined by titration with standardized solution of 0.005 mol L^{-1} H_2SO_4. The statistical analysis of the results was carried out with the aid of the SAS® program. At 14 DAA the total N losses were, on average, for T3 84% (a), T2 33% (b), T4 11% (c), T7 8% (cd), T6 5% (e), T8 3% (ef), T5 1% (ef) and in T1 0.3% (f). The highest loss of N by volatilization was in the treatment with application of Liquid urea (T3). The mixture of vinasse with fluid fertilizers significantly reduced the losses of N (T6 and T7), especially when the urease inhibitor (NBPT) was added (T8).

(8796 - 1381) Use of gypsum and leguminous residue to improvement of soil rootability and increase of nitrogen use efficiency in a cohesive tropical soil.

Emanoel Moura[1]; Stefanny Portela[1]; Karina Vieira[1]; Jessica Nunes[1]
State University of Maranhão[1]

In cohesive soils, crops are able to exploit only a thin surface layer to sustain development due to an increase of fine particles and decreased organic carbon at lower depths, which can limit crop growth when the stock of water and nutrients is not sufficient in this soil volume. We hypothesized that the use of gypsum combined with leguminous residue may extend the soil rootability, and consequently enhance nitrogen uptake, increase growth and maize grain yield. The aim of this work was to evaluate the combined effects of gypsum and leguminous residue on soil rootability nitrogen uptake and maize grain yield in a sandy loam cohesive soil. This study began in January 2011, following a randomized block design with four replications of the following treatments: control; 12 Mg ha^{-1} of dry matter legumes residue; 12 Mg ha^{-1} of dry matter legumes residue + 6 Mg ha^{-1} of gypsum; 90 kg ha^{-1} of N from urea + 6 Mg ha^{-1} of gypsum; 12 Mg ha^{-1} of dry matter legumes residue, 90 kg ha^{-1} of N from urea + 6 Mg ha^{-1} of gypsum; 12 Mg ha^{-1} of dry matter legumes residue, 90 kg ha^{-1} of N from urea, 12 Mg ha^{-1} of gypsum. In the year 2015, the plots of the control treatment were divided into two treatments: C (Control) and U (100 kg ha^{-1} of N from urea). The treatment Urea was created to provide comparative data in N contents and yields components of maize. The results showed that the combination of gypsum with leguminous residue modified the root zone by increasing the calcium and organic matter levels and by reducing the soil penetration strength. For the maize, these changes increased the leaf area index and the remobilization of nitrogen to grains due to greater uptake before and after tasselling stage. This positive effect on the physiological process also produced variations in maize grain yield. For example, the difference in weight of grains between the treatments U, and LG6 (4.33 Mg ha^{-1} to 6.33 Mg ha^{-1}) suggests that, rather than increasing mineral fertilization alone, the gypsum and leguminous residue combination is a more suitable strategy to improve agrosystems in cohesive soils of the humid tropics.

(6983 - 1510) Vegetative development of cotton in drip fertigation under nitrogen fertilizer and water depths

Joyce de Oliveira Rodrigues[1]; Tonny José Araújo da Silva[1]; Paula Caroline Lima Silva[1]; Thiago Franco Duarte[1]; Edna Maria Bonfim-Silva[1]

Universidade Federal de Mato Grosso - UFMT[1]

The Brazil is a major producer of cotton (*Gossypium hirsutum L.*), currently one of the five largest producers of fiber in the world. In relation to national level the Mato Grosso State stands out as the biggest producer of the plume. The objective of this study was to evaluate the performance of the drip fertigated cotton cultivated in Cerrado Oxisol under doses of nitrogen and water depths. The experiment was carried out at the Federal University of Mato Grosso, University Campus de Rondonópolis, in the city of Rondonópolis-MT, from June to December 2017. The treatments were three nitrogen doses (20, 110 and 200 Kg ha^{-1}) via fertigation and three water depths (50, 100 and 150% of ETc) via drip irrigation. The experiment utilized a 3x3 factorial arranged in a randomized complete block with four replications. The experimental unit had dimensions of 6x5 m with total area of 30 m^2. The number of cotton leaves was evaluated at 15 - day intervals, by means of manual counting in nine plants per experimental unit. For the statistical analysis of the variable, the Sisvar software was used, at 5% probability. The number of leaves was significant for nitrogen and water levels at 112 days after emergence (DAE). For nitrogen doses, it is possible to observe increasing linear behavior, with the highest number of leaves (30.61) at the dose of 200 kg ha^{-1} of nitrogen. The water depth corresponding to 116.7% of ETc presented a greater number of leaves of 28.63 per cotton plant. The number of cotton leaves is influenced by nitrogen fertilization and water depths.

(7626 - 2367) Vegetative performance of pepper pout under nitrogen doses

Francielly Gonçalves Barbosa-Oliveira[1]; Márcio Koetz[1]; Edna Maria Bonfim-Silva[1]; Juliane de Souza Beltrão[1]; Jessica Patricia Paula Lima[1]
Universidade Federal do Mato Grosso[1]

The cultivation of peppers in Brazil has great importance for its profitability for family agriculture, which is influenced in the market by regional food habits. The lack of pungency of the pepper pout fruits and their organoleptic characteristics impels the acceptance and preference for several types of consumers, increasing the interest for scientific research. The objective of this study was to evaluate the number of leaves of pepper pout submitted to nitrogen doses. The experiment was conducted in a greenhouse with the experimental units constituted by pots of 5 dm^{-3} with Oxisol, from Cerrado. The experimental design was completely randomized with 5 doses of nitrogen (0, 60, 120, 180 and 240 mg dm^{-3}) and 5 replicates, making 25 experimental units. According to the soil chemical analysis, the base saturation was corrected to 80% and fertilized with 600 mg dm^{-3} of phosphorus, 180 mg dm^{-3} of potassium and nitrogen, divided in 3 times according to the treatments. It was fertilized with micronutrients via solution, applying 5,72 mg dm^{-3} of boron, 3,93 mg dm^{-3} of copper, 10,95 mg dm^{-3} of manganese and 13,51 mg dm^{-3} of zinc. The seeds of the cultivar BRS Moema were seeded in expanded polystyrene trays to be transplanted to the pots, when the seedlings reached an average of 7 cm in height, with 37 days after sowing. Irrigation was performed so that the soil returned to the condition of field capacity, by monitoring the humidity with tensiometers, installed at 10 cm depth in the experimental unit, applying water whenever the water tension in the soil reached 15 kPa. The number of leaves at 15, 30, 45 and 60 days after transplanting (DAT) was evaluated. A significant difference was found in the F-test at 5% significance for 30, 45 and 60 DAT, adjusting to the quadratic regression model using the SISVAR statistical software at 30, 45 and 60 DAT, where it was observed, respectively, that the best nitrogen doses were 32,75, 130,25 and 120,82 mg dm^{-3}. The number of leaves of pepper pout cultivated with Oxisol under greenhouse conditions were influenced by the nitrogen doses.

(5543 - 2351) Volatilization of Ammonia ($N\text{-}NH_3$) in Corn (*Zea mays* L.) in Function of the Application of Urea, Ammonium Sulphate and Polymer Coated Urea

Bruno Maia Abdo Rahmen Cassim[1]; Evandro Antonio Minato[1]; Fabrício Linares Mazzi[1]; Marcos Renan Besen[1]; Éder Junior de Oliveira Zampar[1]; Rodrigo Sakurada Lima[1]; Tadeu Takeyoshi Inoue[1]; Marcelo Augusto Batista[1]
Universidade Estadual de Maringá (UEM)[1]

The urea is the main nitrogen fertilizer used in agriculture. In some situations when applied on the soil, it can present low efficiency because of losses by volatilization, denitrification and leaching. Due to this, the urea coated by materials as resins, waxes and polymers, seeks to diminish the losses by volatilization and to increase the use efficiency by a gradual nutrient release mechanism. The objective of this work was to evaluate the accumulated losses of ammonia (NH_3) of different nitrogen sources over time in corn (*Zea mays* L.) cultivation. The field experiment was conducted in Maringá city, Paraná state, in a Dystrophic Red Acrisol (Ultisol) and Cfa climate. The experimental design was randomized blocks with 6 treatments (T1: control; T2: urea; T3: ammonium sulfate, T4: Agrocoat polymer, T5: FortBlen polymer and T6: polymer kincoat) and 6 replicates. For all treatments the dose used was 60 kg N ha^{-1}. The samplings were made at the 3 °, 5 °, 9º, 13°, 18 °, 23 ° and 27 ° days after fertilizer application. The method used to quantifying the ammonia volatilization was the semi-opened static chamber made of a plastic bottle (PET) with a filter paper strip soaked by a H_2SO_4 0.05 mol L^{-1} + 2% v / v glycerol solution. The determination was made by the colorimetrich method of salicylate, described by Miyazawa (2007). The results were submitted to no-linear regression analysis using logistic model $Y=\alpha/1+\exp[-\gamma(time-\beta)]$. According to the adjusted model, the maximum accumulated losses were 26.4; 26.1; 20.1; 16.8; 1.9; 0.2 kg ha^{-1} of $N\text{-}NH_3$ for urea, Kincoat, Agrocoat FortBlen, ammonium sulfate and control, respectively. It showed the efficiency of the FortBlen polymer, which had a loss reduction of 36.37% of the N applied, when compared to the urea. Among the nitrogen sources, the ammonium sulfate showed the lowest loss by volatilization, because it is an ammoniacal source. According to the adjusted model, the peak of $N\text{-}NH_3$ volatilization was observed at 4.23; 4.49; 4.87; 4.86 and 4.33 days after application of urea, Kincoat, Agrocoat, FortBlen and ammonium sulfate respectively. These peaks represented losses of 3.91; 3.94; 3.12; 2.39; 0.38 kg ha^{-1} d^{-1} of $N\text{-}NH_3$, respectively. The conclusion is that there is a difference among the coated fertilizers, analysed in the work, and some of them have the potential to minimize the losses of $N\text{-}NH_3$.

Keywords: nitrogen sources; fertilizer and logistic model.

(8600 - 1685) Volatilization of NH_3 in nitrogen fertilizers applied on coffee crop with and without straw

Pedro Rocha Santos[1]; Maila Adriely Silva[2]; Mateus Gonçalves de Borba[1]; Leticia Gonçalves Pinheiro[1]; Victor Gustavo Soares Ribeiro[1]; Vanessa Júnia Machado[1]
Centro Universitário de Patos de Minas[1]; Universidade Federal de

Lavras[2]

The nitrogen (N) is the element most exported by the coffee trees, thus it has used higher doses on the fertilization, being the efficiency of this practice responsible to reach the high productive ceiling. Due the dynamic, the nitrogen is transformed easily in compounds that are easily lost, among these losses stands out the volatilization of NH_3 the process that can lead to extremely high losses in urea-based fertilizers. Thus, the present study has the objective quantify the nitrogen losses by NH_3 volatilization in function of the different application of nitrogen fertilizers on coffee crop soil with and without straw. The experiment was conducted in the plantation of coffee Arábica at Fazenda Santiago, Patos de Minas, Minas Gerais State, Brazil. The design used was randomized complete block with Split-plot temporal and factorial 2 x 5 x 6 with 3 repetitions, being two application methods (on the straw and without the straw), four fertilizers sources: F1 = Ammonium Nitrate (32% of N), F2 = Urea (45% of N), F3 = Urea-NBPT (44% of N) and F4 = Polymer-coated urea (45% of N) and the control; and the split plot with eight collections to 3, 6, 10, 17, 24, 38 and 53 days after the fertilizer application. The plots were constituted of chambers made of plastic bottles, following the SALE model proposed by Araújo with area of 0,008 m^2, using a sponge soaked with H_2SO_4 1 mol L^{-1}, that were collected and destilled by method Semimicro Kjeldhal. It was verified that the both application methods the urea showed higher volatilization average per day, respectively with and without straw, 2,44 and 3,53 $Kg.ha^{-1}$ of N, with close average was found respectively, 1,45 and 2,99 $Kg.ha^{-1}$ of N, at the polymer-coated urea, followed by urea NBPT with the average 1,42 and 2,15 $Kg.ha^{-1}$ of N, the best results were found in the ammonium nitrate source, with 0,94 and 0,76 $Kg.ha^{-1}$ of N, and the average close of the control with 0,83 and 0,42 $Kg.ha^{-1}$ of N. The volatilization peaks were found on the days 3 and 6 at the ammonium nitrate and urea sources, and at the polymer-coated urea and urea NBPT was found on the days 6 and 10, showing a delay on that peaks related with the associated technology on these fertilizers.The urease inhibitor and polymer proved to be efficient in the delay of the volatilization peak, while the ammonium nitrate was the source with the lowest loss per volatilization.

(4091 - 3136) Volatilization, Leaching and Nitrogen Runoff according to dose, sources and soil moisture in rice cultivation.

Luis Armando Castilla Lozano[1]
FEDEARROZ[1]

N is one of the most important macronutrients in rice crop, there is a direct correlation between nitrogen fertilization and yields. The soils of the rice areas of Colombia have lost organic matter and this affects the availability of N, which is why the application of significant amounts of nitrogen fertilizers, decreasing the efficiency of fertilization, increasing losses due to runoff, leaching and volatilization. As a strategy to improve efficiency, this study was carried out in a *Typic Haplustalf* soil of the Ibagué Colombia, under a complete random blocks design (CRB), with four replications. Two experiments were carried out: in one, doses of 250 and 125 kg of N ha^{-1} (urea) were evaluated with three levels of soil humidity (50% CC, CC and saturated). Experiment 2 evaluated the effect of different sources of nitrogen fertilizers (urea, ammonium sulfate, urea with urease inhibitors, urea with nitrification inhibitors, physical mixture urea + ammonium sulfate and a control) and irrigation applied immediately and 24 hours after fertilization. In experiment 1, it was found that the volatilization of N was greater at higher doses and in soils at 50% CC (10-12 kg N ha^{-1}) and less at lower doses and in soils at saturation (6 -7 kg N ha^{-1}). Leaching and runoff were higher in saturated soils (25 mg l^{-1}) and at higher doses, than in soils at 50% CC (20 mg l^{-1}) and with lower doses. In experiment 2 it was found that urea and ammonium sulfate are greater loss by volatilization (29.93 and 21.13 kg N ha^{-1}, respectively) contrasting urea with urease inhibitors (10.69 kg N ha^{-1}). The same tendency was found in runoff and leaching. There were no differences in N loss, between applying the irrigation immediately and 24 hours later.

C3.3.2 - Nutrient budgets in agricultural soils

(3626 - 2201) A sequential extraction procedure to study phosphorus binding forms in arable soils

Kristof Dorau[1]; Nina Gerlach[1]; Tim Mansfeldt[1]; Marcel Bucher[1]
University of Cologne[1]

Phosphorus (P) as a major nutrient is of special concern in order to investigate the study plant *Zea mays*. Within the project RECONSTRUCT, we investigated five genotypes of *Zea mays* at the DOK trial in Therwil and at the DEMO trial in Reckenholz (both Switzerland). The farming systems at the trials are managed differently and consist of an organic system (BIODYN) and a conventional system with mineral fertilizer exclusively (CONMIN) at DOK. At the DEMO trial, a fully fertilized soil (by nitrogen (N), potassium (K) and P (NPK)) and a plot with N and K fertilization but without P (NK) were investigated to study the effects of maize growth. Even when P levels exceed plant requirements, it might be possible that symptoms of P starvation occur, because soils can retain P very strongly depending on their mineralogical composition. Therefore, a differentiation into mobile and immobile P fractions is important. We employed the Hedley fractionation procedure and quantified P availability in a stepwise extraction to quantify labile P (resin P and $NaHCO_3$-P), moderately labile P (NaOH-P), and stable P (HCl-P, HCl_{conc} P and residual P). This poster summarizes first results about different P binding forms in soils and their impact on biomass production for a consortium of maize genotypes under variable agricultural management practices.

(5761 - 1917) Application of an Electric Potential to Retain Plant Nutrients Around the Root Zone in Rice (*Oryza sativa* L.)

Gayathree I. Senevirathne[1]; J. A. Surani Chathurika[1]; Manju Gunawardene[1]; Asitha Siriwardena[1]; Kosala Purasinhala[1]; Gehan Amaratunga[2]
Sri Lanka Institute of Nanotechnology, Mahenwata, Pitipana, Homagama, Sri Lanka.[1]; Sri Lanka Institute of Nanotechnology, Mahenwata, Pitipana, Homagama, Sri Lanka. Department of Engineering, University of Cambridge, Trumpington Street, Cambridge, CB2 1PZ, United Kingdom.[2]

Nutrient leaching is one of the major concerns that affect crop production as well as environmental health and human health. Specially, retention of plant nutrients in waterlogged rice cultivation is a challenging task. Therefore this study aims to evaluate the effect of direct electric potential (EP) in retaining soil nutrient around the root zone. This study was conducted in a greenhouse at Sri Lanka

Institute of Nanotechnology, *Homagama*, Sri Lanka. The soil selected for the study was Tipic Tropofluvents. Treatments were arranged according to complete randomized design with four replicates. Treatments were; control (plants without EP around the root zone), treatment 1 (plants with EP around the root zone). A local rice variety (*Oryza sativa* L.) BW 367 was selected as the test crop. Five rice seedlings were planted in pots containing inner and outer cylindrical pots made of iron mesh. Electric potential of 5.0 V was supplied with the minimum direct current of 0.1 A for 8 hours continuously per day until the end of the growing season. Iron mesh was purposely selected to provide excess iron (Fe) to the root zone as rice shows visible symptoms in growth and yield when subjected to Fe toxicity. Inner pot was given positive end (anode) while outer pot was considered as negative end (cathode). Plant height was measured weekly and soil total and available Fe content in three zones (near to the rice plant, near to the anode and near to the cathode) were determined at the time of panicle initiation and at the end of the experiment. Above and below ground biomass, paddy yield, number of seeds per panicle and unfilled grains per panicle were measured at the end of the growing season. Soil total and available Fe content was higher around the cathode zone than the anode zone. Plant height, above ground biomass, and paddy yield were significantly lower in treated plants than the control plants. Treated plants showed 45% reduction in paddy yield compared to the control plants. Below ground biomass and number of seeds per panicle were lower in treated plants compared to the control. Iron uptake in rice grain was higher in treated plants than the control treatment. This confirms that provided excess iron with an electric potential increases the iron concentration around the root zone and enhances the Fe absorption. This study suggest that application of EP around the root zone and rhizosphere can be solution to mitigate nutrient leaching in waterlogged rice soils.

(4752 - 342) Calibrations of phosphorus and potassium modules for an integrated crop macro-nutrients model

Kefeng Zhang[1]
Ningbo Institute of Technology, Zhejiang University, Ningbo 315100, China[1]

Production of quality crops depends on the provision of an optimal supply of essential macro-nutrients of nitrogen (N), phosphorus (P) and potassium (K). With the advances in knowledge of soil and plant sciences, key processes controlling water and nutrients cycles in the soil-crop system could mechanistically be understood, and as a result numerous agro-hydrological models have been proposed for optimising fertiliser application in crop production. In this study, attempts have been made for calibrating P and K modules in the integrated NPK model. The modules were constructed based on the previous PHOSMOD and POTAS models and strong correlations between the percentage content of P (%P) and N (%N) and between the percentage content of K (%K) and N (%N) which were observed experimentally for measurements made on 19 crops grown under the conditions of various combinations of N, P and K fertilisers. Two parameters, the ratios of %N:%P and %N:%K, were introduced for determining critical %P and %K based on critical %N in the integrated model for crop growth. An effective root diameter, which could be obtained by calibration against the results of field experiments, was used for describing the differences in roots ability to absorb P and K. Forty separate experiments each containing 6 different levels of P or K treatments were used for calibrating root radii of 17 crops. The measured dry weights and the calculated dry weights from the calibrated P and K modules under various P and K treatments were then compared. Good agreement between simulated and measured dry weights for different P treatments was achieved (y=0.979x+0.187, R2=0.932, n=221). The correlation for different K treatments was satisfactory (y=0.892x+0.287, R2=0.941, n=222) for most crops, except for few crops including onion that required more attention. Overall the calibrations for P and K modules were successful, and the calibrated modules had the potential to be used for optimal fertiliser application in a range of crop production.

(9010 - 1485) Changes in nutrients reserves of agricultural soils of the eastern lowlands of Georgia

Giorgi Ghambashidze[1]; Giorgi Ormotsadze[2]; Aleksandre Megrelidze[2]; Naira Kentchiachvili[2]; Maia Tarkhnishvili[2]; Giorgi Gventsadze[2]; Tamar Jolokhava[2]; Tea Meskhi[2]
Scientific-Research Centre of Agriculture, 6 Marshal Gelovani Avenue, Tbilisi, 0159, Georgia (giorgi.ghambashidze@srca.gov.ge)[1]; Scientific-Research Centre of Agriculture, 6 Marshal Gelovani Avenue, Tbilisi, 0159, Georgia[2]

Georgia is a mountainous country and has the limited area of arable lands accounting only 15.8% of its whole territory. Therefore, it is essential to maintain the fertility of soils on those lands, the most of which are concentrated in lowland areas. The current study was aimed to evaluate actual content of total and plant available pool of macro- (N, P, K, Ca, Mg) and micronutrients (Fe, Cu, Zn, B, Mn, Mo, Co) in top 30 cm of soil of agricultural lands covering 20 000 ha in the eastern lowlands of Georgia. Alongside with abovementioned elements soil pH, soil organic carbon, particle size distribution and calcium carbonate contents were also measured. The results were compared to the historical datasets to assess the basic trends in soil management practice. The data comparison has shown that main changes were associated with changes in land use affecting total nitrogen, plant-available phosphorus and potassium concentrations. Positive changes in soil organic carbon content were observed in arable lands, which are abandoned and cannot be used as pastures due to their locations.

Keywords: soil fertility, nutrient reserve, macro and micronutrients

(9458 - 3239) Changes in soil phosphorus balance and phosphorus use efficiency in long-term fertilizer application experiment conducted on agriculturally-used Chernozem soils in Germany.

Dirk Freese[1]; Tania Medinski[1]; Thomas Reitz[2]
Chair of Soil Protection and Recultivation, Brandenburg University of Technology Cottbus– Senftenberg[1]; Department of Soil Ecology, Helmholtz Centre for Environmental Research – UFZ[2]

Efficient phosphorus (P) fertilization systems which ensure high yield production and effective usage of expensive and limited P fertilizer are of great focus nowadays. This study investigates changes in soil P in different fertilization treatments applied since 1902 on Chernozem soil at a “Static Fertilization Experiment” in Germany. Total and plant-available soil P, and soil P balances were assessed at 0-30, 30-60, and 60-90 cm soil depth layers in unfertilized “Zero”, mineral “NK” and “NPK”, and combined mineral and organic “FYM+NK” (farmyard manure + NK) and “FYM+NPK” fertilization treatments. Composition of P fractions at different fertilization treatments was assessed using sequential chemical fractionation procedure. P use efficiencies for each crop in the crop rotation (sugar beet, spring barley, potato, and winter wheat) were determined. The 110 years of P fertilization at rates between 22 and 55 t ha^{-1} $year^{-1}$ resulted in significant increase in soil P stocks up to 60 cm depth. The total P accumulation comprised 1.3 t ha^{-1} for NPK, 1.1 t ha^{-1} for FYM+NK, and 3.1 t ha^{-1} for FYM+NPK. The increase in total P was mainly associated with the increase of inorganic phosphorus (Pi) fraction. An increase in organic phosphorus (Po) was only observed in FYM+NPK (0-30cm). The available P

contents also significantly increased to above recommended values in P fertilized treatments. Soil P was mostly presented by Ca- as well as Fe- and Al-bound fractions. Cultivation of crops without P fertilization in Zero and NK treatments resulted in a negative P balances and in a reduction of total and available soil P below recommended levels. Between 1903 and 1981, average P use efficiency of different crops varied between 31 and 70 %. After 1981, a reduction of mineral P application rates, along with crop variety-dependent yield increases, resulted in an improved P use efficiency for all crops, with the highest P use efficiency for winter wheat. Our results revealed, that for the Chernozem soil, an organic fertilization combined with additional supply of N and K mineral fertilizers (FYM+NK) resulted in the highest P use efficiency. P in this treatment is exclusively added in manure form, which reduces fertilization costs, and in addition, manure application may increase soil organic matter, and positively affect soil fertility.

(8293 - 2116) Chemical atributes and the specific surface area of Oxisol under different uses

Antônia Finkler Dias Fernandes[1]; Tatiele Fruett Santos[2]; Alberto Vasconcelos Inda[3]
Graduation student of the agronomy course, Federal University of Rio Grande do Sul / UFRGS, 7712 avenue Bento Gonçalves, Porto Alegre, zipe code 91540000, RS, Brazil, antonia_finkler02@hotmail.com[1]; PhD student, Federal University of Rio Grande do Sul / UFRGS, 7712 avenue Bento Gonçalves, Porto Alegre, zipe code 91540000, RS, Brazil, tatielefruett@yahoo.com.br[2]; Professor, Federal University of Rio Grande do Sul / UFRGS, 7712 avenue Bento Gonçalves, Porto Alegre, zipe code 91540000, RS, Brazil, alberto.inda@ufrgs.br[3]

Soil conversion under field in farming or planted forests alters the dynamic balance of the system and can induce chemical and physical changes. The study was accomplished in a farm in the city of Júlio de Castilhos in the region of plateau of Rio Grande do Sul, Brazil. The objective was to evaluate soil use with soybean farming (FAR) and eucalyptus forest (EUC) on chemical and physical characteristics of a Oxisol, in relation to the same soil under native pasture (NP). The planting of eucalyptus and soybean under no-tillage system began 30 years ago. In the three treatments, the soil was sampled in triplicate at depths 0-5, 5-10, 10-20, 20-40 and 40-60 cm. In the ADFS fraction (Æ<2 mm) was analyzed the particles sizes and the specific surface area (SSA), and chemical characteristics of assorted complex. The particle size analysis was performed by the pipette method. The specific surface area (SSA) was estimated by the water adsorption method. The chemical analyzes were realized in the ADFS for the following components: pH in H2O, Ca, Mg, K, H+Al and P. Were calculated the base sum (BS) and the cation exchange capacity (CEC). The total organic carbon (TOC) fraction in ADFS was determined by dry combustion in a TOC analyzer. The fractions of the particle size analysis didn't differ between treatments. The SSA values were also similar, except in the 0-5 cm layer of the EUC, where SSA increades in relation to the NP. This result is related to the increse of TOC verified in the 0-5 layer of the EUC and corroborates with the positive effect of organic matter on soil SSA values. In the others layers, there were no changes in TOC levels between treatments. The EUC and FAR increased the sum of bases, mainly Ca and Mg, in the depths of 20 and 40 cm, respectively; and the contents of P to the depth of 10 cm. In the EUC, where no correctives and fertilizers were applied, these increases elapsed by biocycling while in FAR they were the result of the addition of limestone and fertilizers containing NPK. The addition of limestone in the FAR reduced the active acidity of the soil up to 40 cm of profundity. Just as the SSA, the CEC differed between treatments only in the 0-5 layer of the EUC, due to the increases in TOC. The results indicated a maintenance of the chemical quality of the Oxisol after thirty years of reforestation with eucalyptus and soybean culture under no-tillage, such as the importance of the organic matter to the SSA and the CEC of the soil.

(6988 - 2305) Chemical fractionation of copper and zinc in some Mollisols of Córdoba (Argentina), in conditions of waterlogging

Eduardo Buffa[1]; Silvia Ratto[2]
Universidad Nacional de Córdoba, Argentina[1]; Universidad de Buenos Aires, Argentina[2]

Excess water in soils of the Pampa plain of Córdoba, Argentina, is frequent and there are no studies that show its effect on the availability of micronutrients. Zinc is regularly applied in crops with variable responses. Cu is less important, poorly applied in crops and more in pastures. The objective of the work was to analyze the effect of waterlogging on the Cu and Zn pools by the following sequential fractionation method: Step 1 to 4: Labile pools extractable with DTPA (reaction time of 30, 30, 60 and 1000 min, respectively). Step 5: Pool in easily reducibles Mn oxides. Step 6: Pool in amorphous Fe oxides. Step 7: Pool in humified OM. Step 8: Residual pool. The soils were entic Haplustol, typical Haplustol and typical Argiustol. The soils were conditioned in 50 ml plastic pots in triplicate, saturated with destilled water during 0, 15, 30 and 60 days. Subsequently, they were air dried and fractionated with the method described above. The following hypotheses were proposed: H1: Waterlogging affects the metal-matrix interaction, modifying the bonds energy with a decrease in stability. H2: Reduction of the ligand energy favors more labile structures. H3: The increment of the labile structures of the element, increases the extractable quantities by complexation. Copper results: The sum of DTPA, steps 1 to 4, increased from 0.5 to 2 mg kg^{-1} with 30 days of waterlogging in the three soils. The residual fraction of Cu (step 8) was the only one favored by the waterlogging, increasing from 0 to 0.5 mg kg^{-1} in the three soils. The total extracted Cu for the fractionation was 9 and 12 mg kg^{-1}, in Haplustols and Argiustol, respectively. Zinc results: Step DTPA 1 increased from 1 to 2 mg kg^{-1} with waterlogging of 30 days in the three soils, without effect in the DTPA 2 to 4 extracts. The most favored Zn bound fraction due to waterlogging was amorphous oxides of Fe that increased from 1.5 to more than 3 mg kg^{-1} in all soils. The total extracted Zn by the fractionation was 9 and 14 mg kg^{-1} in Haplustols and Argiustol, respectively. Conclusions: Waterlogging favored the release of both metals. This results can explain the symptoms of Zn deficiency diagnosed in times of drought and its disappearance with the rewetting of the soil. The hypotheses can be accepted with caution but should be considered in regional experiments with fertilizers because the increments of Zn and Cu extracted due to waterlogging were important.

(3222 - 1548) Chemical properties of a Red Latosol cultivated under a no-till system and under native semi-deciduous dry forest in the Cerrado.

Diogo Barbosa Silva[1]; Sara Aparecida Guimarães de Souza[1]; Cláudia Fabiana Alves Rezende[1]
UniEVANGÉLICA[1]

The effect of vegetation on the soil can be perceived by comparing the soil properties between areas planted to no-till and forest areas. The objective of this work is to investigate the characteristics that increase

the soil fertility of the Cerrado, evaluating conservationist systems and without anthropic action. Samples were collected in a Red Latosol, clayey texture (44%), in two contiguous areas, 00-0,2 and 0,2-0,4 m, in an area of agricultural experimentation and semi-deciduous dry forest area, both located in UniEVANGÉLICA, Experimental Unit (Latitude 16º19"36' S and Longitude 48º27"10' W). Physical and chemical analyses of both samples were performed to evaluate the fertility of the areas. The introduction of the agricultural system caused a nutritional imbalance modifying the chemical properties of the soil. Conservation management leads to improved soil fertility, but not yet matched fertility in native forest area. At the two observed depths there is a statistical difference for K, Ca, Mg and H+Al. There is a discrepancy of values for MO and P, but no statistical differences were observed. There is a greater accumulation of MO, K, Ca and Mg in the native forest area, which is directly linked to the nutrient cycling promoted by the constant deposition of organic residues on the soil surface. The nutrient that dissociates the observation in the superficial and subsurface layer analysis is the P, in greater concentrations in the agricultural area. This difference may be associated with fertilizer residue. It is observed that MO, in higher concentration in the native forest area, provides higher CTC for the soil. The high base saturation observed indicates that most of the soil CTC is occupied with essential cations (Ca, Mg and K), noting that both native forest soil and agricultural soil are suitable for the correct nutrition of the plants. Soil cultivation with frequent MO additions is the most rational and ecological way of increasing soil fertility, which occurs in conservationist management such as no-tillage system. Soil cultivation under tropical conditions managed in a conservationist way shows an improvement in the chemical conditions, making the fertility of these agricultural areas equip themselves with native forest areas.

(6362 - 1420) Control of potential acidity in soil with variable load after surface application of micronized correctives

Jasmine Jurich Pillati[1]; Bruna Simone Siqueira[1]; Adriel Ferreira da Fonseca[1]; Jessica Alves dos Santos[1]
State University of Ponta Grossa[1]

Acidity is one of the main constraints to food production in the world. Limestone material is the most commonplace used product to correct soil acidity, but, requiring a long time for adequate control in the soil layer 0-20 cm, in no till system (NT). Consequently, there is a need to search for more efficient alternatives to control soil acidity. Micronized correctives, which has smaller particle size and higher specific surface area when compared to dolomitic limestone (DL), and can react faster in the soil. The objective of this study was to evaluate the pH values over 48 months after the superficial application of liming materials: granulated micronized calcite (CMG), granulated micronized dolomite (DMG) and carbonated suspension (SC) and compare them with the DL. The experiment was installed in Palmeira -PR, on Inceptisol, under NT for more than 15 years. The experimental design was complete randomized blocks in split-plot desing with four replications. Four liming materials were studied in the plots: DL, GMC, DMG and CS. In the subplots, doses were studied aiming to increase the soil base saturation (V) to 50, 70 and 90%, besides to the control treatment. In June 2012 were applied in the soil surface, without incorporation. At 6, 12, 24, 36 and 48 months after superficial application, soil samples from the 0-5, 5-10, 10-20, 20-40, and 40-60 cm layer were collected and taken to the laboratory for determination of pH values. Data were submitted to univariate and multivariate statistical analyzes. The DL was the least corrective to increase pH values at 6 and 12 months. GMC and CS increased pH over 48 months. The special liming materials were more efficient than the DL in reducing the acidity in the superficial layers of the soil until 24 months after they were applied. Micronized correctives can increaase productivity by the need for exploration of new areas.

(4894 - 2512) Effect of base fertilization with fertilizers with or without sulfur on the soil and the sugarcane

Marcelo de Almeida Silva[1]; Lucas Almeida de Holanda[2]; Gabriel Henrique Germino[1]; Marcela Cristina Brunelli-Nascentes[1]; Vinicius Ribeiro Arantes[1]; Mariana Peduti Vicentini Sab[1]
Sao Paulo State University - School of Agricultural Sciences[1]; IFMT[2]

The objective of this research was to evaluate the soil chemical and nutritional attributes of sugarcane after base fertilization with different fertilizers enriched or not with sulfur. The experiment was conducted in a commercial area, located in Lençóis Paulista, SP, Brazil, in the 2013/2014 season, in production environment C. A randomized blocks experimental design was used, with six treatments, (1) (07-33-18 + 9% S) + 298 kg ha-1 KCl; (2) (06-25-24 + 9% S) + 100 kg ha^{-1} triple superphosphate + 397 kg ha^{-1} KCl; (3) 09-25-25 + 490 kg ha^{-1} of MAP + 87 kg ha^{-1} of urea + 423 kg ha^{-1} of KCl; (4) 04-20-30 + 320 kg ha^{-1} of MAP + 180 kg ha^{-1} of single superphosphate + 500 kg ha^{-1} of KCl; (5) 05-25-25 + 410 kg ha^{-1} of MAP + 173 kg ha^{-1} of single superphosphate + 417 kg ha^{-1} of KCl and (6) (90-23-18 + 15% S) + 300 kg ha^{-1} KCl, with 4 replicates. All treatments received 58.5 kg ha^{-1} of N, 150 kg ha^{-1} of P_2O_5 and 225 kg ha^{-1} of K_2O. The variety used was RB966928. At the time of harvesting, macro and micronutrient contents were evaluated on leaf, stalk and sheath. In addition, leaf analysis was performed 180 days after sprouting and also soil analysis at the end of the crop cycle. Data were submitted to analysis of variance, complemented with the Tukey test, considered significant when $p < 0.05$. Regarding the soil, treatment 1 differed positively from the others as to CTC, sum of bases and calcium content. The highest values of sulfur and boron content were observed in treatments 1 and 6. Regarding foliar analysis at harvest, there was a higher accumulation of nitrogen in treatments 1 and 6. Higher levels of phosphorus, calcium and copper were observed in the treatment 1. The fertilizer with higher concentration of sulfur provided greater accumulation in the leaves of the nutrients sulfur and manganese. The analysis of the sheath indicated that treatment 1 resulted in higher values of nitrogen, phosphorus and potassium, and treatment 6 in the higher sulfur content. Treatment 2 provided the highest nitrogen content exported by the stalk. Treatments 2 and 6 resulted in higher sulfur and copper contents. Treatments 1 and 6 accumulated higher amounts of iron. The highest amount of zinc was accumulated under the treatment 3. Sulfur-enriched fertilizers provided nutritional gains for the sugarcane crop, maintaining the sum of bases and CTC.

(6505 - 1719) Effect of co-inoculation on grain production in Wheat / Soybean succession.

Carolina Fedrigo Coneglian[1]; Marcelo Augusto Batista[1]; Renan de Oliveira Camparoto[1]; Fabricio Linares Mazzi[1]; Bruno Maia Abdo Rahmen Cassim[1]; Rodrigo Sakurada Lima[1]; Marcos Renan Besen[1]; Jessica Caroline Coppo[2]
UEM[1]; [2]

Plant residues left on the soil in succession of crops contribute to the increase of organic matter content, microbiological activity, nutrient availability and grain production. Allied to this, nitrogen fixing bacteria are used for better efficiency in the use of fertilizers. Currently in Brazil

has been used inoculants with Bradyrhizobium japonicum, Azospirillum brasilense and co-noculation with both. In this sense, the objective of this study was to study the effect of co-inoculation on grain production in wheat and soybean succession. The experiment was carried out in Campo Mourão - Paraná - Brazil, in a dystroferric Red Latosol with a very clayey texture. The study was conducted in a randomized complete block design, with 4 treatments, with 5 blocks and 2 replicates, making 40 experimental units of 36.0 m^2 each. The treatments were tested in two production systems, beginning in the wheat harvest and ending in the soybean crop. The inoculants used were the Masterfix L. soybean inoculant (MS) 200 mL/50 kg seed dose in soybean, co-inoculant with Bradyrhizobium japonicum + Azospirillum brasilense (BA) 200 mL ha^{-1} dose in wheat and 200 mL/50 kg seed in soybean and without inoculant (SI). It was sown Tbio Toruk wheat with base fertilization 150 kg ha^{-1} of 16-16-16 and covering 70 kg ha-1 of nitrogen and sowed soybean NA5909 with base fertilization 200 kg ha^{-1} of 02-20-18. The treatments consisted of T1: SI in wheat and MS in soybean, T2: BA in wheat and MS in soybean, T3: SI in wheat and BA in soybean and T4: BA in wheat and BA in soybean. For the statistical analysis were added the average yields of grains and mass of one thousand grains. The collected data were summed and submitted to analysis of variance by the Scott-Knott test (α = 5%) using the statistical program SISVAR (1996). For the sum of the production of grains produced in the wheat and soybean system, no significant statistical differences were observed, with average grain yield for T2 = 9,715,46; T1 = 9,539.91; T3 = 9,526.85 and T4 = 9,333.08 kg ha^{-1}. For the mass sum of a thousand grains no significant statistical differences were also observed, with mean weight for T3 = 183.73; T4 = 183.19; T1 = 183.09 and T2 = 182.09 grams. It was concluded that the co-inoculation in the succession of wheat and soybean did not alter the production of grains and mass of thousand grains produced.

(6106 - 3042) Effect of land use change on soil nitrogen availability in northeastern Amazon

Sílvia Fernanda Mardegan[1]; Arianne Flexa de Castro[1]; Manoela Sena Avelar[1]; Richardson Sandro dos Santos Freitas[1]; Fabio Alexandre Oliveira Teixeira Filho[1]
Federal University of Pará[1]

Nitrogen is known as one of the elements that most limit plant productivity in natural ecosystems. Tropical forests are characterized by high nitrogen (N) inputs and cycling, enabling these systems to accumulate and recycle large amounts of N. With their conversion to croplands, a range of effects on soil physical-chemical properties are likely to be expected, reflecting into changes in ecosystem productivity and nutrient availability. Land-use changes may lead to lower soil N cycling rates, which in turn can increase N gaseous losses, increasing the concentration of greenhouse gases in the atmosphere. Here we assessed how land use change affects soil N availability in northeast Amazon. The study was carried out at Agropalma agroindustry complex, Tailândia – PA, Brazil. Soils sampled are typic dystrophic Yellow Argisol, with sandy texture (around 60%), high acidity (pH around 4), and low fertility (cation exchange capacity around 2 $cmol_c\ dm^3$; sum of bases around 19%). We sampled soils (0-10, 10-20, and 20-30 cm), from organic and conventional oil palm (*Elaeis guineensis* Jacq., Araceae) plantation, under palm rows, frond piles, and inter rows. Additionally, we sampled soil at a terra firme forest nearby, which were used as reference. Whether organic or conventional, oil palm plantation had higher soil N content (0.76 ± 0.03 and 0,67 ± 0,02 g kg^{-1}, respectively) than terra firme forest (0.55 ± 0.33 g kg^{-1}). Soil C:N ratios were similar among land use types (around 14). Soil N stocks at both oil palm plantations were around 1 Mg N ha^{-1}, being almost 30% higher than at terra firme forest. When comparing organic and conventional plantations, we observed a rise in soil N stock from superficial layer (0-10 cm) under frond pile at organic plantation. Evidences suggest a similar trend at palm rows and between them. These early findings suggest the importance of organic plantations to increase nitrogen storage in Amazon systems.

(2513 - 1390) Effect of potassium fertilization different cassava cultivars under tropical conditions

Claudio Hideo Martins da Costa[1]; Rogério Borges de O. Paz[1]; Álvaro Guilherme Oliveira de Melo[1]; Bárbara de Fátima Silva Moura[1]; Letusa Momesso Marques[2]
Universidade Federal de Goiás[1]; Universidade Estadual Paulista[2]

The cassava crop is considered rustic, mainly because it expresses reasonable root production under adverse soil fertility conditions, although the potential of root production and quality of cassava varieties may have better responses in well - managed crop. Thus, potassium is one of the most important nutrients for the growth of cassava plants, by enhancing the development of shoots, carbohydrate and proteins content, as well as improving the use of water. Therefore, with the realease of new materials in the market beyond the study of adaptability, it is necessary to know the potassium requirements for each of them. In this sense, the objective was to evaluate the performance of two new cultivars under different levels of potassium fertilization. The experiment was carried out in Jataí, GO, in a clayey Rhodic Ferralsol. The chemical attributes of the topsoil were: pH 4.6, K of 0.09 $mmol_c\ dm^{-3}$ and base saturation of 37%. The experimental design was a randomized complete block design in a 2x4 factorial scheme, with four replications. The treatments were composed of two cultivars (BRS 396 and BRS 397) and four K rates (0, 30, 60 and 120 kg ha^{-1} K_2O). The cassava was planted in October 2016, using a spacing of 1.00 x 0.80 m at a depth of 0.10 m. The fertilizer used was 20 kg ha^{-1} of N and 50 kg ha^{-1} of P_2O_5, respectively, and for K_2O were used the pre-established rates. The management was performed according to the needs. The harvest was carried out in July 2017. At the time of harvesting, the following variables were evaluated: Fresh and dry shoot production, root yield components, root fresh and dry matter production and partition of assimilates. The cultivars presented similar shoot dry and fresh matter production, differing only in the dry and fresh mass of roots, with higher productivity for the BRS 397 cultivar, about 12% higher, which is associated with higher root production per plant. Potassium fertilization, independently of the cultivar, increased the production of fresh and dry matter of shoots, which provided a linear increase in the number of roots per plant, directly reflecting the root productivity. However, the assimilate partition was not altered by the treatments. Therefore, it is evident that the producers of cassava have not reached all crop potential, since it is a culture considered traditionally rustic, but that is shown highly responsive to potassic fertilization.

(4660 - 629) Eucalyptus productivity at 44 months in a coppice system according to the number of shoots per strain and mineral fertilization

Natasha Mirella Inhã Godoi[1]; Marcelo Carvalho Minhoto Teixeira Filho[1]; Salatiér Buzetti[1]; Thiago de Souza Celestrino[1]; Rodolfo de Niro

Gazola[1]; Willian Lima Rodrigues[1]; Jeferson Silva de Souza[1]
Faculdade de Engenharia de Ilha Solteira - Universidade Estadual Paulista[1]

Forest management through shallow cutting and regeneration by sprouting of the strains characterizes the coppice system, presenting the advantage of a high initial growth rate of shoots when compared to the first production cycle. However, despite the apparent advantage, there is a decrease in productivity between the production cycles, attributed to nutrients removal due to the eucalyptus harvest. The objective of this study was to evaluate the eucalyptus productivity as a function of the number of sprouts per strain and doses of mineral fertilizer. The experiment was conducted in Três Lagoas - MS, Brazil, being in an Entisol (orthosic Quartzarenic Neosol), with the definition of shoots in April 2013. The experimental design was a randomized block with 8 treatments and 4 replicates, arranged in a 2x4 factorial scheme, with: one or two shoots per strain in the second cycle; and four doses of mineral fertilizer (0, 50, 100 or 200% of the recommended, equal to 200 kg ha^{-1} of the formula 06-30-06 + 1% Ca + 3% S + 1% Mg + 1.5% Cu + 1% Zn). The planted eucalyptus clone was I-144, spaced 3 x 2.5 m. Each useful plot contained 49 plants and the evaluations of plant height, diameter at breast height (DBH), estimated volume of bark and average annual increment (AAI) of eucalyptus were performed at 44 months after the definition of shoots. The analysis of variance and Tukey test at 5% probability were used to compare mean number of shoots and adjusted to regression equations to analyze the effect of fertilization doses. Eucalyptus with one sprout per strain showed higher plant height and DBH in relation to two sprouts per strain, evidencing the competition among sprouts of the same strain by water, light and nutrients, in relation to the estimated volume of bark there was no difference in the number of shoots per strain. These eucalyptus evaluations were not influenced by the increment of the mineral fertilizer doses, however, it is worth noting that there was an increase of approximately 14% in the estimated volume of wood in the application of the dose of 100% of the fertilization used. The IAA of eucalyptus was 112.3 m^3 ha^{-1} year, and there was no difference in the conduction of one or two shoots per strain, or effect of the increase in mineral fertilizer doses for IMA, even in sandy soil with low fertility. This is due to the nutrients cycling of litter from both the first eucalyptus production cycle and this second productive cycle.

(1604 - 2976) Evaluation of calcium absorption by 'yellow' melon with green manure use in the Brazilian semiarid

Acacio Figueiredo Neto[1]; Antonio Pereira Filho[1]; Jose Teixeira Filho[2]; Vanderlise Giongo[3]
Universidade Federal do Vale do São Francisco[1]; Universidade Estadual de Campinas[2]; Empresa Brasileira de Pesquisa Agropecuária - Embrapa Semiárido[3]

In Brazil, melon production is mainly concentrated in Northeast region, where about 95% of the melon is produced. The absorption of large amounts of nutrients in short periods of time is a nutritional characteristic of melon. However, the nutrients extraction by a crop depends on factors related to the growing environment, such as soil type, climate and water management, and internal or plant-related factors, among which we can cite its age and genetic potential. The objective was to evaluate the absorption curve and the calcium contribution by green manure in the development of 'yellow' melon produced in the Brazilian semiarid region. A randomized blocks design, in a split-plot scheme, with four replications, is being used. Plots will be composed by three green manure : natural vegetation, composition 1 (25 % grass / oilseed + 75 % legume) and composition 2 (25 % legume + 75 % grass/oilseed) and two tillage systems with and without plowing. The sampling of melon plants were carried out weekly at 11, 18, 25, 32, 39, 46, 53 and 59 days after transplantation, in a total of 8 samplings. The patterns of nutrient accumulation during the plant growth period followed the time course of dry matter production. The accumulation of nutrients was reduced in the first 18 days after transplantation, with mean values of 4.7 kg ha^{-1} Ca, increased markedly in the following week (25 days after transplantation), flowering period, with mean values of 27.9 kg ha^{-1} Ca and intensifying continuously until the end of life cycle. Composition 1 contributed with the highest amount of Ca to the crop, releasing 139.3 kg ha^{-1} Ca during the melon cycle. The organic residues with a higher proportion of legumes, can meet the demand of Ca for melon up to 39 days after transplantation.

(1435 - 512) Fate of phosphorus under long-term grazed pasture in New Zealand Leo Condron Lincoln University, Christchurch, 7647, New Zealand (leo.condron@lincoln.ac.nz)

Leo Condron[1]
Lincoln University[1]

The fate of fertilizer phosphorus in intensively managed agroecosytems remains poorly understood. Using a combination of new and historic data, a mass balance approach was used to assess and quantify the impact of over 60 years of different phosphorus fertilizer and irrigation regimen on the spatial distribution and dynamics of phosphorus under grazed pasture. Replicated field plots had received different inputs of superphosphate fertilizer (nil (Control), 188 kg ha^{-1} $year^{-1}$ (188PA), and 376 kg ha^{-1} $year^{-1}$ (376PA)) and irrigation (nil (base average rainfall of 740 mm $year^{-1}$; control), together with flood irrigation applied when gravimetric moisture in the topsoil dropped below 10 or 20% (i.e. rainfall + 260 mm $year^{-1}$ of supplemental irrigation [$irrigation_{10\%GM}$] and rainfall + 770 mm $year^{-1}$ [$irrigation_{20\%GM}$], respectively). Substantial increases in pasture production and animal grazing capacity occurred in response to fertilizer and irrigation inputs, which in turn resulted in increased phosphorus removal and transfer in animal products, animal excreta (stock camp transfer and irrigation outwash) and by leaching. Accumulation of phosphorus in the soil profile to 100 cm was 5.3 kg P ha^{-1} $year^{-1}$ (31% of applied phosphorus) for the 188PA treatment, compared with 21.7 kg P ha^{-1} $year^{-1}$ (64% of applied phosphorus) for the 376PA treatment, while transfer to stock camps and losses by irrigation outwash were estimated as 3.8-4.6 kg P ha^{-1} $year^{-1}$, which represented 19-22% of applied phosphorus. Combined annual phosphorus removal in animal products, internal dung transfer, and loss in irrigation outwash were also directly related to irrigation frequency and increased from 8 to 18.6 kg P ha^{-1} for the $irrigation_{10\%GM}$ and $irrigation_{20\%GM}$ treatments, respectively. These findings emphasize the need to develop strategies to increase utilization of accumulated legacy phosphorus in soil and reduce phosphorus losses in order to improve fertilizer use efficiency in intensive pastoral agroecosystems.

(6426 - 2157) Influence of biofertilizer in the soybean response to phosphorus and potassium fertilization

Adilson Pelá[1]; Lucas Brennon Romão Crispim[1]; Luiz Henrique Barros Cirino[1]; Rafael Umbelino Bento[1]; Ivan Carneiro Custódio[1]

Universidade Estadual de Goiás, Câmpus Ipameri[1]

The soybean (*Glycine max* (L.) Merrill) is one of the main agricultural crops produced in the world. Currently, large amounts of nutrients are applied to soils, with phosphorus and potassium being key elements for increasing or limiting the production of soybeans and other crops. The use of biofertilizers can stimulate the development of the root system, favor the biodiversity of microorganisms and improve the absorption of nutrients from the soil. The objective of this work was to evaluate the influence of biofertilizer on the response to fertilizations with P and K by the soybean crop. The study was carried out in a field in the municipality of Ipameri - GO (17º43'20 "S and 48º09'44" W) and an altitude of 800 m, in Oxisol (Red-Yellow Latosol). The experimental design was a randomized complete block design, in a 2x5 factorial scheme with four replications. The first factor was the presence or absence of the application of the biofertilizer (Bacsol + Orgasol), containing strains of rhizospheric microorganisms; the second factor was the variations in the doses of phosphorus and potassium in the base fertilization, as follows: complete base fertilization T1 - 100% of the doses of P and K; T2 - 0% P + 100% K; T3 – 100% P + 0% K; T4 – 50% P + 50% K; e T5 - Control (0% of P and K). Based on the soil analysis, the full doses (100%) of phosphorus and potassium were 100 kg ha^{-1} of P_2O_5 and 80 kg ha^{-1} of K_2O, using triple superphosphate and potassium chloride as sources. The plot consisted of eight planting lines with 5 m in length, spaced at 0.42 m. The plot area was the four central lines, discarding 0.5 m at each end. In the treatments that were used the biofertilizer (Bacsol + Orgasol) the application was done via seed treatment. Seeding occurred on November 4, 2015 by mechanical means (Precision Seeder) in order to obtain a population density of 260,000 plants ha^{-1} of the variety Monsoy 7739 IPRO. Plant height and number of pods per plant were not influenced by treatments. The mass of a thousand grains was higher with the biofertilizer only when the fertilization with P and K was integral. Without fertilization with P and K or with only half of the adequate doses of these nutrients, better results were verified when the biofertilizer was used. Phosphorus was the nutrient that most limited soybean yield. The use of the biofertilizer allowed good yields even when no sowing fertilization was used, or when only 50% of the P and K were used.

(9682 - 2518) Influence of proportion and source of potassium fertilizers on soybean yield

Marcelo de Almeida Silva[1]; Marcela Cristina Brunelli-Nascentes[1]; Vinicius Ribeiro Arantes[1]; Mariana Peduti Vicentini Sab[1]; Renan Fonseca Nascentes[1]; Mirela Mayumi Nagaoka[1]
Sao Paulo State University - School of Agricultural Sciences, 1780 Jose Barbosa de Barros St, Botucatu, 18.610-307, Brazil[1]

The objective of this research was to evaluate the influence of the proportion and the source of potassic fertilizers, double magnesium and potassium sulfate ($KMgSO_4$) and potassium chloride (KCl), in soybean production components and yield. The experiment was developed at the School of Agricultural Sciences (FCA/UNESP), in Botucatu, SP, Brazil, in the 2014-2015 and 2015-2016 seasons, in a red dystroferric nitosol. A randomized blocks experimental design was used, with five treatments, which received 200 kg ha^{-1} of the formulated 09-46-00 in the base fertilization: (1) 100% KCl; (2) 75% KCl + 25% $KMgSO_4$; (3) 50% KCl + 50% $KMgSO_4$; (4) 25% KCl + 75% $KMgSO_4$ and (5) 100% $KMgSO_4$, all applied after sowing, before the germination, with 4 replicates. The cultivar used was BMX TURBO RR with density of 18 plants m^{-1}. The evaluations of chlorophyll content, SPAD index and GreenSeeker were performed in the V3, V5 and R3 stages at the first season. In the season 2015-2016 the chlorophyll content and the leaf area index were evaluated in the V4, V5 and V7 stages. Plant height, first pod insertion height, number of branches, number of pods in the branches, number of pods in the main branch, main branch diameter, weight of 100 grains and productivity were evaluated at harvest time. Data were submitted to analysis of variance, complemented with the Tukey test, considered significant when $p < 0.05$. In the experiment of the 2014-2015 season, the highest SPAD index in the V3 stage was verified in the treatment 75% KCl + 25% $KMgSO_4$, whereas in the 100% KCl treatment the lowest one was observed. In the V5 stage, the 100% KCl treatment caused the lowest SPAD index and GreenSeeker, while the lowest values of chlorophyll *a* and *a + b* were verified in the 50% KCl + 50% $KMgSO_4$ treatment. Also, the 100% KCl treatment provided the lowest leaf area and leaf area index, while the highest averages were in the treatment 75% KCl + 25% $KMgSO_4$. The first pod insertion height was higher in the 100% KCl treatment. The highest yields were verified in the treatments 75% KCl + 25% $KMgSO_4$ and 100% $KMgSO_4$, a result that was repeated in the second season with a 14% increase over the 100% KCl treatment. The treatments with $KMgSO_4$ provided higher grain yield, which was influenced by some variables, such as the SPAD index and GreenSeeker in the vegetative stages.

(9944 - 1201) Influence of soil management and depth on pH, Al and organic matter

Patricia Rojas Nerhot[1]; Daisy Leticia Ramirez Monzon[1]; Arnulfo Encina Rojas[1]; Jimmy Walter Rasche Alvarez[2]
Facultad de Ingenieria Agronomica. Universidad Nacional del Este.Paraguay[1]; Facultad de Ingenieria Agronomica. Universidad Nacional del Este. Paraguay[2]

Alto Paraná soils are formed from basaltic igneous rocks, having as main characteristics the high content of clays, iron oxide and aluminum, has a fertility classified between medium to high, pH acid to slightly acidic and high aluminum contents causing a chemical degradation, this last factor being considered as a problem for the farmers of the region, since they have variations according to the soil depths and management, considering this, the research goal was to observe and analyze the relationships between Al^{+3}, pH; organic matter, clays in different ways and depths. The sampling was carried out in the Minga Guazú-Paraguay District, with an area of 489.5 km^2 in four managements; forest, direct seeding, conventional system and pastures, each one at six depths of 0-5, 5-15, 15-30, 30-60, 60-100 and 100-150cm, totaling 216 samples, of a stratified random sampling. The samples were analyzed in the Soil Laboratory of the Facultad de Ingeniería Agronómica in the Universidad Nacional del Este. In the results was observed that the forests pH appeared low, with Al^{+3} in toxic form and high content of organic matter. Al^{+3} levels increased from 30cm depth. On the surface (0-5 cm) the organic matter appeared high, with a low pH. The correlation data were negative between Al^{+3} and organic matter, inversely proportional relationships were also found between pH and Al^{+3}; however, a positive relationship between clay and Al^{+3} was observed according to the *Spearman* analysis. Clay soils such as Oxisols have high Al^{+3} content related to soil formation. Management that involve less soil removal and higher organic matter content can reduce the toxic effect of exchangeable acidity.

(5489 - 736) Investigating polyhalite nutrient movement through soil profiles

Timothy D Lewis[1]; Paul D. Hallett[2]; Graeme I Paton[2]; Luke Harrold[2]
Sirius Minerals[1]; University of Aberdeen[2]

Polyhalite ($K_2SO_4.MgSO_4.2CaSO_4.2H_2O$) is increasingly becoming of interest as a fertiliser with the discovery of the world's largest resource of over 2.5 billion tonnes in North Yorkshire, UK. Important to understanding the agronomic performance of polyhalite is the movement of nutrient through the soil profile over several years. This study uses leaching columns to investigate how the equivalent of several years of leaching affects the movement of nutrients (K, Ca, Mg and S) through an arable, sandy loam soil. The treatments evaluated were: (1) 0 kg ha^{-1} polyhalite, (2) 711 kg ha^{-1} polyhalite powder, (3) 711 kg ha^{-1} polyhalite granules and (4) and 166 kg ha^{-1} potassium chloride. Treatments 2 – 4 represent an application of 100 kg K_2O ha^{-1}. Columns were saturated and a flow rate of 100 mm hr^{-1} was maintained until 4500 mm had been leached through the sample (equivalent to five years UK average rainfall). Leachate analysis showed polyhalite granules yielded greater release of potassium, calcium, magnesium and sulphur than polyhalite powder and potassium chloride over the five-year period. Differences between treatments are likely due to the availability of nutrients from the fertiliser and the subsequent ionic interactions with soil clays. The results suggest that polyhalite provides a viable alternative K fertiliser, with potential added benefits of Ca and Mg.

Keywords: polyhalite, nutrient movement, fertilizer

(3706 - 306) K management strategies to achieve K balance in sandy soils of South central coastal Vietnam

Hoang Thi Thai Hoa[1]; Do Thanh Nhan[2]; Surender Mann[3]; Richard W. Bell[3]
University of Agriculture and Forestry, Hue University, Hue city, Vietnam[1]; Agricultural Science Institute for SCC Vietnam, Quy Nhon, Vietnam[2]; Murdoch University, Perth, Western Australia[3]

Sands are common in Southeast Asia where intense wet season rainfall and irrigation increase the risk of nutrient leaching. Irrigated peanut productivity on the sands in south-central coastal Vietnam can be increased by K fertilizer but the optimum rate for sustainable production has not been determined. The aim of this study, conducted from 2015 – 2016 on two sands in Phu Cat district, Binh Dinh province, Vietnam, was to determine the effects of different K management practices on soil K balance under irrigated peanut crops and to propose the best management practice for K management to increase peanut yield and optimize soil K balance. Peanut yields were the highest at 100 kg K/ha with 19 – 22% increase compared to control. In all three experiments, K outputs always exceeded K inputs resulting in negative soil K balance (from -33 to -110 kg K/ha) even at the highest K rate applied (75 - 100 kg K/ha). At 100 kg K/ha fertilizer application, soil K balance were less negative than the control from -13 to 6 kg K/ha (with added KCl) and -24 to 1 kg K/ha (with added K_2SO_4). Both 8 tons of farm yard manure and 10 tons of rice husk biochar/ha, decreased the negative soil K balance with 50 kg K as fertilizer/ha but did not eliminate it. In the peanut cropping system, K losses occur out of the fields mainly due to removal of crop residues (for animal feed) and leaching. Negative balances at field level in the long term will limit crop yields on deep sands. On-farm recycling of nutrients, especially from organic sources and using slow release K fertilizer are proposed for sustainable farming systems on deep sands. Further work is examining S balance in these cropping systems also.

(2982 - 3233) Making fertilizer practices efficient using polyhalite

Robert Meakin[1]; Kiran Pavuluri[1]; Kwadjo Ahodo Timothy D Lewis[1]; Lino Furia[1]
Sirius Mineral[1]

Inappropriate application of nitrogen has resulted environmental impacts that has led to strict environmental regulation in Europe and elsewhere. Similarly, phosphorus impacts the environment by entering waterways, as a result of soil erosion, causing eutrophication. In England alone, 60% of nitrates and 25% of phosphates originate from agricultural land. At the same time, farmers need to increase yields to be able to feed a world population of 9.8 billion by 2050 whilst being environmentally responsible. Therefore, farmers need to explore new efficient fertilizer practices to adopt. The recent discovery of the world's largest deposit of polyhalite ($K_2SO_4.MgSO_4.2CaSO_4.2H_2O$) has raised interest in the mineral being used as a multi-nutrient fertilizer. Validation of polyhalite as an efficient fertilizer source required an extensive research programme to be commissioned that consists of over 260 trials on 32 crops in 17 different countries. This presentation will focus on presenting global findings from this extensive research programme on globally important crops. Trial results have shown that inclusion of polyhalite into fertilizer plans can increase yields and improve post-harvest soil fertility compared to current practices. The research also highlights that fertilizer plans using polyhalite can be more efficient with improved nutrient uptake for nitrogen, phosphorus, potassium, calcium, magnesium and sulphur.

Keywords: polyhalite, fertilizer use efficiency

(1648 - 2455) Management of the phosphate fertilization of soils with different textures under continuous cultivation of sugarcane in Brazil

Daniela Batista da Costa[1]; Fernando José Freire[2]; Suellen Roberta Vasconcelos da Silva[2]; Janyelle de Oliveira Lemos[2]; Nathalia Sobral Bezerra[2]
UFPB[1]; UFRPE[2]

Phosphate fertilization has been the main management responsible for increasing the productivity of sugarcane in tropical soils, because of the low levels of P in these soils and predominance of clay minerals that intensify P adsorption process. Thus, this research aimed to evaluate P availability in soils with different texture after phosphate fertilization in two crop cycles of the sugarcane and its effects in agricultural productivity. The research was developed in Northeast of Brazil in ultisols of texture clayey ($PVAd_2$), loamy sand (PADx) and sandy ($PVAd_1$). The experimental design was a randomized complete block with four replications, applying the following doses in first crop cycle (plant cane): 0; 40; 80; 120; 160 and 200 kg ha^{-1} of P_2O_5 and 0 and 40 kg ha^{-1} of P_2O_5 in second crop cycle (ratoon), using triple superphosphate as source of P. Its availability was estimated by melich-1 (M1) and anion exchange resin (AER). P contents extracted increased for both solutions, however the extracted rate depended of the soil characteristics, especially with regard to mineralogy, when the solutions was M1. There were evidences that increasing P doses was benefic to sugarcane productivity in both crop cycles for all soils, above all to PDAx in the ratoon, because of its initial higher P content and its lower P fixation capacity, suggesting that the soil has a longer residual effect. Thus, P availability depended of the chemical, physical and mineralogical properties of the soils, but P absorption by plants

might be optimized with the phosphate fertilization also in ratoon, especially on lower buffer capacity soils.
Keywords: Phosphorus availability; sugarcane; productivity.

(7399 - 1538) Mineral footprint of extensive agriculture in Buenos Aires province in the processes of soil acidification

Miriam E. Presutti[1]; Mirta G. García[1]
FCAyF-UNLP[1]

In Buenos Aires, the area allocated to extensive agriculture has been increasing in recent decades to the detriment of mixed systems. Grasses have been replaced with others crops of greater economic attractiveness, like the soybean, that combines its cycle with the wheat, allowing two harvests in the year. This causes a high extraction of nutrients that are not replaced in the same magnitude, generating soil degradation, such as acidification. In this work, two indicators were applied, Mineral Footprint (MF) and Mineral Exports Efficiency Index (MEEI) of the base cations. The MF accounts for the export levels of minerals, the amounts of nutrients contained in the grains produced. The MEEI relates the level of export of nutrients and the physical production of the set of crops in a region, is a measure of efficiency of production processes, the higher the value the lower the efficiency because more minerals are used to produce it. Data on harvested area (ha), production (t) and yield (kg ha^{-1}) per municipality were analyzed for 47 agricultural seasons from 1969/70 to 2015/16, for the main crops: wheat, corn, soybean and sunflower. The data were split into 5 decades, calculating the mean yield of each crop by summing the production divided by the sum of the harvested area in the same period. The MF/ha was determined, that is, the quantities extracted by the harvested grains of the basic cations Ca, Mg and K, expressed in kg ha^{-1}. Maps were generated to determine the spatial distributions of those extractions and therefore the vulnerability to acidification. The extractions in t for each decade of each nutrient were calculated multiplying the MF/ha by the harvested area. Summing all the municipalities the total MF for each crop and for each decade were obtained. The results indicate that 9.36 million tons of basic nutrients were extracted, in the 47 seasons for the 4 crops, corresponding 10% for Ca, 21% for Mg and 69% for K. Similar proportion is observed in all decades, although they are exponentially increasing. The soybean, in all periods, except the first one, was the crop with the highest total MF, leading to the extraction of 80% of Ca and K and 64% of Mg. Regarding the MEEI, they remained constant in all the periods for each crop; soy being the one that shows higher values: 0.26, 0.3 and 1.64 for Ca, Mg and K respectively; corn is the crop that showed the minimum values, being the most efficient; the values were 0.02, 0.14 and 0.34 for Ca, Mg and K.

(9370 - 1613) Nitrogen use efficiency associated with molybdenum

Lílian Angélica Moreira[1]; Geovânia Morais de Rezende[1]; Italo Kaye Pinho de Faria[1]; Edson Pereira da Mota[1]; Rafael Otto[1]
ESALQ/USP[1]

Maize is the most produced cereal in the world exceeding 1 billion tons. Nitrogen (N), among other nutrients, is the one that can more easily result in significant increases in yield. Among the micronutrients, molybdenum (Mo) is responsibility for nitrate reductase and consequently influence N use efficiency. In this way, a synergistic effect between Mo and N is observed, due to the Mo attend in N metabolism. The aim of this author was to evaluate the foliar Mo application in the efficiency of N fertilization and yield of second season maize. An experiment in an agricultural area located in the city of Uberlândia - MG (latitude 19º11'16,60" S, longitude 48º0'16,64"' W and altitude of 700 m). The climate of the region is classified as Cwa. The experiment was installed on February 23, 2017, after soybean crop harvesting, following the "out of season" maize (second season). The hybrid used was AS1633, VT PRO 3 technology. The plant population adopted was 56,000 plants ha^{-1}, spacing 0.5 m between rows. It was adopted a randomized block experimental design, with four replications, in a 4 x 2 factorial scheme, represented by four N rates (check plot, 60, 90 and 120 kg ha^{-1}), and two treatments of Mo supply (without Mo supply and foliar application of 55 g ha^{-1}). Treatments were applied at the V6 phenological stage of the crop. The maize harvest was performed on July 24, 2017. Analyzing the set of variables, it was found statistical differentiation for leaf Mo content regardless of the N rates applied (LSD, $P < 0.01$). The N rates influenced protein content (LSD, $P = 0.086$) and yield (LSD, $P = 0.067$) regardless of the Mo supply. The absence for interaction between Mo and N is explained by the N content in leaf, which evidenced this not to be a limiting factor; also the Mo dose applied may have been low. Although the Mo content has increased this was not responsible for increasing N use efficiency due the absence of yield gain under Mo application. The protein content in the grain had linear increase with yield gain, possibly because N rates. Second season maize showed response to N fertilization regardless of foliar Mo supply. Foliar Mo application at the V6 stage increased Mo foliar content to all N rates. However, under the conditions of this study, foliar Mo application was not useful in increasing N use efficiency.

(8821 - 1084) Nutritional characteristics of commercial organic fertilizers circulated in Korea

Seok-Cheol Kim[1]; Myung-Sook Kim[1]; Seong-Jin Park[1]; Chang-Hoon Lee[1]
NIAS[1]

The total content of nitrogen, phosphate, potash are important factors to determine the application amount of the organic fertilizers for agricultural lands. The concentration of nutrient, organic matter, salt, water, heavy metal in mixed perilla cakes and mixed organic fertilizers in circulation were investigated with 141 and 179, respectively. The mean contents of total nitrogen, total phosphate, and total potash in organic fertilizers of 2015~2017 years were 4.9%, 2.8%, 1.7%, respectively. The mean concentration of total potash was increased more 1.3 times than that of 2009~2010 years. The average contents of organic matter, salt, and water were 77%, 11.5%, and 0.26%, in mixed perilla cakes, and 72.2%, 11.7%, 0.49% in mixed organic fertilizer, respectively. The maximum concentrations of Cr, Cu, Ni, and Zn were found to be in accordance with the official standard of commercial fertilizer. On the other hand, in order to promote balanced nutrient absorption of crops, it is necessary to increase the content of the organic fertilizers having the lowest concentration of total potash

(6936 - 1699) Perspectives of using Infrared and X-ray fluorescence sensor technology in a Hungarian soil testing and in nutrient management services

Viktória Vona[1]; Csaba Centeri[2]; Renátó Kalocsai[1]; Attila József Kovács[1]; Márton Vona[3]; Peter van Erp[4]
Széchenyi István University Hungary, Faculty of Agricultural and Food Sciences, Department of Biosystems and Food Engineering[1]; Szent István Ubiversity, Faculty of Agricultural and Environmental Sciences, Institute if Nature Conservation and Landscape Management[2];

Csernozjom Lp.[3]; Soil Cares[4]

The soil fertility status of agricultural land in Hungary is under pressure and there is a need for proper soil nutrient management strategies. Such strategies should be based on information of the actual soil fertility status. Since traditional soil testing is time consuming and expensive, there is a need for techniques and instruments that allow rapid, affordable and precise routine soil testing. Five years ago SoilCares Research started a research program focusing on the development and implementation of a quick, precise and affordable soil quality testing method using Infrared and X-ray fluorescence (XRF) sensor technology. One of the major challenges of such a concept is the derivation of reliable prediction models linking sensor spectra to traditional wet chemistry data. Together with SoilCares a calibration and validation study has been started in Hungary in 2017. In total 550 soil samples have been taken representing Hungarian agricultural lands. These samples have been analysed at the calibration laboratory of SoilCares to determine the MIR and XRF spectra and about 90 soil parameters. Moreover 100 samples have been analysed at a local Hungarian laboratory to find relationships between results of Hungarian soil testing methods and SoilCares testing methods. In this paper the first results will be presented of the calibration and conversion study and the perspectives of the SoilCares concept of using MIR/XRF for routine soil testing will be discussed. There are certain soil parameters that correlate very well between soluble based and MIR/XRF based measurements and there are parameters from the Hungarian soils that tremendously reduce the similarity if the old and new methods, reducing the goodness of correlation tremendously. We can conclude that the XRF technology is a very good alternative of the old, soluble based technology, however the reginal validation is a must.

(9350 - 3151) Potassium, calcium and magnesium contents as a function of rotation crops and cover crops under no-tillage system in Cerrado soil

Hugo Henrique Andrade Meneghette[1]; Raul Sobrinho Pivetta[1]; Edson Lazarini[1]; João Willian Bossolani[1]; Izabela Rodrigues Sanches[1]
Faculdade de Engenharia/UNESP – Campus de Ilha Solteira[1]

The Direct Planting System (DPS) is a rational way of cultivating, by attenuating problems of nutrient losses and recommending the maintenance of straw on the soil and crop rotation is one of the basic conditions for the sustainability of the system. The objective of this work was to verify the effects of no - tillage 15 years after its establishment and rotational or single crop in succession to cover crops (CC), on Ca, Mg and K contents in the soil, in Cerrado region. The experiment started in October 1999. The experimental design was a randomized block, with treatments arranged in subdivided plots. The treatments were constituted by monoculture of corn or rotated with soybean. The plots were subdivided with the CC, sown in the spring (*Crotalaria spectabilis*, *Pennisetum glaucum*, *C. juncea* and *Panicum miliaceum*), in addition to a fallow area. The levels of calcium (Ca), magnesium (Mg) and potassium (K) of the soil in the 0-0.10 m and 0.10-0.20 m layers were evaluated. Statistical analyzes of the data were performed by SISVAR software. Soil management in DPS, associated with crop rotation, provided significant changes in the attributes of the arable layer of the soil. There was a significant interaction between management and CC for the attributes under study. Note the contribution of corn crop management, after the establishment of the DPS, where straw residues on the soil as well as the straw contribution conferred by the CC, exerted a great influence on the evaluated attributes. The areas managed with either corn rotated with soybean or monoculture, presented higher levels of K in the soil when *C. spectabilis* was used. The Ca contents of the studied strains were positively influenced by CC cultivation only in the area under monoculture. The same behavior was not observed for the area with rotated corn, where the Ca content of the fallow area did not differ from the CC areas. In the treatment with *Pennisetum glaucum*, the contents of Ca were the lowest among the CCs, being higher in the monoculture. For Mg, CCs in the area submitted to monoculture had higher values in relation to the fallow area, differing only for *C. spectabilis*. The contents found are between medium (5 to 8 $mmol_c$ dm^{-3}) to high (> 8 $mmol_c$ dm^{-3}). Crop rotation between corn and soybean, with CC sown in spring, promoted a better balance of soil chemical attributes studied.

(3643 - 1464) Poultry litter applications and cropping sequences drive dynamic soil properties and soil diversity under no-tillage

Amanda Ashworth[1]; Fred Allen[2]; Phillip Owens[3]; Jennifer DeBruyn[4]; Carl Sams[2]
USDA-ARS, Poultry Production and Product Safety Research Unit[1]; University of Tennessee, Plant Sciences Department[2]; USDA-ARS, Dale Bumpers Small Farms Research Center[3]; University of Tennessee, Department of Biosystems Engineering and Soil Science[4]

Dynamic soil physiochemical interactions with conservation agricultural practices and soil biota are largely unknown. Therefore, this study aims to quantify long-term (12-yr) impacts of cover crops, poultry litter, crop rotations, and conservation tillage and their interactions on soil physiochemical properties, and determine their relationships with nutrient cycling, crop yield, and soil biodiversity (soil microbial and earthworm communities). Main effects were 13 different cropping sequences of soybean (*Glycine max*), corn (*Zea mays*), and cotton (*Gossypium hirsutum*) at the Research and Education Center at Milan, TN, and 8 sequences of corn and soybean at the Middle Tennessee Research and Education Center, Spring Hill, TN. Sequences were repeated in 4-yr phases from 2002 to 2014. Split-block cover crop treatments consisted of winter wheat (*Triticum aestivum*), hairy vetch (*Vicia villosa*), poultry litter, and a fallow control. Soil carbon and nutrient fluxes were calculated at surface (0-5 cm) and sub-surface (5-15 cm) during years 0, 2, 4, 8 and 12. After 12 years of cropping systems, weighted means (0-15 cm) of soil pH, P, K, Ca, Mg, total N and C were greatest under poultry litter amended soils compared to cover crops (P<0.05). In addition, continuous corn sequences resulted in greatest soil K, N, and C concentrations, compared to soybean-soybean-corn-corn rotations (P<0.05). Poultry litter treatments were positively correlated to greater soil physiochemical levels, as well as higher crop yield and soil biodiversity. These results underscore linkages between manure additions and cropping sequences, within the nutrient cycling, soil health, and crop health and production continuum.

(4484 - 3015) Response of corn hybrids genotypes to two different levels of soil fertility

Anna Carla Lima Villela[1]; Adilson de Oliveira Junior[2]
Agronomic Institute of Parana, Km 375, Celso Garcia Road, Londrina, 86057-902, Brazil (anna.carla.villela@gmail.com)[1]; Embrapa Soybean, Carlos Joao Strass Road, Londrina, 86001-970, Brazil[2]

Parana is one of the greatest producers of second corn crop in Brazil, which is grown after soybean crop and is commonly cultivated under minor fertilization conditions than the main crop. For this reason, in order to evaluate corn hybrids genotypes response to soil acidity and

fertilization management, eight genotypes were grown in two different levels of soil fertility divided into a limed and an acidic area. The corn hybrids used in this study were DKB 330 PRO2, Biomatrix 709 VT PRO 2, 2B 655 PW, SYN 7205, AG 7098, Syngenta Impacto, P30F35 and 30A91PW. The experiment was sowed in March 2017, at Embrapa Soybean experimental farm, in Londrina, Parana in an eutrophic Red Latosol. The high fertility plots were fertilized at the base of 20 Kg de N.ha^{-1}, 50 Kg de P_2O_5.ha $^{-1}$, 50 Kg.ha $^{-1}$ de K_2O at the sowing while the low fertility area was not fertilized. At the vegetative stage V4, both areas were top dressing fertilized with 50 kg of N.ha^{-1} in the high fertility plot and 70 kg of N.ha^{-1} in the acid plot. The corn hybrids were classidied by their efficiency and responsiveness to soil correction and fertilization, using the quadrants defined from the average yields of corn hybrids genotypes in low and high fertility areas. In conclusion among the genotypes, the hybrid 30A91PW was classified as responsible and efficient, due to the average yield was higher in low and high fertility areas; the hybrids, Biomatrix 709 VT PRO 2, Syngenta Impacto, P30F35 were classified as responsive and the genotypes 2B 655 PW and AG 7098 were classified as efficient. Due to lower average yield among the genotypes used in this study, the hybrids DKB 330 PRO2 and SYN 7205 were inefficient and not responsive.

(3951 - 3143) Response of sugarcane (*Saccharum officinarum* L.) RB92579 under increasing levels of manganese cultivated in sandy soil of the Coastal Tablelands of the Brazilian Northeastern.

Antonio Eduardo Freire Damasceno[1]; Wildson de Morais Silva[1]; Emídio Cantídio Almeida de Oliveira[1]; Amanda Michele Santos de Lima[1]
Universidade Federal Rural de Pernambuco[1]

Sandy soils are limited soils regarding nutrient availability due to its low cation exchange capacity and high loss of added elements via leaching. Manganese is a limiting micronutrient in the sugarcane production areas of the northeastern region, where the crop has presented symptoms of nutritional deficiency. The application of humic substances to chelate the nutrients is a management option to reduce leaching losses. Thus, this work aims to evaluate the effect of increasing levels of manganese in the soil and in the nutrition of sugarcane plants. The experiment took place in a sugarcane field with the RB92579 (a sugarcane variety) under five levels of manganese (0; 2,5; 5; 7; 9 kg ha^{-1}), with and without humic substances distributed in a statistical arrangement of randomized blocks, with four replications, in a 2x5 factorial design. Soil samples were collected before and 30 days after applying the fertilizers in order to quantify the levels of micronutrients recovered by the soil. A biometric analysis (height, stem diameter, number of tillers and plant biomass) as well as an indirect measurement of chlorophyll content by using a chlorophyll meter on the leave 3+ (SPAD index) were made 120 days after applying the fertilizers. The increase of the manganese dose showed a positive linear correlation with the levels recovered by the soil, the biometric parameters and the chlorophyll content. The use of humic substances was more efficient in soil nutrient recovery and resulted in higher SPAD indices. For the biometric parameters the increasing levels reflected in an increase of biomass for the treatments without humic substances. In the treatments with humic substances it was possible to obtain the maximum agronomic efficiency dose of 5 kg ha-1.

(5567 - 2502) Rock dust as part of the world's fertilizer mix

David Manning[1]; Suzi Theodoro[2]
Newcastle University[1]; Universidade de Brasília[2]

Crushed and milled silicate rocks have a long history as potential sources of nutrients required for plant nutrition. Their effectiveness depends essentially on the mineralogical composition of the soil. In the north, with soils dominated by glacial till parent materials, it can be difficult to show their value. In deeply leached tropical soils, dominated by oxide and hydroxide minerals, both theory and practice demonstrate that addition of silicate rocks provides an alternative to conventional chemical fertilizers, especially where these are inaccessible on the grounds of cost or poor infrastructure for import and internal distribution. Through the Rochagem movement, Brazil has led the way in bringing the use of rock dust into practice, with recent changes in federal law and regulations (Law No. 12,890/2013; Decree No. 8,384/2014 and Normative Instruction No. 05/2016). There is now a clear definition of rock dust, and NI 05/2016 sets out standards that materials should meet. Thus these materials can now be used within a strong regulatory framework to provide crop nutrients. It is vital that this approach is extended to other countries with deeply leached tropical soils, especially in Africa. According to FAO figures, current use of conventional fertilisers in Africa is a tenth of what would be expected if nutrient balance was achieved, for the current population of 1 billion people. In these circumstances it is very difficult to see how African soils will feed 2 billion people by 2050. Amongst other innovations, the development of polyhalite as a multi-nutrient crushed rock fertiliser, especially in the UK, is an example of a major change in the fertilizer industry. Delivering K, Ca, Mg and S, polyhalite will be produced from two deep mines, one of which is designed to have a capacity equivalent to Canada's current potash production. Parallel innovation in Brazil involves planning for the large scale exploitation of potassium feldspar, in the form of syenite, on a scale sufficient to significantly reduce dependency on imports. These developments reinforce the need for a thorough understanding of the fundamental processes which allow silicate and other minerals to decompose in soils of different types, so that appropriate fertilizer choice can be based on sound science.

(1131 - 268) Selenium bioavailabiliy in soils from Jequitinhonha Valley

Vico Mendes Pereira Lima[1]; Roberta Pereira Matos[1]; Ricardo de Matos Silva[1]; Matheus Gobira Lacerda[1]
IFNMG[1]

Selenium (Se) is a micronutrient of great interest due to the narrow range between the essential and toxic levels. Most of the selenium ingested by animals and humans is from the soil, where plants and vegetables absorb this element. In this study, 12 class of soils were collected (horizons A and B) from the Jequitinhonha Valley, Minas Gerais state, Brazil. Total Se concentration in these soils was determined by hydride generation atomic absorption spectrometry (HG AAS). Physicochemical characteristics of soils, such as sand, silt, clay, pH, organic matter and oxides of Al, Fe and Si were determined. Se concentration ranged from <0.30 ± 0.03 to 5.97 ± 0.2 mg kg^{-1}. The average Se concentration in the A horizon was 1.09 ± 0.72 mg kg-1, while in the B horizon the average was 1.63 ± 1.63 mg kg^{-1}. For most soils, no significant differences in the concentration of Se between the horizons of the same class were observed. The physicochemical characteristics were correlated with the Se content in the soils using Pearson's correlation coefficient and principal component analysis (PCA). The natural concentrations of selenium total in the soil samples studied are in agreement with data reported in the literature for Brazilian soils. Among the soils, Spodosol showed highest content, but selenium was found in a very deep layer, meaning it is not readily

available. In Latosols (both red and red-yellow), significant quantities were found in the surface layers, which may be available to the plants. However, weathered soils with high concentrations of Fe and Al oxides in the clay fraction can adsorb selenite, reducing its availability to plants. For most soils, we observed a significant difference in Se concentration between the two horizons of the same profile. In general, selenium is associated with the clay fraction, which is more related to oxides of Al than iron oxides. Furthermore, the organic matter content may have influenced the characteristics of some soils. Although pH does not appear to be a correlation factor, we believe that low pH of the soil may have contributed to adsorption of selenium anions in some soils. The integrated assessment of characteristics of a group of heterogeneous samples with use of chemometric techniques such as PCA and HCA enabled a better understanding of the correlation between the concentration of Se and the physicochemical characteristics of the soil samples, as well as the correlation between soils.

(7887 - 2546) Sugar cane yield by crop removal of nutrients from the field

Eduardo Renato Moreto[1]; José Marcos Garrido Beraldo[1]
Instituto Federal de São Paulo[1]

The choice sugarcane variety is one of the most important steps in the productive process, which sustains the permanence of the plant in the field reducing the cost of production and and influences the renewal of sugarcane. The variety RB 928064 stands out due to its lower retention of water, favoring regions that present water deficit at some times of the year. Despite being cultivated in production environments with high fertility and water availability, to obtain a yield response is the need availability soil nutrient and acidity. In conditions of low fertility, a low response in yield crops is expected, which can cause the farmer proceed with the renewal of the sugarcane early, raising the cost of production. The objective of this work was to evaluate the yield sugarcane of the variety RB 928064, cultivated in soil under no nutritional replacement. The research was conducted in an experimental area under Oxissol. The experimental plot consisted of four rows of 12.0 m in length with spacing of 1.5 m. The seedlings already sprouted of the variety RB 928064 have been used. No correction of soil and fertilization of plan was carried out. The harvest was taken manually in November 2015 and March 2016, where the dry matter production was evaluated. From the dry matter production, sugar cane yield was calculated. It was observed an extraction of the nutrient contents of the soil, due to non-replenishment by liming and fertilization. Soil organic matter contents did not change throughout the crop. Phosphorus and potassium content in the soil decreased. The calcium and magnesium contents decreased during the cultivation, but no nutritional deficiencies were observed. The dry matter production ranged from 589.68 kg in the 2015 harvest to 286.15 kg in the 2016 harvest. The Sugar cane yield ranged from 81.90 Mg ha^{-1} to 39.74 Mg ha^{-1}. These results indicate a half reduction in Sugar cane yield. The correction of soil and fertilization is limiting for the longevity of the sugar cane field. These results have a direct impact on the development of the plant and confirm the need for renewal of the sugarcane, causing losses to the farmer due to the costs for implantation.

(4995 - 1524) Total carbon, nitrogen and phosphorus stocks in agroecosystems of the Chiloé island, Chile

Silvia Cano[1]; Mauricio Galleguillos[2]; Bruce Osborne[3]; Jorge F. Perez-Quezada[2]
Programa de Magíster en Manejo de Suelos y Aguas, Universidad de Chile, Casilla 1004, Santiago, Chile[1]; Departamento de Ciencias Ambientales y Recursos Naturales, Facultad de Ciencias Agronómicas, Universidad de Chile, Casilla 1004, Santiago, Chile[2]; School of Biology and Environmental Science, University College Dublin, Belfield, Dublin 4, Irlanda[3]

In recent years the island of Chiloé, located in southern Chile, has undergone several processes of transformation in the use of soil, moving from native forests to peatlands and other anthropogenic uses. Therefore, soils with natural vegetation have been transformed into intervened and modified soils, in which agricultural practices have been intensified in order to increase the yields of species of agricultural interest. It is presumed that these changes alter the carbon (C) stocks and the balance of greenhouse gases, so it is necessary to quantify this change, since the soil is the component of the biosphere that that stores more C. The main objective of the study was to quantify the total stocks of C, nitrogen (N) and phosphorus (P) in the agroecosystems of the island of Chiloé, comparing the effect of different types of land use in agroecosystems. The agroecosystems to study are grasslands, shrubalands invaded by espinillo (*Ulex europaeus*) and retamo (*Cytisus striatus*), natural shrubland and potato croplands. The sampling will be carried out in three plots, defined in each type of agroecosystem, with which a composite sample will be formed. In each plot, soil samples will be collected in three depth intervals (0-10, 10-30, >30 cm); In the same way in each plot the biomass will be harvested and the total C, N and P stocks will be estimated, both for the aboveground and belowground components. The results obtained are compared with previous studies conducted in the same area, where the total stock of C was determined in a native forest and a peatland. Finally, the effect of land use change on the C, N and P stocks in the soil is analyzed.

(6418 - 3154) Yield of vine under protected environment using fertirrigation with different nutrient doses

Katiúscia Fonseca dos Santos Strassburger[1]; Leonardo Meggiolaro[1]; Andre Samuel Strassburger[2]
Universidade de Caxias do Sul[1]; Universidade Federal do Rio Grande do Sul[2]

Niagara Rosada grapes cultivar (Vitis labrusca L.) is very importance to the agricultural economy of the Serra Gaúcha (RS). The protected cultivation associated with fertigation has shown advantages over conventional farming, as: better quality of grapes, reducing the use of agrochemicals and labor-intensive and more efficient fertilizer application. The aim of this study was evaluate the quality and production of grape in covered area and chemical changes in the soil and plant by different doses of nutrient applications. The treatments studied were T1: control (irrigation only), T2: 100%, T3: 50% T4: 200% of the recommended dose for the grapevine applied by fertigation. The experimental design was completely randomized, with four replications; each experimental plot consisted of 40 plants and 5 units of observation. The evaluation of the effects of fertigation on vine was based on production and size of harvested bunches, chemical analysis of soil and leaf analysis. Through the experiment it could be seen that the variables, the bunch size, the acidity, the brix degree and the phosphorus levels were not significantly different, since the other variables, nitrogen and boron showed interaction (dose - time). In this context, it is concluded that increasing of the dose of nutrients applied by fertigation improve the productivity. Reviews with greater and longer concentrations periods should be performed to assess residual effects and possible improvement the yield.

C3.3.3 - Advancement of plant nutrition studies for sustainable agriculture

(7795 - 3156) Accumulation of N forms in 'Pérola' pineapple as a function of N and P doses

Anne Carolline Maia Linhares[1]; Alexandre Paiva da Silva[1]; Sonaria de Sousa Silva[1]; Josinaldo Lopes de Araújo[2]; Alessandra Alves Rodrigues[1]; Fernando Julião de Medeiros Junior[1]
Universidade Federal da Paraíba[1]; Universidade Federal de Campina Grande[2]

Although the pineapple is well studied in nutritional terms, information on the effects of mineral fertilization on the nitrogen metabolism of the crop is still scarce. The objective of this work was to evaluate the effect of nitrogen (N) and phosphorus (P) doses on the accumulation of different N forms in 'Pérola' pineapple. The experiment was carried out in a Red Yellow Argisol (pH in water = 4.8, organic matter = 18.3 g kg^{-1}, P = 25.6 mg dm^{-3}, K^{+} = 52.4 mg dm^{-3}, clay = 163 g kg^{-1}) of the municipality of Itapororoca, in Paraiba State, Brazil. The experimental design was the randomized blocks with the treatments arranged in a factorial scheme 6 × 5, with three replications. (N1P2 = 1.2 g plant-1 of N and 2.8 g plant-1 of P2O5; N2P1 = 7.2 g plant -1 of N and 0.48 g plant-1 of P2O5; N2P2 = 7.8 g plant-1 of N and 2.8 g plant-1 of P2O5; N2P3 = 7.2 g plant-1 of N and 6,7 g plant-1 of P2O5; N3P2 = 16 g plant-1 of N and 2.8 g plant-1 of P2O5; N3P3 = 16 g plant-1 of N and 6.7 g plant-1 of P2O5) and five morphological parts of the pineapple: [root, stem, new leaves (A, B and C), leaf 'D' and old leaves (E and F)]. Before planting (60 days) 1.0 t ha-1 of dolomitic limestone (PRNT 62%, depth of 0.20 m, total area) was applied. Slip seedlings were planted in double rows at a spacing of 0.80 × 0.40 × 0.40 m. At 180 days after planting, total nitrogen (N-total) and inorganic (N-NO3-) and ammonium (N-NH4 +) accumulations were determined in the different morphological parts of the plant. The N and P doses did not influence (P> 0.05) the accumulations of N-total, N-NO3- and N-NH4 +. However, a higher accumulation of N-total (330.73 mg kg-1) in the N2P1 treatment (7.2 g plant-1 of N and 0.48 g plant-1 of P2O5) was observed, and a tendency of accumulation of N-NO3- and increased accumulation of N-NH4 + with the increase of N and P doses. A higher accumulation of N-total was observed in 'D' leaves (443.81 mg kg -1). In relation to nitrate and ammonium, there were larger accumulations in the stem (1.77 and 4.32 mg kg-1, respectively). It was concluded that at 180 dap N and P doses do not influence the accumulation of N-total and N-inorganic forms of 'Pérola' pineapple; however, there is greater accumulation of N-total in leaf 'D' and of ammonium and nitrate in the stem

Keywords: nitrate, ammonium, assimilation of N.

(4420 - 3171) Accumulation of P forms in 'Pérola' pineapple as a function of N and P doses

Sonaria de Sousa Silva[1]; Alexandre Paiva da Silva[1]; Anne Carolline Maia Linhares[1]; Josinaldo Lopes de Araújo[2]; Alessandra Alves Rodrigues[1]; Fernando Julião de Medeiros Junior[1]
Universidade Federal da Paraíba[1]; Universidade Federal de Campina Grande[2]

Although the pineapple is well studied in nutritional terms, information on the effects of mineral fertilization on the partition of the different forms of P in the tissues of the crop is still scarce. The objective of this work was to evaluate the effect of the application of nitrogen (N) and phosphorus (P) doses on the accumulation of different P forms in 'Pérola' pineapple. The experiment was carried out in a Red Yellow Argisol (pH in water = 4.8, organic matter = 18.3 g kg-1, P = 25.6 mg dm-3, K + = 52.4 mg dm-3, clay = 163 g kg-1) of the municipality of Itapororoca, region of Coastal Tablelands, in Paraiba State, Brazil. The experimental design was the randomized blocks with the treatments arranged in a factorial scheme 6 × 5, with three replications. (N1P2 = 1.2 g plant-1 of N and 2.8 g plant-1 of P2O5; N2P1 = 7.2 g plant -1 of N and 0.48 g plant-1 of P2O5, N2P2 = 7.8 g plant-1 of N and 2.8 g plant-1 of P2O5, N2P3 = 7.2 g plant-1 of N and 6 , 7 g plant-1 of P2O5, N3P2 = 16 g of plant-1 of N and 2.8 g of plant-1 of P2O5, N3P3 = 16 g of plant-1 of N and 6.7 g of plant-1 of P2O5) and five morphological parts of the pineapple: [root, stem, new leaves (A, B and C), leaf 'D' and old leaves (E and F)]. Before planting (60 days) 1.0 t ha-1 of dolomitic limestone (PRNT 62%, depth of 0.20 m, total area) was applied. Slips seedlings were planted in double rows at a spacing of 0.80 × 0.40 × 0.40 m. The accumulation of total phosphorus (P-total), inorganic (Pi) and organic (Po) in the different morphological parts of the plant was determined 180 days after planting. The doses of N and P significantly influenced (P ≤ 0.05) the accumulations of P-total and Po, but did not affect the contents of Pi. The highest accumulations of P-total (17.5 g kg-1) and Po (16.5 g kg-1) were obtained with the combination of the doses of 7.2 g plant N and 6.7 g P plant. It was observed that the highest accumulations of P-total (21.7 mg), Po (19.4 mg) and Pi (2.3 mg) were obtained in the stem, while the lowest accumulations were recorded in the root (2.80, 2.43 and 0.30 mg, respectively). It was concluded that, at 180 dap, N and P doses influence only the accumulations of P-total and Po forms of 'Pérola' pineapple; and that the stem presents the largest and the roots the smallest accumulations of all fractions evaluated.

(9872 - 2929) Activity of the nitrate reductase enzyme and nitrate and ammonium concentrations in brachiaria palisadegrass as a function of fertilization with nitrogen sources and rates

Marcio Mahmoud Megda[1]; Michele Xavier Vieira Megda[1]; Marcelo Andreotti[2]; Paulo César Ocheuze Trivelin[3]; Salatiér Buzetti[2]
UNIMONTES[1]; UNESP/Ilha Solteira[2]; CENA/USP[3]

The activity of nitrate reductase (At.RNO_3) is the main limitation of nitrogen (N) assimilation by the plant and this activity is dependent on the N form and the continuous nitrate transport by the xylem. The objective of this study was to evaluate the At.RNO_3 and nitrate and ammonium concentrations in the leaf blades (LR) of brachiaria grass, as a function of the application of N doses and sources. The experiment was conducted in a degraded pasture area with the brachiaria palisadegrass (Brachiaria decumbens). The experimental treatments were five annual rates of N: 0, 150, 300, 450 and 600 kg ha^{-1} with three sources of ammonium sulfate, ammonium nitrate and urea, in a 5x3 factorial. The design was in randomized complete blocks and three replications, totaling 45 experimental units. At.$RNO_3$was determined in the LRs. The spectrophotometer was read at 540 nm. To determine the concentration of nitrate and ammonium, extraction was carried out by stirring with potassium chloride and distillation using Devard's alloy and calcined magnesium oxide. The results were submitted to analysis of variance for the sources and rates of N and, with significance at the 5% level, the unfolding was performed. Otherwise, the ANOVA procedure was applied with the Tukey test for N sources and the first and second degree regression study for the rates effects of N. The interaction rates of N x sources of N was not significant for the concentration nitrate, ammonium and At.RNO_3. In the case of nitrate, for urea, ammonium sulfate and ammonium nitrate, maximum concentrations of nitrate were observed of 587, 603 and 693 mg kg^{-1} at the N rates of 454; 448 and 475 kg ha^{-1} $year^{-1}$, respectively. Ammonium concentrations, for urea, ammonium sulfate and ammonium nitrate, presented linear adjustments varying

from 538; 590 and 607 mg kg^{-1} for non-application of N to 704; 746 and 818 mg kg^{-1} for application of the maximum N dose of 600 kg ha^{-1} year-1, respectively. For the sources of N urea, ammonium sulphate and ammonium nitrate the point of maximum At.RNO_3 of 0.0327; 0.0333 and 0.0329 µmol g^{-1} h^{-1} NO_2^- were at N rates of 444; 424 and 397 kg ha^{-1} $year^{-1}$, respectively. The At.RNO_3 and the nitrate and ammonium concentrations were altered by the supply of N rates. For the maintenance of the At.RNO_3, adequate nitrate levels were required. The concentration of ammonium in the LRs was higher than that of nitrate in the brachiaria palisagrass.

(6714 - 567) Adjustment in the recommendation of fertilization by leaf analysis in banana "Prata" fertigated

José Aridiano Lima de Deus[1]; Júlio César Lima Neves[2]; Ismail Soares[3]; Víctor Hugo Alvarez V.[4]; Fabrício Martinazzo Regis de Albuquerque[4]; Lauana Lopes dos Santos[4]; Lucas Carvalho Gomes[4]; William Natale[3]

Federal University of Ceará, 2977 Mister Hull Ave, Fortaleza, Ceará, 60440-554, Brazil[1]; Federal University of Viçosa, Campus Universitário, Peter Henry Rolfs Ave, Viçosa, Minas Gerais, 36570-900, Brazil[2]; Federal University of Ceará[3]; Federal University of Viçosa[4]

Fertilization recommendations are made almost exclusively on the basis of soil chemical analysis, without considering the leaf analysis and the expected yield, which may aid in the adjustment in fertilization programs. The objective of this study was to develop a method for the recommendation of macronutrient doses that integrates information of leaf analysis, soil chemical analysis and yield. The chemical analyzes of soil and leaves and yield were carried out in the first and second semester from 2010 to 2015, in fertigated banana 'Prata' commercial crops. Yield was related to the values of organic matter (OM) and macronutrient concentrations (P, K, Ca and Mg) present in the soil to obtain the critical level (cl_Nu_i). Then, the nutrient contents in the leaf were plotted on the dispersion plot, as a function of soil concentrations, using the Plant-Soil Relationship Quadrant Diagram (DPQps) method. From the foliar analysis, the recommended doses were simulated for four plots, and compared to doses recommended by Ferticalc-banana and Recommendation Table. The values of cl_Nu_i obtained were: 13.2 g dm^{-3} for OM; 97.5 and 91.5 mg dm^{-3} for P and K; 2.71 and 0.61 $cmol_c$ dm^{-3} for Ca and Mg. The recommended doses based on leaf analysis were 16.6 kg ha^{-1} of N, 230.6 kg ha^{-1} of P_2O_5, 21.6 kg ha^{-1} of K_2O, 626.5 kg ha^{-1} of Ca and 1,0 kg ha^{-1} of SO_4, being different from the recommendations of the other methods. The proposed method presents an advantage to the evaluation of nutritional status of plants in decision making in relation to fertilization or not. In addition, the method is sensitive to nutritional and non-nutritional factors that affect productivity, recommending doses only for cases where the limitations are due to nutritional factors. Leaf analysis satisfactorily adjusts recommended doses of nutrients and brings advantages when incorporated into nutritional balance models. In addition, its use in an integrated way with soil chemical analysis and yield, increasing the precision in the recommendation of banana fertilization.

(9442 - 1261) Agronomic biofortification of rice grain with selenium

Josimar Henrique de Lima Lessa[1]; Mateus Bilisário de Assis[1]; Jéssica Francisco Raymundo[1]; Liniker André Ferreira[1]; Gabrielly Nayara Tavares da Silva[1]; Maria Jéssica Vieira dos Santos[1]; Anderson Mendes Araujo[1]; Fábio Aurélio Dias Martins[2]; Luiz Roberto Guimarães Guilherme[1]; Guilherme Lopes[1]

Federal University of Lavras[1]; Agricultural Research Company of Minas Gerais[2]

The enrichment of plants with selenium (Se), an essential element for humans and animals, through agronomic biofortification is relevante in countries where Se contents in the soils are low, such as in Brazil. In this context, studies involving the addition of Se by foliar spray in rice plants were carried out in two experimental farms of the EPAMIG (Lambari and Patos de Minas). Both experiments were arranged in complete randomized blocks, with 2 Se sources (selenate or selenite), six Se doses (0; 5; 10; 20; 40 and 80 g ha^{-1}), and 4 replicates. Se doses were split in two applications with interval of 2 weeks between the first and the second application and were applied as foliar spray during the flowering period. Rice plants were harvested at the end of the cycle and the grain yield were quantified. Se contents in rice grains were measured by GFAAS after the digestion process, which was performed according 3051A method of the United States Environmental Protection Agency, using HNO_3. Results show that the Se contents in rice grains increased upon increasing Se doses applied as foliar spray, being found higher Se contents when the selenate was used as Se source. This fact indicates that selenate is more easily transported through the phloem compared with selenite, when applied in the rice leaves. Comparing the two location where the studies were performed, the rice grain yield was greater in Patos de Minas compared with Lambari, and this higher productivity affected negatively the biofortification of the grains due to the dilution effect. Therefore, this study provides useful information concerning agronomic biofortification of rice, showing that both Se sources (selenate and selenite) could be used as foliar spray to increase Se contents in rice grains.

(9921 - 728) Alfalfa production under base saturation levels in Cerrado Oxisol

Camila Thaina Rueda da Silva[1]; Edna Maria Bonfim-Silva[1]; Tonny José Araújo da Silva[1]; Antonio Rodrigues da Silva[1]

UFMT[1]

Generally, most agricultural crops express their best performance under soil conditions with about 50% base saturation. However, alfalfa, considered one of the most important forage plants in the world, requires base saturation around 90%, limiting the expansion of the crop in tropical soils. In this context, the objective of this study was to evaluate the effects of base saturation levels on dry mass production of alfalfa grown in Oxisol of the Brazilian Cerrado region. The experiment was carried out in a greenhouse at Federal University of Mato Grosso, Campus of Rondonópolis-MT. The experimental design was completely randomized with six base saturation levels (V%) (10, 30, 50, 70, 90 and 110%) with five repetitions. The soil was collected in a region under Cerrado vegetation, sieved and corrected with dolomitic limestone 30 days before sowing, raising to saturation levels by preestablished bases. Each experimental unit consisted of a 2 dm^3 vessel containing five plants. The fertilization consisted of 150 mg dm^{-3} of potassium (K_2O) using as a source the potassium chloride divided in two times, 60% at sowing and 40% after the first cut, 800

mg dm^{-3} of phosphorus (P_2O_5) in the superphosphate form and micronutrients of 15 mg dm^{-3} of FTE (9% - Zn; 1.8% - B; 0.8% - Cu; 2% - Mn; 3.5% - Fe and 0.1% - Mo) both added at the time of sowing. Irrigation management was performed by the gravimetric method, maintaining 60% of the maximum soil water retention capacity. Plant cutting at 45 days after sowing. The shoot dry mass was weighed, and oven dried at 65°C until constant weight. The results were submitted to analysis of variance by the t-test and regression analysis, both at the 5% error probability level, using the SISVAR software. The shoot dry mass of alfalfa presented a significant difference in the base saturation soil levels, adjusting to the quadratic regression model. The maximum shoot dry mass accumulation estimated was 2.02 g pot^{-1} at 61.25% of base saturation. Thus, the base saturation levels interfered significantly in the development of the crop when cultivated in Cerrado Oxisol.

(2264 - 2732) Biofortification: study under application of n rates by two wheat cultivars

Jana Daisy Honorato Borgo[1]; Daniel Ramos Pontoni[2]; Milton Ferreira de Moraes[3]; Volnei Pauletti[1]

Universidade Federal do Paraná[1]; Instituto Brasileiro de Geografia e Estatística[2]; Universidade Federal do Mato Grosso[3]

The use of wheat cultivars with higher capacity for protein and Zn allocation in grains is an alternative to attenuate nutritional deficiencies in humans. The objective of this work was to evaluate the application of N doses in two cultivars regarding the allocation of protein and Zn in the grains, in flag leaf and aerial biomass. The 2x7 factorial arrangement was installed in a greenhouse, combining two cultivars Quartz and BRS Parrudo with application of 12, 20, 27, 35, 42, 50, 75 mg dm^{-3} of N. During the development of the crop were evaluated the protein concentration and Zn in flag leaf, at physiological maturity, protein concentration and Zn in the grains and aerial biomass. Partitioned grains such as spikes were separated into three equal parts (proximal, medial and distal) which confer as medial, upper and inferior parts of the spike. The total nitrogen content (N) was determined by dry combustion using the VARIO EL III - Elementar®. The N% obtained was multiplied by 6.25 to obtain the protein and transformed to g kg^{-1}. The Zn was determined by means of Optical Emission Spectroscopy with induced plasma (ICP-OES), after the digestion with nitric-peroxide solution in microwave. The cultivar BRS Parrudo was distinguished by the higher concentration of protein and Zn in the grains, biomass productivity. The increase of the N supply contributed to the reduction of the protein concentration and Zn in the grains. With respect to the accumulation of protein and Zn the cultivar Quartzo was more efficient in relation to BRS Parrudo. In spike partitioning, the concentration of Zn were significantly increased in the grains of the proximal to medium part of the spike. The protein did not respond to the grain parts analyzed in the spike. The effect of the cultivar is preponderant regarding the efficient use of N in the reserve allocation of proteins in the grains. It was concluded that the cultivar Quartzo was more efficient in protein accumulation, whereas BRS Parrudo was more efficient for accumulation of Zn. The concentration of protein and Zn varied according to the site in the evaluated spike, with higher concentration in the proximal and middle parts in relation to distal.

(5356 - 3117) Biomass and volume of wood in clonal stands of Tectona grandis in Mato Grosso estimated by allometric equations

Márcio Luiz dos Santos[1]; Rayanne Oliveira Teixeira[1]; Thaís Seelent[1]; Valéria Santos Cavalcante[1]; Júlio César Lima Neves[1]

Federal University of Viçosa[1]

Nutritional management is fundamental for the good growth and productivity of teak stands (Tectona grandis), especially in low fertility soils. Obtaining good estimates of volumetric production and biomass of the trees, together with the nutrient utilization efficiency, allows the definition of nutritional demand and requirements. The objective of this work was to obtain allometric equations for volumetric and biomass production in teak plantations. The study was carried out in Nova Maringá - MT in clones of 15, 51, 63 and 75 months of age. At each planting, the circumference at chest height (CCH) of all the trees in the plots was determined, the mean (x) and the standard deviation (s) of CCH were determined, and the stratification of the trees was done according to the 3 diameter classes: 1 - Inferior ($\leq x - s$), 2 - Mean ($x - s \leq x \leq x + s$) and 3 - Upper ($\geq x + s$). A tree was selected within each class, thus totaling 12 trees sampled for the set of studied stands, which were felled and separated in leaf, twig, bark and wood, weighed in the field. For the calculation of trunk volume, the Smalian formula was applied. With the fresh matter weights and humidity values, the production of dry biomass (DB) was obtained from all compartments. The wood density was obtained from the quotient of its DB and volume. For the trunk volumes (Vtr) and the wood (Vw), and for the biomasses of the aerial part (Bap), the trunk (Btr) and the wood (Bw), all per tree, allometric equations were adjusted according to the diameter breast height (Dbh) at 1.3 m, whose coefficients were tested at 0.1% probability, by the t test. The allometric equations obtained, all with statistically significant coefficients ($p < 0.001$) and R^2 values greater than 0.99, were: Log Vtr = -3.8889 + 2.4826 Log Dbh; Log Vv = -3.8892 + 2.3889 Log Dbh; Log Bap = -1.2471 + 2.4561 Log Dbh; Log Btr = -1.5285 + 2.5933 Log Dbh; Log Bw = -1.6480 + 2.6361 Log Dbh. These equations, besides having a high predictive capacity, have a high degree of universality, since they are estimated as a function of a population variable that reflects the growth of the trees and not according to the chronological age, and can therefore be used for clonal teak plantations under varying soil and climatic conditions. Allometric equations were obtained for the estimation of volumetric and biomass production in clonal teak plantations, with high predictive capacity and degree of universality.

(8732 - 2376) Calcium speciation in limed brazilian oxisols using ca k-edge xanes spectroscopy

Welldy Gonçalves Teixeira[1]; Dean Hesterberg[2]; Leonardus Vergütz[1]; Víctor Hugo Alvarez V.[1]

Universidade Federal de Viçosa[1]; North Carolina State University[2]

Calcium deficiency along with Al toxicity are the major chemical constraints on brazilian acidic soils. There have been a number of studies in Brazil to re-evaluate lime requirement (LR), but information regarding how Ca and Al interact on different soil components across a wide pH range following liming is required to estimate changes in pH due to alkaline imputs, and to improve LR predictions for soils high in exchangeable Al. Our primary objective was to measure trends in Ca speciation with progressive liming of Oxisols of varying soil organic matter (SOM) content. We hypothesized that SOM-bound Ca species would increase with increasing SOM content, regardless of pH. The secondary aim was to determine whether dehydration by heating at 120 °C might potentially change the molecular bonding environment of Ca on different soil matrix components. Samples of three Oxisols (10 - 27 g C kg^{-1}) were reacted in aqueous suspensions with increasing

rates of calcite to achieve pH ranging from 4.5 - 6 (native pH) to 8.2 (excess lime). Calcium K-edge XANES spectra were collected at the Brazilian Synchrotron Light Source (LNLS) on 23 soil samples and standards of SOM-complexed Ca (Ca-humic acid and Ca-peat) and organic-Ca compounds (Ca-cellulose and Ca-oxalate), mineral-adsorbed Ca (Ca-montmorillonite, Ca-kaolinite, Ca-goethite, Ca-bayerite and Ca-non-crystalline Al-hydroxide), calcite and other Ca minerals. A distinct signature of undissolved calcite appeared at pH ≥ 8.1. Our results suggest that regardless of the SOM content, Ca-Al exchange occurs on SOM, kaolinite, and Fe and Al oxides across the pH range of limed soils, in addition to production of non-crystalline Al-hydroxide. Although the fitting results showed no significant increase in organic-associated Ca with increasing pH, the results did suggest greater diversity of organic-associated Ca species for the two soil samples containing higher SOM. Heating to 120 °C changed the bonding configuration of Ca in montmorillonite, but minimal spectral changes were found for other Ca species. Although we found limited sensitivity of Ca K-edge XANES spectroscopy to different forms of adsorbed and organic-associated Ca, a distinct spectrum for calcite would make this technique particularly suitable for detecting undissolved calcite in acidic soils to assess overliming. Moreover, our results indicate that deterministic models for recommending LR should account for both SOM and mineral effects on Ca sorption.

(2623 - 3102) Concentration of N, P and K in corn diagnostic leaf as a function of phosphorus doses associated with inoculation with plant growth promoting bacteria

Nathália Cristina Marchiori Pereira[1]; Marcelo Carvalho Minhoto Teixeira Filho[1]; Elisângela Dupas[2]; Salatiér Buzetti[1]; Fernando Shintate Galindo[1]; Willian Lima Rodrigues[1]; Poliana Aparecida Leonel Rosa[1]; Laura Britto Garcia de Oliveira[1]; Maikon Richer de Azambuja Pereira[1]

UNESP Ilha Solteira[1]; UFGD[2]

Phosphate fertilizers are applied in large amounts in corn, despite its low demand by plants when compared to nitrogen and potassium. Phosphorus is one of the most limiting nutrients in the development of this cereal, especially in tropical soils that generally have a low P content and a predominance of acidity. For this reason, for a more sustainable agriculture, the use of bacteria with the capacity to solubilize the unavailable phosphorus and to promote the growth of plants, especially of roots, can increase the efficiency of the phosphate fertilization, seems to be an interesting alternative to the current agriculture, lacking research. Thus, the objective of this research was to evaluate the effect of phosphorus doses associated with inoculation with *Azospirillum brasilense*, *Pseudomonas fluorescens* or *Bacillus subtilis*, in the concentration of N, P and K in corn diagnostic leaf. The experiment will be carried out in an experimental area belonging to the Faculty of Engineering of Ilha Solteira - UNESP, in Selvíria – MS (Brazilian Cerrado region), in an Oxisol with a clay texture, mean P content and pH ($CaCl_2$) of 5.3. The experimental design was in randomized blocks with four replications, arranged in a 4 x 5 factorial scheme, being: 4 types of inoculation (with *A. brasilense*, with *P. fluorescens*, with *B. subtilis* and without inoculation) and 5 doses of P_2O_5 (0; 17.5 kg ha^{-1} being 25% of the recommended dose, 35 kg ha^{-1} being 50% of the recommended dose, 70 kg ha^{-1} being the recommended dose and 105 kg ha^{-1} being 150% of the dose recommended), applied in the sowing line. At the time of flowering was collected the average third of the leaf below the spike to determine N, P and K concentrations. The analysis of variance was used for the F test and Tukey's test at 5% probability for comparison of mean values of types of inoculation, and regression equations for the effect of P_2O_5 doses. Leaf N, P and K concentrations were adequate. There was no effect of phosphorus doses and inoculation with bacteria for N leaf concentration. With the inoculation of *Azospirillum brasilense*, was observed higher concentratio of P in the leaves, but not differing from the treatment without inoculation. *Bacillus subtilis* was highlighted by potentiating the effect of phosphate fertilization on P and K uptake. The three bacteria tested associated with the increase of phosphorus doses had a positive effect on the K uptake.

Keywords: Foliar diagnosis; phosphate fertilization; *Azospirillum brasilense; Bacillus subtilis; Pseudomonas fluorescens.*

(1392 - 1154) Controlled release fertilizer in the first production cycle of the banana crop

Leandro José Grava de Godoy[1]; Camila Aparecida Nunes de Souza[2]; Matheus Gabriel de Borba[1]; Rafael Paulo Kabata[1]; Gabriella Dutra Bortolini[1]; Bruno Donizeti Reschini[1]

Universidade Estadual Paulista (UNESP) - Campus Registro[1]; Universidade Estadual Paulista (UNESP) - FCA/Campus Botucatu[2]

The high demand for nitrogen and potassium by the banana crop and the losses of these nutrients, mainly by leaching, justify the split application of fertilizers, which is often manual and requires a lot of labor. The use of controlled release fertilizer may be an interesting alternative for these conditions. The experiment was conducted in Sete Barras, SP, Brazil, with the cultivar Zelig (Cavendish), at 2,0 x 2,5 m spacing. The soil of the area was classified as Haplic Cambisol medium texture with the following characteristics: pH 5,2; 9,6; 87; 47 e 19 $mmol_c\ dm^{-3}$ of K, Ca, Mg and potential acidity, respectively, 299 mg dm^{-3} P (resin); 9; 1,72; 4,1; 70; 11,6 and 16 mg dm^{-3} of S, B, Cu, Fe, Mn and Zn respectively, bases saturation of 88% and 13 g dm^{-3} organic matter; 312, 299 e 389 g kg^{-1} of sand, clay and silt, respectively. The experimental design was a randomized block, with six replications and six treatments: four doses of NPK controlled release fertilizer (CRF) in five to six months (Polyblen® 13-00-34 + 8S+ 0,2Zn) - 100%, 75%, 50% and 25% of the conventional dose (250 Kg ha^{-1} N; 250 Kg ha^{-1} P_2O_5, 750 Kg ha^{-1} K_2O), supplemented with single superphosphate; treatment using conventional fertilizer (CF) NPK 10-10-30, in four applications and control treatment (without fertilization). The CRF has granules of urea and potassium chloride coated by a layer of sulfur and another layer of polymer. The treatments with CRF were applied at once time. The CF was split into four applications in the proportion of 20, 30, 30 and 20% of the total dose. The content of K in the diagnostic leaf presented a quadratic adjustment for the doses of CRF. The indirect measurement of chlorophyll (SPAD-502) increased linearly according to the doses of CRF. The CRF-100% maintained the soil K and Zn levels, greater than or equal to the CF, from 45 to 105 days after fertilization. There was a linear increase in the weight of the bunches, number of hands, diameter and fruit length as a function of the CRF dose. The treatments with CRF-100% and CRF-75% provided heavier bunches and advanced the harvest, compared to treatments with CF and control. The losses by volatilization were very small in the treatments with the CRF. The use of controlled release fertilizer in the first production cycle of the banana crop is an interesting and viable alternative.

(7215 - 2954) Correlation between soil fertility and nutrient accumulation in arabica coffee grains

Aymbiré Angeletti da Fonseca[1]; Renato Correa Taques[2]; Aymbiré Francisco Almeida da Fonseca[3]; Aldemar Polonini Moreli[2]; Luiz Carlos Prezotti[2]

Universidade Federal do Espírito Santo[1]; Instituto Capixaba de Pesquisa Assistência Técnica e Extensão Rural[2]; Empresa Brasileira de Pesquisa Agropecuária[3]

Brazilian Coffee Exports in 2017 total more than 30.7 million bags, of which 5.1 million were “special coffees”. Of the total exchange revenue, equivalent to US$ 5.2 billion, special coffees accounted for 19.6%. This justifies the great importance of the development of studies that allow the increase of Brazil's participation in this distinct market, whose coffees have greater added value. When evaluated the determining factors for the quality of coffee drink, many studies highlight the environmental conditions, the care in post-harvest processing and the presence of some nutrients, for example nitrogen and potassium, as the most important factors. However, there are few studies in the literature on the direct relationship between soil fertility and nutrient content in coffee grains. So that excessive application of nutrients can become an environmental problem over time. In this context, the objective of this study is to understand how soil chemical attributes correlate with nutrient contents in coffee grains. For this, 142 areas were cultivated with arabica coffee of the Catuaí Vermelho variety, being distributed in 20 municipalities of the mountain region of the state of Espírito Santo. Soil samples were collected under the plants to a depth of 0-20 cm, and subjected to chemical characterization. On the other hand, nutrient content in the grains was obtained through a sampling performed when most of fruits reached the cherry stage. The results were submitted to Pearson correlation. Copper and manganese were the only nutrients that showed a direct and significant (*p<0,01)* correlation between their soil availability and their fruit content. In general, the attributes of the soil present low correlation with the nutrient content in the fruits, mainly in the macronutrient contents. Among the nutrient contents evaluated, manganese presented the highest correlation with soil attributes. The larger positive correlation was with the availability of this nutrient in the soil and the larger negative correlation with the organic matter concentration. For most of the studied nutrientes the increase in their availability in the soil does not necessarily indicate that will present higher fruit contents. Therefore, excessive fertilization aimed at such a response should be avoided, reducing risks such as eutrophication of springs.

(9402 - 2118) Cover crops associated with nutrient sources in the initial recovery of degraded areas in bauxite mining in the central-west region of Brazil

Atila Reis da Silva[1]; Wilson Mozena Leandro[2]; Leonardo Santos Collier[2]; Vinícius Almeida Oliveira[3]; Rilner Alves Flores[2]

Instituto Federal Goiano[1]; Universidade Federal de Goiás[2]; Faculdade Metropolitana de Anápolis-FAMA[3]

The mine bauxite Barro Alto is the first ore economically viable bauxite in the central- west region of Brazil and has peculiar characteristics. After mining, the chemical, physical and biological soil characteristics are unsuitable for replanting, making it difficult to environmental recovery. The aim of this study was to evaluate the use of green manure in organic and mineral fertilizer and their influence on the physical and chemical attributes of the area to be reclaimed. This work was developed in degraded area located at Barro Alto, Goias The study area has 5000 m^2 and is in the process of recovery since February 2012. Two cycles of planting green manure the first in March 2012 were performed, and the second. In December 2012 the treatments were: 1- pigeonpea; 2- jack bean; 3- sunn hemp; 4- velvet bean; 5- milhet intercropping with faba bean; 6 - millet intercropped with beans pork; 7 - milhet intercropped with sunn hemp; 8- milhet intercropped with velvet bean and three nutrient sources: 1- fertilization with phosphate Arad; 2- the cattle manure; 3- mineral fertilizer controlled release fertilizers. Phytotechnical the characteristics of green manures (height, chlorophyll content, biomass production and nutrient accumulation) , chemical properties (pH, macronutrients and soil organic matter) and physical soil (bulk density, macro and micropores, volume total pore, gravimetric moisture and penetration resistance). The results showed that 17.1% of the biomass originated in pearl millet indicating legumes are the main factors of increase in that variable. The use of mineral source (NPK) significantly increased the biomass of green manure, nutrient accumulation and plant height in relation to the Arad phosphate and manure. With the introduction of green manuring, the content of exchangeable soil Al, H + Al and Al saturation (m%) reduced by 55%, 18.46% and 37.47% in relation to beginning of recovery, respectively. The use of green manure increased the soil organic matter, base saturation and potassium in 156%, 41.71% and 52.41% in relation to beginning of recovery, respectively. The macro and microporosity, in addition to resistance to penetration, improved after 18 months of implementation of the recovery, demonstrating that cropping practices adopted for recovery of degraded in the study area is being active.

(8495 - 759) Crude protein in diagnostic leaves of wheat brs 394 irrigated and fertilized with nitrogen and sulfur

Luana Aparecida Menegaz Meneghetti[1]; Edna Maria Bonfim-Silva[1]; Thiago Henrique Ferreira Matos Castañon[1]; Tonny José Araújo Silva[1]

Universidade Federal de Mato Grosso[1]

There is a large demand of wheat in Brazil, whose production supplies just half of the national consumption. The Brazilian Cerrado region has huge potential for wheat in the country. The Oxisol of this region have low natural availability of nitrogen and sulfur. The objective of this study was evaluate the crude protein content in diagnostic wheat leaves BRS 394, irrigated under combinations of nitrogen and sulfur doses, in the Brazilian Cerrado region. The experiment was carried out in the field, at the Federal University of Mato Grosso, Campus of Rondonópolis, in 2017. The soil of the region was classified as a Oxisol. Five nitrogen doses were applied (0, 70, 140, 210 e 280 kg ha^{-1}) and five sulfur doses (0, 25, 50, 75 e 100 kg ha^{-1}), using randomized blocks design, in factorial scheme 5x5, with four replications. The sulfur was applied in a single rate at sowing and nitrogen in a split-plot, 30% at sowing and 70% at 15 days after plant emergence. Urea fertilizer were used for nitrogen fertilization and elemental sulfur for sulfur fertilization. The analyzed variable was crude protein content in wheat leaves at 45 days after emergence of the plants. Twenty diagnostic leaves (10 leaves +1 and 10 leaves +2) were collected from the useful area of each experimental plot. The crude protein content of the leaves at 45 days after emergence of the plants was significant in isolation for nitrogen and sulfur treatments. For the nitrogen, the protein adjusted to the linear regression model with increase of 18.73% in comparison between the highest nitrogen dose (280 kg ha^{-1}) and absence of fertilization. For sulfur, the protein content was adjusted to the linear regression model, obtaining an increase of

2.66% when compared to the higher sulfur dose (100 kg ha^{-1}) with the absence of fertilization. The crude protein content in wheat leaves BRS 394 irrigated increases with nitrogen and sulfur fertilization.

(6499 - 2257) Decomposition and nutrient release from cover crops residues of different species growing in peach orchards under subtropical climate

Adriele Tassinari[1]; Jovani Zalamena[2]; Raí Augusto Schwalbert[3]; George Wellington Bastos de Melo[2]; Amanda Veridiana Krug[1]; Carlos Alberto Ceretta[1]; Paulo Ademar Avelar Ferreira[4]; Rafael da Rosa Couto[5]; Rodolfo Assis de Oliveira[5]; Gustavo Brunetto[1]
Universidade Federal de Santa Maria, Av. Roraima nº 1000, Santa Maria, 97105-900, Brasil[1]; Embrapa Uva e Vinho, Rua Livramento nº 515, Bento Gonçalves, 95701-008, Brasil,[2]; Kansas State University, Throckmorton Plant Sciences Center 1712, Manhattan, KS 66502, United States of America[3]; Universidade Federal de Santa Maria, Rua Ernesto Barros nº1345, Cachoeira do Sul, 96506-322, Brasil[4]; Universidade Federal de Santa Catarina, Campus Universitário Reitor João David Ferreira Lima, Florianópolis, 88040-900, Brasil[5]

Cover crops are used in peach (*Prunus persica* (L.) Batsch) orchards to protect soil against water erosion and part of the nutrients contained in the tissue can be released into the soil and uptake by the plants. However, the decomposition and nutrient release rate is dependent on the biochemical composition of the added residue and the edaphoclimatic conditions. The objective of this study was to evaluate the decomposition and nutrient release rate of *Avena strigosa* Schreb (black oats) and *Lolium multiflorum* L. (ryegrass) aboveground section, growing in peach orchards. The experiment was carried out in Bento Gonçalves, southern Brazil, during the 2014/15 season. The peach cultivar was 'Chimarrita', grafted on the 'Capdeboscq' rootstock. Black oats and ryegrass were seeded in the total orchard area. At the cover crop flowering the total aboveground section of the plants were sampled. The first fraction one was dried at 65 °C for quantification of dry matter production and, the second one was packed in litter bags with dimensions of 40x40 cm and added on the soil surface around the canopy of the plants. 35 litter bags were added to the total and five samples were collected at each collection (0, 30, 60, 90, 120, 150, 180 days) to determine the remaining dry matter and C, N, P, K, Ca, Mg, cellulose, lignin and non-structural components concentrations. Decomposition of residues and release of nutrients rate were estimated by the variation of the initial amount of dry matter, C, N, P, K, Ca and Mg in relation to the remaining contents in litter bags in each sample time. The determination of the remaining percentage of each one of the parameters was estimated through an exponential mathematical model described by Wieder & Lang (1982), $X=Xo\ e^{(-kt)}$, where Xo is the amount of dry matter or nutrient remaining after a period of time t, in days, and K is the decomposition constant. The half-life was calculated with the value of K ($t½= 0.693/K$). The remaining percentage of black oats residues was higher over time compare to the ryegrass residues. This happened because the residues of black oats had lower content of cellulose and higher content of lignin and C/N ratio, furthermore, the highest percentages of P, Ca and Mg. The highest amounts of N and K occurred in flowering, period of higher root emission and nutrient uptake. Black oats residues promotes greater soil protection throughout the peach growing season, but releases smaller amounts of nutrients into the soil.

(4181 - 497) Determine nutrient balances of wheat (*Triticumaestivum* L) plants with CND-ilr method and their validation

Adel Reyhanitabar[1]; Abolfazl Geiklooi[1]; Nosratollah Najafi[1]
University of Tabriz[1]

Nutrition status in plants are diagnosed commonly using concentration and nutrient ratio ranges which are biased in order to neglect compositional data properties, leading to conflicting results and wrong inferences. The objective of this study was to use isometric log ratio (ilr) technique for nutrient diagnosis in cultivated wheat plants (*Triticum aestivum* L.) at Aridisols and Entisols. Foliar sample were collected at booting stage in 96 fields in Moghan agro-industrial Company of Ardabil province,NW, Iran. Resulted balances were validated by two separated field trials that were laid out in factorial form at randomized complete block design with three replication. Ten nutrients contains N, P, K, Ca, Mg, Zn, Fe, Mn, Cu and B were analyzed. The raw data of nutrient concentration were represented by unbiased balances computed as ilr. The ilr technique authorize scheming the simplex into a Euclidean space of *D*-1 non-overlapping orthogonal log contrasts. For diagnostic purposes, there is a need to split the crops into low- and high-yielding. A receiver operating characteristic (ROC) curve was used to classify tissue nutrient concentrations between balanced/misbalanced and high/low-yielders. The ROC partitioning method for data of wheat fields and field validation test respectively showed that the critical Mahalanobis distance of 4.67 and 4.02 with yield cut-off of 5304 $kgha^{-1}$ and 6559 $kgha^{-1}$ separate balanced from imbalanced specimens (area under curve = 0.83 and 0.88). Tukey test showed significant differences in nutritional balance between reference (high-yielding) and non-reference (low-yielding) group. The [Fe,Mn,Zn,Cu | B,Mg,Ca,K,P,N] and [Mn | Zn,Cu] balances were significantly higher in reference specimens and other hand the [Zn | Cu] and [Fe | Mn,Zn,Cu] balances were significantly higher in non-reference specimens. Balance dendrogram showed that the [Fe | Mn,Zn,Cu]‹ [Mn | Zn,Cu]‹[Zn | Cu]‹ [Fe,Mn,Zn,Cu | B,Mg,Ca,K,P,N] and [Ca, Mg | K] balances were found to be sources of misbalance in the studied fields. By applying fertilizer treatments in the validation test was balanced the concentration of nutrients in the wheat plants.

(9077 - 1085) Development of multifunctional food waste fertilizer having the capability of biocontrol, and phosphate solubility. -A new horizons of food waste recycle using microorganism-

Rio Iguchi[1]; Ahmad Mahmood[1]; Ryota Kataoka[1]
University of Yamanashi[1]

The recycling of food waste is very important for sustainable society. An increase in domestic food waste recycle is necessary in Japan, as it is still lower as compared to trade refuse. Moreover, making compost from food waste has been carried out in Japan, but nutrients of the compost are consumed as a result of microbial growth. However, if the food waste is dried instead of composting, its composition can be maintained, besides, providing the opportunity for growing certain functional microbes like biocontrol agents on the same material. In this study, we tried to isolate the functional fungi from soil, and then grew it using dried food waste to develop a functional fertilizer. About the functionality, we focused on abilities of the biocontrol, and phosphate solubilization. For biocontrol ability, the confrontation assay was performed using isolated fungal strains against *Fusarium* spp. Only one strain out of 157 isolates showed the growth inhibition of *Fusarium* spp. and was named as strain UY2015_11. The sequencing analysis of Internal transcribed spacer (ITS) region showed that strain UY2015_11 was closely related to *Aspergillus niger*. In addition, strain UY2015_11 also showed the ability to solubilize the hardly soluble

phosphates such as calcium, and iron type. Therefore, we used dried food waste to grow strain UY2015_11, and evaluated the response of vegetable growth with this strain inoculated material. Food waste was collected from the restaurant of University of Yamanashi several times, and dried using garbage dryer (HITACHI). The dried food waste was homogenized by mixing, and grounded by grinding mill followed by storage at 4°C until use. The 12.7 g of dried food waste, moisture level adjusted to 30%, was inoculated by a disk of strain UY2015_11, and incubated for 2 weeks at 25°C. Since strain UY2015_11 was capable of growing on the dried food waste, so the material was mixed with soil followed by sowing each of *Lactuca sativa* (lettuce) and *Brassica rapa* seeds. The plants were grown for 50 days, harvested, and plant growth parameters were measured. The results indicated that the dried food wastes with strain UY2015_11 inoculated dried food waste material showed same vegetable growth as chemical fertilizer and organic fertilizer (rapeseed oil cake).

(6593 - 636) Discovering spatial dependence between experimental units of a fertilization field trial in an andean blackberry crop (*Rubus glaucus benth*.) in Colombia

Joan Sebastián Gutiérrez Díaz[1]; Martha Marina Bolaños Benavides[2]; Carmen Rosa Bonilla Correa[1]; William Andrés Cardona[2]

Universidad Nacional de Colombia[1]; Corporación Colombiana de Investigación Agropecuaria[2]

The Andean blackberry crop (*Rubus glaucus* Benth.) has shown a rapid growth in production and area sown in Colombia, given its demand in the domestic market and its potential for export. Its value for small and medium farmers is highlighted as it is a source of income, as well as for the food industry. However, there is little information on the management of soil fertility for the crop in Colombia. The objective of this study was to reveal the existence of spatial dependence between experimental units and remove it, in an experimental field trial in an Andean blackberry crop in Colombia. The experimental plot was established in the municipality of Silvania, Cundinamarca, in a response surface design with 25 treatments, combinations of five different doses of each nutrient N (13.3, 22, 43, 64 and 72.7 kg ha-1), P (1.5 , 4, 10, 16 and 18.5 kg ha-1), K (71.7, 80, 100, 120 and 128.3 kg ha-1) and Ca (31.7, 40, 60, 80 and 88.3 kg ha-1); three blocks and 75 experimental units. In the productive stage, a soil sample was taken from each experimental unit georeferenced for the determination of chemical properties, and the average productivity of blackberry was recorded. The influence of the geographical location of the experimental units on the distribution of each response variable was verified. For the variables that present a distribution conditioned by the spatial location, trend surface models were adjusted to eliminate the spatial dependence between the observations and then verify the effect of the treatments. For the other variables, a non-spatial multivariate inferential analysis, ASCA (ANOVA Simultaneous Component Analysis) was used. By removing spatial dependence, the effect of treatments on crop productivity was highly significant, so the structured variability of the experimental error was not allowed to express the effect of treatments. The soil chemical properties were not affected by the application of N, P, K and Ca treatments. The most appropriate fertilization strategy for the Andean Blackberry crop, removing the spatial dependence, must consider the soil mineralogy, to adjust the quantities of N, P, K and Ca that are required. This study shows an adequate dose for the crop fertilization in productive stage and represent an important advancement of Andean Blackberry nutrition studies for sustainable agriculture in Colombia. With this technique more accurate results can be obtained in experimental field trials and can be applied in soil science.

(3923 - 2264) Dry mass of leaves and stems in pasture in recovery using vegetal ash

Louisy Oliveira da Silva[1]; Helon Hébano de Freitas Sousa[1]; Edna Maria Bonfim-Silva[1]; Tonny José Araújo da Silva[1]; Alessana Schlichting[1]

Federal University of Mato Grosso - University Campus of Rondonópolis[1]

The objective of this study was to evaluate the dry matter yield of leaves and stems of Brachiaria brizantha cv. Marandu in recovery, submitted to doses of vegetal ash and forms of application. The experiment was conducted, in its third year, at the experimental farm of the Institute Mato Grosso do Algodão-IMAmt, in Rondonópolis - MT, from December 2016 to April 2017. The experimental design was randomized blocks, in a factorial scheme in the range, 6x2, corresponding to six doses of plant ash (0, 3, 6, 9, 12 and 15 t-1) and two treatments of ash application (incorporated and not incorporated to the soil with light grid), with four replications. The experimental plots (8x30 m) received the doses of vegetal ash, while the subplots (8x15 m) the application management. The application of the ashes was carried out manually, and the built-in handling performed with a light grid. Four evaluations were performed with a 30-day interval. The plants for evaluation were cut at a height of 0.05 m in the internal area of a rectangle of 0.25m², randomly played twice within the limits of the useful plot. The dry mass production of leaves and tillers was evaluated. The results were submitted to analysis of variance up to 5% of probability and, when significant, to the doses of vegetal ash, regression analysis was applied and, for the application management factor, the means were compared by the Tukey test, through the statistical program SISVAR. There was no interaction between treatments in any of the evaluated sections. For plant ash doses, except for the dry mass of stalks in the first cut, the data for all cuts for the two variables were adjusted to the quadratic regression model, with maximum yields observed at doses above 9 t -1. Regarding the application management, for the dry mass of leaves, only a significant difference was observed in the 1st and 2nd cuts, and in the first cut the unincorporated treatment promoted greater production and, in the second cut, the reverse was observed. The dry mass of stalks showed only a significant difference for the handling of the application in the 3 rd and 4 th cuts, in the two cases the ash incorporated into the soil promoted higher results. Vegetable ash promoted an increase in the production of dry mass of leaves and stems, and can be used for pasture recovery, the incorporated application method damages dry mass production in the first cut, but it is more efficient in the following.

(8794 - 883) Dry mass production of pasture in recovery under wood ash doses and application forms

Tallys Henrique Bonfim-Silva[1]; Helon Hébano de Freitas Sousa[1]; Edna Maria Bonfim-Silva[1]; Tonny José Araújo da Silva[1]

Universidade Federal de Mato Grosso[1]

The wood ash is a residue of industries in the production of thermic energy by mean of the burning of the vegetal biomass, is an organic fertilizer alternative and soil corrective that can positively influence the recovery of degraded areas. The objective of this study was evaluate the dry mass production of the pasture in recovery under wood ash doses and two forms of application. The experiment was carried out in the field in his third year of conduction, in the municipality of Rondonópolis, Mato Grosso, at the experimental farm

of the Instituto Mato-grossense do Algodão (IMAmt). The experimental design was in randomized blocks with plot subdivided into strips, in factorial scheme 6x2, corresponding to six wood ash doses (0, 3, 6, 9, 12 and 15 Mg ha^{-1}) in the plots and two applications (incorporated with light and non-incorporated grid), in four replications. The experimental plots (8x30 m) received the wood ash doses, while the subplots (8x15 m) the application management totaling 24 plots and 48 subplots. The application of wood ash was carried out the flight, manually. The evaluations of the plants were performed in four predetermined intervals cuts of 30 days with each other. The cuts of the plants were carried out at the time of 0.15 m of the soil surface in an area bounded by a rectangle of 1.00x0.25 m (0.25 m^2) sampled in the area that best represents the treatment in the useful area of each subplot. Significant effect was observed for wood ash doses in the 1st, 2nd and 4th cuts, setting the quadratic regression model, being respectively the highest wood ash doses (15.3, 10.7 and 10 Mg ha^{-1}) and dry mass (1.6, 0.7and 0.9 Mg ha^{-1}). The 3rd cut had a significant effect only for the wood ash doses, and there was no significant difference for the application management, adjusting also to the quadratic regression model, with the highest dose 27 Mg ha^{-1} producing 1.5 Mg ha^{-1} of dry mass. The doses and fertilization management with wood ash increases the production of dry mass in pasture in recovery in the Brazilian Cerrado.

(8921 - 3011) Effect of excessive B-spraying on growth and antioxidant activity of European hazelnut cv. Tonda di Giffoni

Cristian Meriño-Gergichevich[1]; David Alarcón[2]; Elizabeth Ulloa-Inostroza[3]; Ana Luengo Escobar[3]; Marjorie Reyes-Díaz[3]
Scientific and Technological Bioresource Nucleus (BIOREN-UFRO), Universidad de La Frontera, Temuco, Chile (cristian.merino@ufrontera.cl)[1]; Laboratorio de Fisiología y Nutrición de Frutales Caducifolios, Universidad de La Frontera, Temuco, Chile.[2]; Scientific and Technological Bioresource Nucleus (BIOREN-UFRO), Universidad de La Frontera, Temuco, Chile[3]

Boron (B) is essential to the growth and development of many crops, by its role in sugar transport, cell wall structure and phenol metabolism. However, low B availability in acid soils (pH ≤ 5.5), due to its leaching by high precipitation and calcareous amendment management, affect its uptake by roots. In fruit crops, B spraying is an agronomic tool which enables optimize B use, reducing the typical symptomatology of B deficit in plants, such as stunted development, necrotic meristems, reduced fruit set and fruit abortion, among others. In Chile, European hazelnut (*Corylus avellana* L.) is an important nut fruit with high volumes of exportation. However, hazelnut production presents serious difficulties to obtain viable fruit, due to fertility problems. All this, present many problems in the production chain, limiting the volume for fruit production and hindering the post-harvest management by vain fruits. Based on the above mentioned, the knowledge of boron as foliar fertilization program can improve hazelnut productivity. Therefore, the aim of this study was to determinate the effect of B foliar-applied on antioxidant performance and productivity of European hazelnut. The experiment was carried out in the 2016-2017 season, in a commercial orchard in Cunco County, La Araucanía region, Chile (39° 29` S; 72° 23` W). Ten years old plant cv. Tonda di Giffoni grew in an Andisol (Typic Hapludands) with low B concentration (0.37 mg kg^{-1}). Doses of 0, 800 and 1600 mg L^{-1} (B0, B800, B1600 respectively) were sprayed four times (October 15th to November 30th) in a randomized design with three replications. Treatments B800 and B1600 increased ten-folds foliar B in comparison to non-treated B0 (P≤0.05). At B1600, leaf water potential (Ψ_{leaf}) showed more negative values (-1.1 MPa) and stomatal density (stomata per mm^{-2}) was significantly increased at 140 stomata mm^{-2} in lower leaf surface compared to control (97). Dry matter was a 10% higher at B800 than B0 (P≤0.05). Lipid peroxidation was reduced concomitantly with increased antioxidant activity in leaves, in comparison with control treatment. Hazelnut seems to be a species that accumulate high B concentration in leaves, whereas it is involved in an improved antioxidant activity.

(2895 - 2926) Effect of macronutrient deficiency in the development of the african mogno (Khaya ivorensis)

Mateus Gonçalves de Borba[1]; Gustavo Ferreira de Sousa[1]; Maila Adriely Silva[1]; Juliana Luíza Cagarmos da Costa[1]
Centro universitário de Patos de Minas-UNIPAM[1]

African mahogany (Khaya ivorensis) is one of the main alternatives for the recovery of deforested and degraded areas, due to its excellent climatic adaptation and high economic value, although there is little scientific knowledge about its nutritional requirements. The objective of this work was to evaluate the African mahogany development (Khaya ivorensis) when submitted to macronutrient deficiency separately. The experiment was carried out in an experimental greenhouse at the University of Patos de Minas-MG, Brazil, consisting of an experimental DBC (randomized block design) with 8 treatments and 4 replicates, using 100 day old seedlings, duly selected from certified nursery, transplanted to pots with sand washed with distilled water, submitted weekly to the application of nutrient solution specific to the appropriate treatments T1 (without application of nutrients), T2 (complete nutrient solution application), T3 (nutrient solution without Ca 2+ addition), and T4 (nutrient solution without K +), T5 (nutrient solution without N), T6 (nutrient solution without S), T7 (nutrient solution without P), T8 (nutrient solution without Mg^2 +) for 120 days, evaluating agronomic characteristics at the end, the data were submitted to analysis of variance and their means were compared by the Tukey test at 5% of error probability. There were differences in the agronomic aspect, according to the solutions, nitrogen being the nutrient that presented as main limiting factor to the development and growth of the African mahogany in comparison to the other macronutrients, this fact is related because it is the nutrient responsible for the cellular growth and by the formation of numerous enzymes present in the plant cell, its deficiency acts directly on the vegetative development throughout the whole cycle. In this context, N was the macronutrients that most limited the growth and quality of the Khaya ivorensis seedlings.

(7212 - 2602) Effect of silicon addition on (*Sorghum bicolor* l.) moench plant grown under iron deficiency

Márcia Masson Mendes dos Santos[1]; Alexander Calero Hurtado[1]; Diego Correia Sodré[1]; Isaias dos Santos Reis[1]; Renato de Mello Prado[1]
UNESP[1]

With de objective to study the physiologic and biochemical to changing stimulate by iron deficiency in sorghum plant (Sorghum bicolor L.) Moench and researcher the role of silicon addition in the acclimation induction of this specie under iron deficiency. The sorghum cv Dekalb 540 were cultivated plants were grown hydroponically in a complete nutrient solution with or without Si supply and sufficient and deficient Fe, with modification in the iron

source Fe-EDDHMA, keeping the pH value of solution nutritive was 5.5, adapted for the crops. The treatments were in a 2x2 factorial scheme and the first factor corresponding to sources of Si Potassium Silicate is the standard source with 128.00 g L^{-1} of Si and 126.5 g L^{-1} of K_2O in Si concentration and 0,4983g L^{-1} and the second factor, the Fe being the Fe-EDDHMA (Fe = 6%) source in the concentrations 0.2 and 4.12 g L^{-1} being in the first week the measure of the deficiency was 0.1 g L^{-1} totaling 20 experimental plots. The sowing was done in trays of styrofoam filled with vermiculite medium and irrigated 5 ml per cell with nutrient solution of Hoagland and Arnon (1950) with and without silicon being the source the potassium silicate until the transplant. After four weeks until the transplant was assessment the fallowing variables: plant height, dry matter of roots and shoots, Fe and Si accumulate in roots and shoots, lipid peroxidation in roots and shoots, chlorophyll and carotenoids. The results showed that the presence of Si in the culture media induced the acclimation of sorghum plant under iron deficiency, in conclusion in growing highest of sorghum plant. The acclimation of the sorghum plant on iron deficiency mediated by silicon see related with the increment of chlorophyll and carotenoids, major and better distribution and iron accumulate and achieve the dry matter production in roots and shoots and decrease the MDA in roots and shoots of sorghum plants.

(8444 - 1432) Effect of urea application on soybean nodulation, CO_2 assimilation and dry matter production at early phenological stage

Nícolas Braga Casarin[1]; Maria Clara Faria Chaves[1]; Gil Miguel de Sousa Câmara[2]; José Lavres Júnior[1]
Center of Nuclear Energy in Agriculture - University of São Paulo (CENA-USP)[1]; Luiz de Queiroz College of Agriculture - University of São Paulo (ESALQ-USP)[2]

Biological nitrogen fixation (BNF) is the main source of nitrogen (N) uptake and assimilation by soybean crop. However, the application of mineral nitrogen fertilizers can affect nodulation and its efficiency and may not represent gains of grains yield and shoot biomass. This work aims to evaluate the main effect of BNF, the application of mineral nitrogen (urea) at V1 phenological stage (20 kg ha^{-1}), flowering – R2 stage (2 kg ha^{-1}), and both times, on soybean nodulation, CO_2 assimilation, shoot and roots dry matter yield. The experiment has been carried out in a greenhouse at the Center for Nuclear Energy in Agriculture (CENA-USP) in Piracicaba, São Paulo State, Brazil, since December 2017. Two plants of an indeterminate growth habit cultivar (BMX Potência RR) are being cultivated per pot, each containing 5 dm^3 of soil from a Typic Hapludox (LVAd), using the experimental design of complete blocks at random, with treatments arranged in a 4 x 5 factorial scheme (four forms of N application x five times of evaluation – plant growth stage), with five blocks. The seeds were inoculated with strains of *Bradyrhizobium elkanii* (SEMIA 5019) and *Bradyrhizobium japonicum* (SEMIA 5079). The CO_2 assimilation has been determined by using an *Infrared Gas Analyser – IRGA, LI 6400 XT*. The leaves, stem+petioles and roots were separated and oven-dried (60 °C) and later each part was weighed to obtain its dry matter. The nodules were collected at harvest of the plants. The results were submitted to analysis of variance ($p<0.05$) using a SAS statistical package. The number of nodules significantly decreased at V4 stage when urea was applied at sowing, although leaves, stem+petioles and roots dry matter did not differ among the treatments. Mineral nitrogen application has not influenced CO_2 assimilation at both V4 and flowering (R2) stages, however, there was a difference between the stages with an increase of carbon assimilation at R2 for all treatments, supporting the idea that soybean has a photosynthesis peak at flowering. Further results will be obtained, since the experiment is still being conducted.

(8160 - 659) Efficiency of organomineral fertilizers in the development of corn plants, cultived in a cerrado soil.

Angelica Araujo Queiroz[1]; Luiza De Freitas Nehme[1]; Gabriel Camargo De Jezus[1]
IFTM, campus Uberlandia[1]

The corn, for your productive potential, chemical composition and nutritional value, is one of the most important cereals consumed and cultivated in the world. Productivity depends on factors such as climate and adequate supply of nutrients, through fertilization. The organomineral fertilizer has potential for use in agriculture, because it comes from other productive systems, such as chicken manure. The purpose of the study was to analyze the influence of organominerals on the initial development of corn plants in a cerrado soil. The experiment was conducted at the nursery for seedling production at IFTM, campus Uberlândia – MG. Soil sampling (Oxisoil, cerrado soil) was performed for the chemical characterization. It was used dolomitic limestone to raise base saturation to 50%. The seeding occurred in nursery pots with a capacity of 5 m^3 of soil, and 15 days after sowing (DAS), a urea cover fertilization was performed. The experimental design was used in randomized blocks, with five treatments and five replications. The organomineral fertilizer used was the formulated 4-10-10 in the proportions 140% (1200 kg ha^{-1}), 120% (1000 kg ha^{-1}), 100% (800 kg ha^{-1}), 80% (600 kg ha^{-1}) e 60% (400 kg ha^{-1}) of the recommended dose of organomineral fertilizer for maize. The following parameters were evaluated: phosphorus content (P) in the soil at 60 DAS, pH value of the soil, SPAD index in the upper middle third of each plant at 30 and 60 DAS and diameter and stem height at 30 and 60 DAS. According to the results, it was verified that there was influence of the rates tested for the P levels in the soil, which increases linearly as a function of the rates tested. At the highest rate, corresponding to 140% (1200 kg ha^{-1}) of the recommended rate, a content of 10,6 mg dm^{-3} of P in soil was found, approximately 2,5 times higher than the P content in rate of 60% (400 kg ha^{-1}). Concludes that the proportions of the formulation applied in the soil influenced the P levels in the soil, but did not interfere with soil pH and SPAD index.

(7946 - 887) Efficiency of Polyhalite as fertilizer to banana crop in Brazil

Renato Agnelo da Silva[1]; Fabio Vale[2]; Danilo Ramos Sério[3]
Monterra Consultoria[1]; International Potash Institute[2]; ICL Fertilizers[3]

Banana cultivation reaches a large area in Brazil, being the most consumed fruit the country, generating 4,5 billion dollars in income for the farmers in 2016. Fertilization with KCl in high rates is common in the management of crop, leaving soils with high concentration of potassium and usually with high salinity. This can influence the development of plants and their nutrition, mainly with calcium and magnesium. The aim of the research was to evaluate the efficiency of Polyhalite as fertilizer to banana crop in a high fertility soil, common in banana areas in Brazil. Polyhalite is a natural fertilizer extracted from a single crystal complex with two molecules of water of crystallization, the chemical formula of the mineral is:

$K_2Ca_2Mg(SO_4)_4.2(H_2O)$, and it contains 19.2% of sulfur (S), 14% of potash (K_2O), 12% of calcium (Ca), 3.6% of magnesium (Mg). Important characteristics of Polyhalite are the slow release and higher availability of nutrients due to its sulphate form, and the lower salinity in function of the low contents of chloride (Cl) and sodium (Na). Trial was made at Lagoinha farm, in Juquia, Sao Paulo state, Brazil. Experimental design in randomized blocks with 7 treatments and 4 replications. Treatments were blends of KCl and Polyhalite, relative to the weight of fertilizers, to provide 360 kg ha^{-1} of K_2O, except Treatment 1, Control without nutrient application. Treatments: 1- Control; 2 - 100% KCl; 3 - 80% KCl/20% Polyhalite; 4 - 60% KCl/40% Polyhalite; 5 - 40% KCl/60% Polyhalite; 6-20% KCl / 80% Polyhalite; 7 - 100% Polyhalite. There wasn't significant effect for the KCl application in relation to the control, with reduction of 1.5% in fruit yield due to the K_2O fertilization. However, the best results were observed with the fertilization with blends Polyhalite and KCl, and the best result was obtained with the 60% Polyhalite / 40% KCl ratio, which increased yield by 13.2% compared to conventional fertilization with KCl. Plants that received Polyhalite showed the bunches with greater vigor, and the plants had larger diameter of the stem. Polyhalite is a viable alternative for use in banana fertilization because it improves the nutritional balance with supply of Ca, Mg and S, besides decreasing the salinity and increasing the yield potential.

(7938 - 1914) Enhancing micronutrient availability in different soils: Laboratory incubation study

Tapasya Babu[1]; Fabio Scudeler[1]; Daniela Vitti[1]
Produquímica - Compass Minerals[1]

Significant advances in sustainable agriculture can be attained by improving the efficiency of sources of micronutrients for crops. The EDTA (Ethylenediaminetetraacetic acid) chelates of micronutrients are known to perform better than other conventional sources. Nonetheless, most chelates of these trace elements, particularly Zn (Zinc) chelate (Disodium-Zn-EDTA) have a lower stability than the corresponding Cu (Copper) or iron (Fe) chelates that tend to replace Zn from within the complex and rapidly dominate the soil solution. The study was initiated with the goal of identifying the combination and ratio that will maintain the soil solution concentration of that micronutrient at a level significantly more than capable by other sources. Series of experiments with three micronutrients, i.e., Zn, Cu and Mn (Manganese) were conducted using two different soils, acidic (pH=4.6) and alkaline (pH=7.8). The different treatments with three replications that were included in each experiment were control (soil only), Metal (M)-sulfate, M-chloride, Disodium-M-EDTA, M-sulfate +Disodium-M-EDTA and M-chloride +Disodium-M-EDTA. Metal concentration of 10 ppm was added in the soil before shaking them for up to 4 hours on a reciprocal shaker, centrifuging, and filtering. Zinc, Cu, Fe, calcium (Ca) and Mn equilibrium concentrations in the filtrate were determined using ICP-MS. The results revealed that by adding sulfate form of the micronutrient along with the chelate form in the ratio near equal to 1:1(sulfate: chelate) in such a way that 1 part of total zinc was supplemented by the chelate and 3 parts of the total zinc were supplemented by the sulfate, more Zn or Cu ($p<0.001$) was maintained in solution than other source combinations tested with respect to Zn and Cu. This could be attributed to the decrease in exchange of micronutrient from within the Disodium-metal-EDTA complex and thereby its loss from soil solution phase by providing a temporary competitive advantage of concentration to the metal or micronutrient used in the combination over others in soil solution. This was further supported by the results of concentrations of the competing ions like calcium and Fe that were considerably lower ($p<0.001$) when Zn or Cu was added as sulfate+Disodium-M-EDTA mix rather than Metal (M)-sulfate, M-chloride, or Disodium-M-EDTA. This study generated new information for the development of high efficiency new generation soil-applied micronutrient formulations.

Keywords: Chelated Zinc, micronutrient availability, soil fertilizer, EDTA

(2773 - 916) Growth and carbon isotopic composition in *Eucalyptus* seedlings in function of potassium and sodium variable supplies

Nikolas de Souza Mateus[1]; Eric Victor de Oliveira Ferreira[2]; Greice Leal Pereira[3]; Alexandre de Vicente Ferraz[4]; José Lavres[1]; José Leonardo de Moraes Gonçalves[5]
Center for Nuclear Energy in Agriculture[1]; Amazon Rural Federal University[2]; Federal University of Viçosa[3]; Forest Science and Research Institute[4]; University of São Paulo[5]

Potassium (K) is the most required and taken up macronutrient by the *Eucalyptus* plant, while sodium (Na) can partially substitute some specific physiologic functions of K. Despite the positive responses of K replacement by Na, sodium supply may also be toxic for plants, hampering tree physiology. Since plants responses to salinity are very close to those of water stress, physiologic changes in salinity conditions can be measured by the carbon isotopic composition ($\delta^{13}C$ ‰). Then, specific studies for *Eucalyptus* are needed to identify the process involving Na in *Eucalyptus* physiology, as in $\delta^{13}C$ and its correlation with growth variables (e.g., dry matter yield and leaf area). The experiment was carried out in a greenhouse at the Center for Nuclear Energy in Agriculture (CENA-USP) in Piracicaba, São Paulo State, Brazil, from November 2014 to February 2015. The experiment replaced the original K rate of Clark's nutrient solution (1.80 mmol L^{-1}) by increasing percentage of Na applied (as NaCl), in *Eucalyptus* clone IPB8 (*E. urophylla* × *E. grandis* hybrid). Thus, the treatments consisted of five combinations of Na and K application rates (0/1.80, 0.45/1.35, 0.90/0.90, 1.35/0.45 and 1.80/0 mmol L^{-1} of Na/mmol L^{-1} of K). The higher Na rate (1.80 mmol L^{-1}), with no K supply (0 mmol L^{-1}), represented the stressful treatment to plants. The study was arranged in randomized blocks with four replications, accounting 20 experimental units (pots of 5 L), with one plant in each pot. The leaf area (LA) determination was taken by passing all leaves through a leaf area integrator (LI-3100). Later, the leaves, stems, branches and roots were oven-dried (65 °C) and after each part was weighed to obtain its dry matter. The $\delta^{13}C$ ‰ isotope composition of the leaves was determined using a mass spectrometer coupled to a C automatic analyzer and values of $\delta^{13}C$ (‰) were calculated as described by Cernusak et al. (2013). The results were submitted to analysis of variance ($p<0.05$) using a SAS statistical package. The LA and total dry matter decreased with increased Na rates, according to the quadratic model. The Na application did not influence the $\delta^{13}C$ value of E*ucalyptus* seedlings, while the Na rate of 1.8 mmol L^{-1} provided the trend of a higher average value of $\delta^{13}C$ (-31.65 ‰). Besides not significant at 5%, there is a trend for negative correlation among $\delta^{13}C$ and shoot dry matter.

(5288 - 2790) Influence of aluminum on emergence and root growth of *Hancornia speciosa* Gomes

Douglas Almeida Rodrigues[1]; Arthur Almeida Rodrigues[1]; Sebastião Carvalho Vasconcelos Filho[1]; Cássia Lino Rodrigues[1]; Eduardo Matheus Guimarães Teles[1]

Goiano Federal Institute of Education, Science and Technology (IFGoiano), Campus Rio Verde[1]

Hancornia speciosa, Gomes, is a species with several medicinal and nutritional applications presenting important economic potential, is typical of sandy, acid and nutrient poor soils. The study of native plants of regions with soils with presence of aluminum at levels toxic to most of the cultivated species, has been considered the best alternative in increasing the production in acid soils with high concentrations of this cation. The objective of this study was to characterize the effect of aluminum on emergence and root growth of *H. speciosa* seedlings. The effect of Al in *Hancornia speciosa* was examined via sand emergency test with calcium chloride solution (0.1 mM $CaCl_2$, pH 4.0) and culture in nutrient solution (pH 4.0) with macro and micronutrients; $(Al_2O_4)_3 \cdot 18H_2O$) and Al_2O_3 (Al_2O_3) at the end of the experiment. In the emergence, the emergence velocity index and root diameter of the seedlings were significantly reduced with Al treatment. In hydroponic cultivation, aluminum promoted greater root growth at the concentration 300 µmol L^{-1} of Al. It was concluded that the seeds of *H. speciosa*, showed greater sensitivity to Al^{3+} with negative effects on seedling emergence, in the solution culture the tolerance of the seedlings to Al^{3+} are indicative of the action of mechanisms that possibly act in the detoxification of Al in the plant allowing the species to survive in high concentrations of this cátion.

(2883 - 2475) Influence of base fertilization with fertilizers with or without sulfur on sugarcane productivity

Marcelo de Almeida Silva[1]; Lucas Almeida de Holanda[2]; Gabriel Henrique Germino[1]; Marcela Cristina Brunelli-Nascentes[1]; Mariana Peduti Vicentini Sab[1]; Vinicius Ribeiro Arantes[1]
São Paulo State University - School of Agricultural Sciences[1]; IFMT - Advanced Campus Guarantã do Norte[2]

The objective of this research was to evaluate the effect of sulfur-enriched or non-enriched fertilizers applied in base fertilization on the production components and yield of sugarcane. The experiment was conducted in a commercial area, located in Lençóis Paulista, SP, Brazil, in the 2013/2014 season, in production environment C. A randomized blocks experimental design was used, with six treatments, (1) (07-33-18 + 9% S) + 298 kg ha-1 KCl; (2) (06-25-24 + 9% S) + 100 kg ha^{-1} triple superphosphate + 397 kg ha^{-1} KCl; (3) 09-25-25 + 490 kg ha^{-1} of MAP + 87 kg ha^{-1} of urea + 423 kg ha^{-1} of KCl; (4) 04-20-30 + 320 kg ha^{-1} of MAP + 180 kg ha^{-1} of single superphosphate + 500 kg ha^{-1} of KCl; (5) 05-25-25 + 410 kg ha^{-1} of MAP + 173 kg ha^{-1} of single superphosphate + 417 kg ha^{-1} of KCl and (6) (90-23-18 + 15% S) + 300 kg ha^{-1} KCl, with 4 replicates. All treatments received 58.5 kg ha^{-1} of N, 150 kg ha^{-1} of P_2O_5 and 225 kg ha^{-1} of K_2O. The variety used was RB966928. At 120 days after sprouting (DAS), faults greater than 50 cm (%) and number of tillers were evaluated, while at harvest, diameter, length and number of stalks per meter, yield of stalks (TCH) and sugar (TAH), total recoverable sugars (ATR), Pol, purity and fiber. Data were submitted to analysis of variance, complemented with the Tukey test, considered significant when $p < 0.05$. The treatments 4 and 5 presented the biggest faults in the stand while in the treatment 1, with 9% of sulfur, the lowest value was verified. The highest TCH were observed in treatments 1 and 6 and the lowest in treatment 4. Despite no difference in the number of tillers at 120 DAS, treatment 1 had the highest number of stalks harvested. The highest TAH was obtained in the treatment 07-33-18 + 9% S, due to the higher TCH, since the ATR did not differ between the treatments. These results demonstrate the beneficial influence of fertilizer sources containing both, sulfur in the form of readily available sulfate and in elemental form with gradual release, on sugarcane production. The high concentration of sulfur and the adequate ratios of this nutrient with nitrogen and phosphorus provide an increase in the efficiency of nutrient absorption and consequently higher production.

(5709 - 1586) Influence of silicon supply on different wheat cultivars grown under phosphorus deficiency

Paula Cartes[1]; Teresa Sepúlveda[1]; Marlys Ulloa[2]; Paulina Jara[3]; Sofía Pontigo[2]
Departamento de Ciencias Químicas y Recursos Naturales, Facultad de Ingeniería y Ciencias, Universidad de La Frontera, P.O. Box 54-D, Temuco, 4811230, Chile[1]; Programa de Doctorado en Ciencias de Recursos Naturales, Universidad de La Frontera, P.O. Box 54-D, Temuco, 4811230, Chile[2]; Center of Plant-Soil Interaction and Natural Resources Biotechnology, Scientific and Technological Bioresource Nucleus (BIOREN-UFRO),Universidad de La Frontera, P.O. Box 54-D, Temuco, 4811230, Chile[3]

Phosphorus (P) is an essential nutrient for plants, but low P availability strongly limits crop production in most of soils. Current evidence has shown that silicon (Si) can ameliorate the deleterious effects derived from P deficiency in vascular plants. However, the mechanisms regarding these responses are still poorly understood. This study aimed to assess the influence of Si supply on P uptake, plant growth, and phenols production with either antioxidant or structural function in two wheat cultivars differing in their tolerance to P deficiency. Wheat (*Triticum aestivum*) cultivars (Púrpura-sensitive and Fritz-tolerant) were hydroponically grown with P (0, 0.01 or 0.1 mM; supplied as K_2HPO_4) in combination with Si (0, 1 or 2 mM; supplied as Na_2SiO_3). At harvest, plant growth, P concentration, lipid peroxidation, radical scavenging activity (DPPH) and total phenols concentration were determined in shoots. In addition, lignin distribution pattern and hydrogen peroxide (H_2O_2) production in chloroplasts were analyzed. Phosphorus concentration was steadily reduced in shoots of wheat cultivars as the level of applied P decreased from 0.1 mM P to 0 mM P. A significant increase of shoot lipid peroxidation coincided with the reduction of shoot dry weight when Purpura and Fritz were subjected to low P supply. Nevertheless, Si applied to P-stressed plants improved shoot dry matter production of Purpura and counteracted the P-induced oxidative damage by up to 39% and 22% in Purpura and Fritz, respectively. Whereas P deficiency augmented both the antioxidant activity and phenolics concentration in shoots of the P-sensitive cultivar, Si application diminished the radical scavenging activity as well as soluble phenols. By contrast, an evident enhancement of lignin deposition was detected in shoots of both cultivars as level of Si increased. Moreover, greater lignifications induced by Si was observed in Fritz, which also showed a lower intracellular H_2O_2 production when Si was applied. These findings will contribute to the understanding the impact of Si on wheat plants grown under P deficiency conditions, as well as its potential benefits on crops production.

(7701 - 2627) Influence of Zn/Cu ratio on production components of soybean

Marcelo de Almeida Silva[1]; Amanda Mei Furuya[1]; Marcela Cristina Brunelli-Nascentes[1]; Hariane Luiz Santos[2]
Sao Paulo State University - School of Agricultural Sciences, 1780 Jose Barbosa de Barros St, Botucatu, 18.610-307, Brazil.[1]; Sao Paulo State University - School of Agricultural Sciences, 1780 Jose Barbosa de Barros St, Botucatu, 18.610-307, Brazil (harianeluiz@gmail.com).[2]

The objective of this study was to evaluate the influence of Zn/Cu ratio in the production components of BRS 133 soybean variety. This experiment was conducted at School of Agricultural Sciences – FCA/UNESP, Botucatu/SP, carried out in greenhouse with semi controlled temperature and relative humidity. The experimental design used was randomized blocks, carried out in pots filled with low Cu content soil (0,3 mg dm-³), with four treatments applied in sowing: (T1) Standart; (T2) 0,6% Zn, 0,6% Mn, 0,3% B; (T3) 0,6% Zn, 0,6% Mn, 0,1% Cu, 0,3% B; (T4) 0,6% Zn, 0,6% Mn, 0,2% Cu, 0,3% B, with five replicates. All pots received the same basic fertilization: 0,4 g pot^{-1} of Muriate of potash (MOP) (sowing + covering), 0,78 g pot^{-1} of Super Triple, 0,042 g pot^{-1} $ZnCl_2$, and were inoculated with 160 mL 100 kg^{-1} *Bradyrhizobium*. The production components were evaluated in the harvest. The data was submitted to normality test and to variance analysis, and the averages compared through Tukey test (P<0,05). Significant differences were not observed among the treatments for length of seedpods with three seeds (cm), length of seedpods with two seeds (cm), number of seedpods with a single seed, number of seedpods without seeds, number of branches, number of seedpods in the main branch, number of seedpods in the branches, total of seeds per plant, total of expected seeds, production (g $plant^{-1}$), mass of 100 seeds (g), stem dry mass (g) and root dry mass (g). However, it was observed differences regarding the number of seedpods with three seeds among treatments, that is the greater values were observed in treatments 2 and 3, while treatment 4 was similar to standart. Treatments 2 and 4 propitiated the lower values of number of seedpods of two seeds, while treatment 3 propitiated the greater value on length in seedpods with a single seed. Although most of the variables evaluated did not show differentiated effects among the treatments, there was a tendency of positive response to the application of muriate of potash with micronutrients fertilizer, however, it was possible to observe the reduction of positive effects with an increase of Cu in relation to Zn in the fertilizer formula. That tendency may indicate an antagonistic effect between Cu and Zn, that is explained through the competition of bivalent cations by bearers in plasma membrane absorption sites.

Keywords: *Glycine max*, micronutrients, muriate of potash.

(8447 - 1984) Interaction between lime and zinc fertilizer in plant cane

Edilson Cavalli[1]; Estêvão Vicari Mellis[1]; Cleide Aparecida de Abreu[1]; Luiz Antonio Junqueira Teixeira[1]; José Antonio Quaggio[1]; Cassiano Cavalli[1]
Campinas Agronomic Institute / IAC[1]

Although the liming is common practice, it is observed in the literature little response to sugarcane. Recent studies showed positive increases in productivity of the plant cane with the application of Zn. Thus, the low sugarcane response to liming may occur due to Zn deficiency. The objective of this study was to evaluate the interaction between liming and fertilization with Zn in plant cane in tropical soils in São Paulo State, Brazil. The experiment was conducted on two types of soil, a clayey soil and other sandy, 4x4 factorial design with 5 replications arranged in randomized blocks. Treatments consisted of 4 managements liming: Dolomitic (DO), Dolomitic+10 kg ha^{-1} Zn (DO+Zn) Zincal (correction with 0.3% Zn in composition) (ZI) and Zincal + complement reaching 10 kg ha^{-1} Zn (ZI+Zn) and 4 of limestone (clay: 0, 1, 2, and 3 and sandy: 0, 1, 1.5 and 2 Mg ha^{-1}). The liming was applied in total area and Zn-sulfate in the furrow. Were evaluated cane yield (TCH), Zn content and the carbonic anhydrase enzyme activity in leaves. The results were compared by Tukey's test and regression analysis, 10% probability. The Zn content in the leaf showed response to managing in both soils. The averages obtained in clay soil were 16,7a; 16,4ab; 15,5b and 15,4b and 14,8ab; 16,0a; 13,6b and 13,9b in mg kg^{-1} in sandy soil, respectively for DO+Zn, ZI+Zn, DO e ZI. The activity of the carbonic anhydrase presented interaction between managements and rates. The regression was not significant for the ZI+Zn treatment in the clay soil and in the treatments with application of Zn-sulphate in the sandy soil. The effect is quadratic in clay soil for treatments: DO ($y=136.16+36.61x-11.64x^2$) DO+Zn ($y=129.55+108.22x-31.36x^2$) and ZI ($y=129,25+43,18x-13,54x^2$) and treatments DO ($y=137.31+61.55x-29.82x^2$) and ZI ($y=130,47+53,62x-26,38x^2$) in sandy. The TCH increased with the application of Zn-sulfate. There was interaction between management and rates only on clay soil. The management DO, DO+Zn and ZI+Zn, showed a quadratic response ($y=170,37+4,73x-5,07x^2$; $y=166,86+24,65x-7,56x^2$ e $y=167,76-12,04x+6,2x^2$, respectively). For ZIN management, the response was linear ($y=151.7+68,59x$). On sandy soil obtained answer to managements (97.1a; 95.4ab; 93.6b 92.8b and Mg ha^{-1}, respectively for ZI+Zn, DO+Zn, ZI and DO) and rates ($y=91.57+10.02x-4.47x^2$), was not observed interaction. Soil correction together with ZN-sulfate fertilization increased TCH, regardless of the limestone used.

(2132 - 2927) Intercalation of borate ions in layered double hydroxides: matrices for source of boron for plant growth

Gustavo Franco de Castro[1]; Jader Alves Ferreira[1]; Roberto Ferreira Novais[1]; Frederico Garcia Pinto[1]; Jairo Tronto[1]
Universidade Federal de Viçosa[1]

The increase of the absorption efficiency of Boron (B) by plants is essential for increasing crop productivity. The intercalation of B in Layered Double Hydroxides (LDH) is an alternative to evaluate how these materials can provide B to plants. This work thus had following objectives: to synthesize and characterize a magnesium and aluminum LDH intercalated with borate ions (Mg_2Al-B-LDH), and to evaluate, by means of a bioassay, the potential of the material produced as a matrix for storage and sustained release of B for plants. To characterize Mg_2Al-B-LDH, the following analysis techniques were used: X-ray powder diffraction (XRD), Fourier-transform infrared absorption spectroscopy with attenuated total reflectance (FTIR/ATR), Scanning Electron Microscopy (SEM), and Ultraviolet-Visible (UV-Vis) molecular absorption spectrophotometry. The treatments a biossay were defined by the combination of 2 x 6 factorial, two sources of B (LDH-B and boric acid) and six doses of B (0.0, 0.5, 1.0, 2.0, 3.0 and 5.0 mg dm^{-3}). The experimental design was performed in randomized blocks (RBD) with four replications. Four sunflower plants (*Helianthus annuus*) were cultivated in each pot. The results were submitted to analysis of variance and regression. The diffractogram profile is characteristic of LDH. For this material, the basal spacing value calculated by the Bragg law equation was 12.0 Å. The FTIR/ATR spectrum shown bands in the region between 1600 and 500 cm^{-1}, this bands are attributed to the various modes of vibration related to the presence of borate anions. The morphology of the Mg_2Al-B-LDH analyzed by SEM presented a surface with many spherical aggregates, with diameters varying between 1 and 5 µm. The total B content in Mg_2Al-B-LDH as determined by UV-Vis was 45.23

mg g^{-1} of B per LDH. For the plants that received the treatments with Mg_2Al-B-LDH and H_3BO_3, there was an increase in the dry matter (DM) and B content in the aerial part of the plants. DM production did not differ statistically in relation to the two sources of B used. Before cultivation, the pH presented average values between 5.73 and 6.15. This pH range, chemically classifies the soil as having medium to weak acidity. This acidity provided destabilization of the lamellar structure of Mg_2Al-B-LDH and the subsequent release of B. The no statistical difference for plant yield between the two sources of B suggests no stability of the Mg_2Al-B-LDH structure under the acidic condition of the soil.

Keywords: Slow-release fertilizer; plant nutrition; LDH matrix; micronutrient; bioassay.

State University of Goias[1]

Corn (Zea mays L.) is one of the world's most important cereals because of its versatility of use in industry, food and feed. Fertilization is the factor that presents the highest contribution to corn yield, due to its highly demanding on nutrients, especially nitrogen. For a more sustainable management, it is necessary to use alternatives that reduce the use of inputs and the cost of production, such as biofertilizers. The objective of this work was to evaluate the action of the biofertilizer Bacsol + Orgasol on the efficiency of nitrogen fertilization in corn yield. The experiment was carried out on an Oxisol (17º 43 '07 "S, 48º 08' 42" W) in the agricultural year 2016/2017. The experimental design was a randomized block design, in a 5x2 factorial scheme, with four replications. The first factor consisted in the presence or absence of the Bacsol + Orgasol biofertilizer, containing rhizospheric microorganisms; the second factor was the nitrogen fertilization rates (0, 40, 80, 120 and 160 kg ha^{-1} of N). The plot consisted of eight planting lines with 5 m in length, spaced at 0.42 m. The plot area was the four central lines, discarding 0.5 m at each end. Seeding was done manually, aiming to obtain a population of 60,000 ha^{-1} plants of the simple hybrid SYN7205 TLTG Viptera. The application of the biofertilizer was done in the seed treatment. In the sowing fertilization, 30 kg ha^{-1} of N, 100 kg ha^{-1} of P_2O_5 and 75 kg ha^{-1} of K_2O were applied. The cover fertilization was done at the phenological stage V3, the haul in the planting line, using urea (45% N) as the source. Maize was harvested manually after the physiological maturation of the grains. The number of rows per scob, grain per row, dry mass of 1,000 grains and grain yield (14% moisture) were evaluated. Greater mass of 1,000 grains was verified with the application of the biofertilizer in the treatment of seeds, while the number of grains per row and rows per scob were not influenced. Higher yields were obtained when the biofertilizer Bacsol + Orgasol, 10,022 kg ha^{-1}, 578 kg ha^{-1} was used more than the treatments without inoculation, in the average of doses of N. The maximum yield was 10,729 kg ha^{-1} at the dose of 86.7 kg ha^{-1} of N in coverage when using biofertilizers in seed treatment. Without biofertilizer, the highest productivity was obtained with the dose of 93.1 kg ha^{-1} of N in coverage, of 9,975 kg ha^{-1}.

(9133 - 328) Morphophysiological and nutritional characteristics of pineapple cv. Pérola and their influence on size and fruit quality

André Guarçoni[1]; Sara Dousseau Arantes[2]; José Aires Ventura[2]
Instituto Capixaba de Pesquisa, Assistência Técnica e Extensão Rural (INCAPER) (guarconi@incaper.es.gov.br)[1]; Instituto Capixaba de Pesquisa, Assistência Técnica e Extensão Rural (INCAPER)[2]

The morphological, physiological and nutritional characteristics of pineapples, at the time of floral induction, have a great influence on crop productivity and fruit quality. The objective of this study was to determine the relationship between the morphological characteristics of 'D' leaf, the nutritional status of the plant, at the time of artificial floral induction, and the size and fruit quality of the pineapple cv. Pérola. In a 'Pérola' pineapple plantation, 120 plants were randomly marked and 'D' leaves were removed at the floral induction time. The pineapple plants were cropped and receiving the same cultural management, being identified in the field with the same numbers of 'D' leaves sampled. The variables of 'D' leaves (length-LL and fresh matter mass -FMM) were evaluated in cm and g, respectively, and the SPAD indices in the upper third (SAF) and the middle third (SMF) were measured with a portable chlorophyllometer. Thirty groups of samples were formed with four leaves each, considering the length of 'D' leaves, that is, the 'D' leaves were classified in ascending order of length, forming groups every four leaves. Three fractions of 'D' leaves were separated: apical fraction - upper third of 'D' leaf (AF), median fraction - middle of 'D' leaf (MF) and basal fraction - basal part aclorophyll of 'D' leaf (BF). The fractions were oven-dried at 70ºC, until reaching constant weight. The leaf fractions of the 30 groups were chemically analyzed for macro and micronutrient contents. After harvested, were determined the mass of the fruits with crowns (WHCM), mass of the fruits without crowns (WTCM), fruit length (FL), fruit circumference (FC), total soluble solids (TSS) and the titratable acidity of the pulp (TAP), determining the mean per sample. Correlation analyzes were performed between the leaf and fruit variables (30 samples each). The developmental characteristics of the leaf (LL and FMM) and the SPAD indices values (SAF and SMF) showed a significant and positive linear correlation ($r > 0,70$; $p > 0,01$) with the fruit growth variables (WHCM, WTCM, FL and FC), but not with the pulp quality characteristics (TSS and TAP). The apical fraction of 'D' leaf (AF) presented the highest levels of nutrients, with the exception of K and Zn. The median fraction of 'D' leaf (MF) must be analyzed for nutritional evaluation of 'Pérola' pineapple.

(8586 - 2260) Multivariate analysis in corn cultivars productivity submitted to fertilization and spacing between rows

Joicelene Costa de Moraes[1]; Anailson de Sousa Alves[2]; Jackson de Mesquita Alves[2]; Luana Ribeiro de Andrade[3]; Suedêmio de Lima Silva[4]; Thainara Brenda Lameira das Neves[1]
Universidade Federal Rural da Amazônia[1]; Universidade Estadual do Maranhão[2]; Universidade Estadual da Paraíba[3]; Universidade Federal Rural do Semi-Árido[4]

The maize is important in various contexts of Brazilian agricultural production, both with regard to economic factors as the social factors. This study assessed through multivariate methods, the productive performance of maize cultivars in terms of three types of fertilization and row spacings, identifying the correlation between the variables and the group throughout the experiment. The experiment was conducted at the Experimental Farm Rafael Fernandes, in Mossoro, RN, adopting a randomized complete block design in a factorial 3 x 2 x 2, with four replications, and the treatments consisted of three fertilizer (AO - Organic fertilization; AOM - organic- mineral fertilization and AM - Mineral fertilization), two corn cultivars (Bras

3010 and Potiguar) and two row spacing (80 cm and 50 cm). The highest yield was obtained with the use of organic fertilizer in Potiguar spaced 80 cm between rows. The final population, productivity and thousand-grain weight were the components that most influenced the evaluation of all the data. Each corn cultivar evaluated responded differently to fertilization and evaluated spacings. The agreement between the results of cluster analysis and principal component analysis with the analysis of variance shows the appropriateness of multivariate statistical techniques used in this study. The combined use of multivariate techniques allowed inferring more safely in groups formed between treatments and their characteristics.

Keywords: organic-mineral fertilization; spatial arrangement.

(2999 - 644) N supply strategies to young vineyards at begging of production

Lincon Oliveira Stefanello[1]; Raíssa Schwalbert[1]; Raí Augusto Schwalbert[1]; Luana Paula Garlet[1]; Simoni Weide Belles[1]; Rodrigo Knevitz Hammerschmitt[1]; Beatriz Baticini Vitto[1]; Letícia Morsch[1]; Vanessa Marques[1]; Gustavo Brunetto[1]
UFSM[1]

Sandy soils with low organic matter content usually presents low nitrogen (N) availability to the vines and therefore mineral N supply is necessary. However, it is not sufficiently known which is the best way of supplying N, allowing rapid grapevine growth, maximum yield of grape, without depreciating the quality of the must. The study aimed to establish the most appropriate way of supplying N in vines at the beginning of production. The experiment was carried in vineyard implanted in 2011, in Santana do Livramento, region of Campanha Gaúcha - Rio Grande do Sul State, southern region of Brazil. Four years data were collected for this study. The cultivar was '*Alicante Bouschet*', grafted on the 'Paulsen 1103'. The vines were grown under the cordon training method, with spacing of 1.2 m between plants and 2.8 m between rows. The weather of the region is Cfa-subtropical, humid without drought. The soil is classified as a Typic Hapludalf. The experimental design was random blocks with five repetitions, each repetition was composed for five vines. The treatments were: without N application (WN), application of 20+20 kg N ha^{-1} without irrigation (NWI), application of 20+20 kg N ha^{-1} followed by irrigation (NFI), application of 20+20 kg N ha^{-1} via fertigation (NF) and application of 20 kg N ha^{-1} via fertigation (½ NF). Urea (45% N) was used as the N source. In treatments with N application via NWI and NFI, urea was applied to the soil surface in the crown projection of the plants. In NF and ½ NF, 1 kg N day^{-1} was supplied. During the flowering and veraison, the leaves located opposite to the bunch were collected to determination of the N concentration, and stem diameter measurements. Grape yield, number of cluster per plant, average weight of cluster and mass of 100 berries were determined in the end of each season. The total soluble solids (TSS), pH, total titratable acidity (TTA) and total anthocyanins (TA) were determined in must of berries. Vines cultivated in the soil submitted to the application of NFI and NF showed larger stem diameter, higher N concentrations in the leaves, higher grape yields and, the lowest values for TSS, TTA and TA, which is not desired. Increases in N uptake conducted to increases in grape yield, but depreciated the composition of the grape, which may negatively affect the quality of the wine. Vines submitted to WN and NWI presented lower grape yield, however, must of chemical composition more suitable for winemaking.

(4290 - 195) Nitrogen concentration and SPAD value in off-season maize intercropped with ruzi grass as a function of nitrogen topdressing fertilization

Karina Batista[1]; Waldssimiler Teixeira de Mattos[1]; Alessandra Aparecida Giacomini[1]; Luciana Gerdes[1]; Ivani Pozar Otsuk[1]
Instituto de Zootecnia[1]

The study of nitrogen topdressing fertilization in the off-season maize intercropped with ruzi grass in no-tillage system is of great importance since in the first five years of the adoption of the no-tillage system the requirement of N is high due to its immobilization. Researches showed that the relationship between the chlorophyll content determined by the chlorophyll meter in SPAD value and the concentration of N in the leaves of annual plants is promising to evaluate the nutritional status in relation to the nitrogen of these plants. Thus, starting from the hypothesis that there is competition for N among intercropped plants, the objective of this study was to evaluate the responses of the off-season maize intercropped with *Brachiaria ruziziensis* cv. Common (ruzi grass) in no-tillage system for nitrogen topdressing fertilization. The experiment was carried out in an Ultisol in the period from March 11, 2015 to October 5, 2015. The treatments were four nitrogen topdressing fertilization rates (0, 30, 60 and 90 kg ha^{-1}) in the off-season maize and in the ruzi grass. A randomized complete block design was used, with four replicates. N was supplied as ammonium nitrate. The SPAD value and the N concentration in the diagnostic leaves of the off-season maize on the occasion of its flowering were evaluated. All the results received the recommended statistical treatment, through the use of SAS, adopting the level of 5% of significance. The analysis of variance was performed by the F test and then the first and second degree regression study for the effect of N rates. The study of correlation between the variables was also performed. The SPAD value and the N concentration in the diagnostic leaves of the off-season maize at the time of flowering corresponded linearly to the N topdressing fertilization rates. It was observed a positive correlation between the SPAD value and the N concentration in the diagnostic leaves of the off-season maize. It was concluded that the nitrogen topdressing fertilization for the off-season maize intercropped with ruzi grass interferes with the concentration of N in the leaves of the off-season maize, and that the SPAD value can be indicative of the nutritional status in N of the off-season maize.

(4844 - 1747) Nitrogen uptake and removal in normal and short cycle common bean cultivars

Fernando Vieira Costa Guidorizzi[1]; Rogério Peres Soratto[1]; Adalton Mazetti Fernandes[2]; Lohan de Oliveira Gomes Pinto[1]; Carolina Ragoni Maniero[1]; Gustavo Felipe Andrews da Silva[1]; Tiago Aranda Catuchi[3]
São Paulo State University (UNESP)-College of Agricultural Sciences, Department of Crop Science, Rua José Barbosa de Barros, nº1780, Botucatu, 18610-307, Brazil[1]; São Paulo State University (UNESP)-Center for Tropical Roots and Starches, Rua José Barbosa de Barros, nº1780, Botucatu, 18610-307, Brazil[2]; University of Western São Paulo, Rodovia Raposo Tavares, km 572, Presidente Prudente, 19026-310, Brazil[3]

Knowledge about nutrient uptake and removal is important for the management of fertilization in agricultural crops; however, in common bean cultivars with short cycle and determined growth habit there is little information about nitrogen (N) uptake and removal. The objective of this study was to evaluate the uptake along the cycle and the removal of N in the common bean cultivars Pérola (normal cycle and indeterminate growth habit) and IPR Andorinha (short cycle and determined growth habit). The experiment was conducted during "rainy season" of the growing season 2016/17 in a dystrophic Red Nitosol. The experiment was arranged in a randomized complete block design with split plots and four replications. Plots were composed of two cultivars and the subplots for seven sampling

periods during the common bean development cycle (14, 28, 42, 56, 70, 77, and 84 days after emergency (DAE)). The cultivars Pérola and IPR Andorinha showed low N uptake up to the sampling period at 14 DAE (first trifoliate leaf), in which they reached approximately 10% of the maximum N uptake. Subsequently, there was an increase in N uptake in both common bean cultivars up to 42 DAE (flowering), when cvs. Pérola and IPR Andorinha reached approximately 80 and 90% of the maximum N accumulation, respectively. Between sampling periods at 42 and 56 DAE (flowering and pod filling) occurred maximum N uptake in cv. IPR Andorinha (107 kg of N ha^{-1}), estimated at 55 DAE (filling of pods), while between at 56 and 70 DAE (pod formation and filling of pods), occurred maximum N uptake in cv. Pérola (116 kg of N ha^{-1}), estimated at 59 DAE (filling of pods). After 56 and 70 DAE, there was a reduction of about 10% of the N uptake by both common bean cultivars. Nitrogen removal was not statistically influenced by the cultivars, which may have occurred due to the similarity in N concentration in grains and grain yield. Nitrogen removal in cvs. Pérola and IPR Andorinha were 84 and 75 kg of N ha^{-1}, respectively. Therefore, it was possible to conclude that the cultivars IPR Andorinha and Pérola did not present important differences in the N uptake and removal.

(7726 - 1177) Number of leaves of safflower crop under soil moisture maintenance methods

Lucas Tavares Da Silva[1]; Tonny José Araújo da Silva[1]; Julyane Vieira Fontenelli[1]; Edna Maria Bonfim-Silva[1]; William Fenner[1]
UFMT[1]

Plant growth and development are directly influenced by the soil moisture. Thus, the correct management of soil moisture throughout the cycle is fundamental, with the objective of ensuring the adequate supply and distribution of soil water to supply the physiological demand and the vegetal production. When soil fertility is not limiting, water becomes the main limiting factor to growth and development, and its impact can be measured by morphometric characteristics, such as number of leaves. Thus, the objective was test soil moisture maintenance methods, evaluating the number of leaves in safflower crop, cultivated in a protected environment. The experiment was carried out at the Federal University of Mato Grosso, Campus of Rondonópolis, in a completely randomized design, with 4 soil moisture maintenance methods (Gravimetric, Irrigas, Tensiometer and Self-irrigation) and 8 replications in a greenhouse. The safflower cultivar used was IMA 0213, sown in the experimental plots, composed of pots of 3.18 dm^3, filled with Oxisol collected in the 0 - 0.2 m layer in an area of native Cerrado vegetation. After liming to raise base saturation to 60%, the soil remained incubated for 30 days. The soil was fertilized with 150 mg dm^{-3} of P_2O_5 (superphosphate simple), 100 mg dm^{-3} of K_2O (potassium chloride) and 15 mg dm^{-3} of FTE BR 12 to provide micronutrients. Nitrogen fertilization (200 mg dm^{-3}) was divided into three urea applications at 10, 20 and 40 days after emergence (DAE). The soil water retention characteristic was used for moisture management and humidity equivalent to 80% of field capacity for all treatments except the Self-irrigation. The soil moisture in the Gravimetric method was determined by mass difference. In Irrigas replacement was performed when the tension of 20 kPa was reached. For the Tensiometer the tension of 5 kPa was considered and for the Self-irrigation 3 kPa. The readings were performed at 7 and 14 h daily. Leaves count was performed at 15, 22, 29 and 69 DAE and data submitted to ANOVA and Tukey test at 5% probability. The average leaves production was 22.41, 48.53, 59.59 and 134.38 leaves per pot at 15, 22, 29 and 69 DAE, respectively. At 69 DAE, Gravimetric differed significantly from the Irrigas, Tensiometer and Self-irrigation methods with the highest number of leaves.

(5354 - 1038) Number of Safflower leaves submitted to doses of vegetal ash and soil compaction levels in Oxisol

Horácio Manfrin Mazero[1]; Edna Maria Bonfim-Silva[1]; Túlio Martinez Santos[1]; Tonny José Araújo da Silva[1]
Universidade Federal de Mato Grosso[1]

Soil compaction and poor fertility are important limiting factors for agricultural production. Besides that, there are economic and environmental requirements to apply wastes, such as vegetable ash, to fertilize the soil. In this context, the scope of this study was to evaluate the effect of vegetal ash doses coupled to levels of soil compaction in the numbering of safflower leaves. The experiment was performed in a greenhouse under randomized complete block design with five levels of soil compaction (1.0, 1.2, 1.4, 1.6 and 1.8 Mg m^{-3}) and fertilized with five vegetable ash doses (0, 8, 16, 24, 32 g dm^{-3}). The applications of the ash doses occurred immediately after the gathering of the soil according to the respective treatments. Each experimental unit was formed a PVC vase with three isometric rings attached by silver tape. The vases had 200 mm of internal diameter and 300 mm of height, with a total of 9.4 dm^3 of soil. The intermediate ring was compacted using the hydraulic press (P15ST, BOVENAU) according to the treatments, while the upper and lower rings were filled with soil with a density of 1.0 Mg m^{-3}. Because no nitrogen was expected to exist in the vegetal ash due to its loss by combustion, fertilization with nitrogen of 150 mg dm^{-3} was performed in all vessels to meet the plant's needs. This fertilization was divided in three fortnightly applications from the 15th day after emergence (DAE): 40, 55 and 55 mg dm^{-3} at 15, 30 and 45 DAE, respectively. The results (number of leaves) were submitted to analysis of variance and significance was verified to the regression analysis using the SISVAR software with significance of 5%. The number of leaves variation occurred linearly for both ash doses and soil compaction levels, being a positive correlation for the increase of the doses, and negative for the elevation of the compaction levels. On the 15th day, the best results (5.88 leaves per plant) were observed in the highest dose of vegetable ash (32 g dm^{-3}), and there was no statistical difference in the results for different compaction levels. On the 30th day, the best treatments provided 29.43 leaves, observed for 32 g dm^{-3} of dose and 1.4 Mg m^{-3} of compaction. Finally, on the 45th day, the best treatments provided 55.63 leaves per plant, observed for 24 g dm^{-3} of dose and 1.0 Mg m^{-3} of compaction. The number of leaves of the safflower cultivated in the Oxisol from Cerrado was influenced by fertilization with vegetal ash and soil compaction levels.

(3162 - 638) Phosphorus forms in organs of *Cordia trichotoma* subjected the phosphate fertilization

Matheus Severo de Souza Kulmann[1]; Lincon Oliveira Stefanello[1]; Yohana Porto Calegari Alves[1]; Álvaro Luís Pasquetti Berghetti[1]; Wagner Squizani Arruda[1]; Simone Weide Belles[1]; Rodrigo Otavio Schneider Souza[1]; Jacson Hindesrmann[1]; Maristela Machado Araujo[1]; Gustavo Brunetto[1]

UFSM[1]

The Louro-Pardo (*Cordia trichotoma*) has high potential for reforestation, because it has a rapid increase in biomass and wood of density high. However, it has higher productivity and better growth when grown on fertile soils. Therefore, when the need is diagnosed, nutrients are supplied, such as phosphorus (P). However, in plants of *Cordia trichotoma* in growing, it is not known if the application of P doses and the increase of their availability in the soil, it can modify a distribution of forms of P, as P_{SI} and P_{SO} in interior of the plant, and increase the production of biomass. This study aimed to evaluate the distribution of forms of P in organs of *Cordia trichotoma* grown in Argissolo Vermelho Distrófico arênico subjected to the application of 0, 120 and 360 kg P_2O_5 ha^{-1}. After 24 months of fertilization, the plants of *Cordia trichotoma* were cut and removed. The roots, leaves, branches and stems were collected, dried, weighed and ground. The tissues of the organs were subjected to chemical forms of P, which estimates forms of total soluble P (P_{ST}), soluble inorganic P (P_{SI}), soluble organic P (P_{SO}) (difference between P_{ST} and P_{SI}). The highest production of dry matter of stem, branches and leaves for observation in plants grown with 120 kg P_2O_5 ha^{-1}, followed by plants grown with 360 kg P_2O_5 ha^{-1} and those without P. The highest production of dry matter root was observed in the plants grown with 120 kg P_2O_5 ha^{-1}, followed of plants subjected the application of 360 kg P_2O_5 ha^{-1} and those without application of P. P in the tissue of annual organs, as leaves, of *Cordia trichotoma* was preferentially accumulated in soluble inorganic (P_{SI}), in plants grown in the soil without application of P and with the addition of 120 and 360 kg P_2O_5 ha^{-1}. On the other hand, P in perennial organs, such as stems and branches, was preferentially accumulated in soluble organic (P_{SO}), in plants grown in the soil without application of P and with the addition of 120 and 360 kg P_2O_5 ha^{-1}. The application of the higher dose of P (360 kg P_2O_5 ha^{-1}) stimulated the accumulation of P preferentially in the forms soluble organic (P_{SO}) in roots, as a reserve organ. Plants of *Cordia trichotoma* grown with 120 kg P_2O_5 ha^{-1} had more efficient use of P available in the soil, using P within the plant in its metabolism, in the form P_{SI}, allowing the increase of cell membrane complexes, such as thylakoid, allowing a higher photosynthetic rate by the plant, which stimulated biomass production.

(5874 - 891) Photosynthesis in young peach trees submitted to application of nitrogen sources in soil with and without presence of cover crops

Betania Vahl de Paula[1]; Álvaro Luis Pasquetti Berghetti[2]; Camila Peligrinotti Tarouco[2]; Beatriz Baticini Vitto[2]; Gabriel Alberto Sans[2]; Luana Paula Garlet[2]; Wagner Squizani de Arruda[2]; George Wellington Bastos de Melo[3]; Carlos Alberto Ceretta[2]; Gustavo Brunetto[2]
Federal University of Santa Maria, Av. Roraima nº 1000, Camobi, Santa Maria - RS, CEP: 9710500, Brazil. behdepaula@hotmail.com.[1]; Federal University of Santa Maria, Av. Roraima nº 1000, Camobi, Santa Maria - RS, CEP: 97105-900, Brazil.[2]; Embrapa Uva e Vinho, Livramento Street, 515, CEP: 95701-008 - Bento Gonçalves – RS, Brazil.[3]

The Peach Tree (*Prunus persica* L.) is the third most fruit tree species in the world, behind apple and pear trees. Nitrogen (N) is extremely important for plant nutrition, especially as it is an essential constituent of proteins and directly interferes with the photosynthetic process, being present in the chloroplasts as a constituent of the chlorophyll molecule. However, the information on the best sources of N to be applied to young Peach Trees with presence or absence of cover crops in the planting line still are scarce. The study aimed to evaluate the photosynthetic parameters in young Peach Tree with application of N sources, with and without presence of cover crops. The experiment was conducted in greenhouse from October 2016 to April 2017. Plants of the cultivar Chimarrita, grafted on the one year old Capedebosq rootstock, were transplanted in pots containing samples of Humic Cambisol soil, normally cultivated with Peach Trees in the Brazil. After 15 days of the Peach Tree transplant, six shoots of *Paspalum notatum* were transplanted into 50% of the pots. After 21 days, the following treatments were installed: Control (cultivation of Peach without fertilization and without cover crops), urea (U), urea + cover crops (UPC), organic compost (C), organic compost + cover crops (CPC) and cover crops plans (PC). The dose of urea and organic compost was equivalent to 40 kg N ha^{-1}. The experimental design was completely randomized, with 5 replicates. The photosynthetic parameters were evaluated at 120 days after the experiment was installed, using the portable infrared analyzer LI-COR (IRGA), model LI-6400 XT, we evaluated the net assimilation rate of CO_2 (μmol CO_2 m^2s^1), water use efficiency (mol CO_2 mol H_2O), and the carboxylation efficiency of Rubisco. The minimum fluorescence (F_0), maximum fluorescence (F_m) and electron transport rate (ETR) was evaluated using portable modulated light fluorometer (JUNIOR-PAM). The N sources used did not showed difference between the treatments. However, Peach plants cultivated without intercropping with cover crops presented higher rates of CO_2 net assimilation, higher water use and Rubisco carboxylation efficiency, as well as higher ETR and lower F_m. This suggests that when there are cohabiting plants with peach trees, which do not yet have a large volume of roots, there is competition for water and nutrients between the two species, causing a negative effect on the physiological parameters of the Peach plants.

(2480 - 242) Photosynthetic activity of upland rice plants in response to selenium applicationPhotosynthetic activity of upland rice plants in response to selenium application

Maria Luiza Nunes Palone Fauvel[1]; Eduardo Henrique Marcandalli Boleta[1]; André Rodrigues dos Reis[2]
São Paulo State University - UNESP/Ilha Solteira[1]; São Paulo State University - UNESP/Tupã[2]

Selenium (Se) is an essential element for humans and animals due to antioxidative properties. There are conclusive evidences about Se deficiency in Brazilian soils. The application of Se in low concentration can decrease the lipid peroxidation, enhance the antioxidant metabolism and photosynthesis of plants. Agronomic biofortification through fertilizer application, is a good strategy to increase the Se concentration in plants. This study aimed to evaluate the photosynthetic activity of upland rice plants in response to Se rates and application methods (foliar and soil). The experimental design used was randomized blocks containing 7 rates of Se (0; 2,5; 5; 7,5; 10; 15; 20 g ha^{-1}) via soil application and 7 rates of Se (0; 1; 2; 4; 6; 8; 10; g ha^{-1}) via foliar application. Sodium selenate was used, as Se source applied to BRS Esmeralda cultivar. After 15 days of Se application, the net photosynthesis was analyzed using a portable system of infrared

gas analyzer (LC pro-SD – ADC BioScientific Ltda., Herts, UK). The CO_2 liquid assimilation (A, µmol CO_2 m^{-2} s^{-1}) and the stomatal conductance (Gs, mol H_2O m^{-2} s^{-1}) were measured. Soil and foliar Se application increased significantly the A rates. The largest doses of soil and foliar application increased 31,89% and 63,44%, respectively, when compared to the control. The Gs increased up to 10 g ha^{-1} of Se via soil, and up to 2 g ha^{-1} via foliar application. The increase of A and Gs in response to Se application suggest the protective effect of Se to rice plants. The application of Se up to 20 g ha^{-1} via soil and 10 g ha^{-1} via foliar increased the photosynthetic activity of rice plants.

Keywords: Selenium, photosynthesis, antioxidation

(8822 - 674) Physico-Chemical Properties of Soil in Sweetpotato Cultivated Area in Korea

Kyeong-Bo Lee[1]; Sang-Sik Nam, Yong-Gu Kang, Jung-Wook Yang, Gyeong-Dan Yu, Seung-Yong Lee, Hyeong-Un Lee, Eung-Gi Je[1]
National Institute of Crop Science, RDA[1]

Sweetpotato [*Ipomoea batatas* (L) Lam.] cultivated area has grown at a rapid rate over the past several years in Korea and the area spread to 20 thousands hectares. The production per unit was 15 ton/ha which has been stable since 2000. The average production in 2016 was 341 thousand M/T which was 79% in 1990's. About 30 cultivars used for eating, processing, viewing and brewing etc. have been bred since 1990. The latest cultivars are the most popular because of their resistance against disease and their production quality. The largest cultivated area of sweetpotato in Korea is Jeonnam-province (24.9%) followed by Jeonbuk (18%), Gyeonggi (15.6%) and Chungnam (14%) province, respectively. The quality of sweetpotato is dependent on various features of cultivated soil environment. For that reason, we analyzed and evaluated the physico-chemical properties of soil of major cultivated area in order to provide baseline data for researching the quality characteristics of sweetpotato. Physico-chemical properties includes soil pH, organic matter, P_2O_5 content, T-N content, potassium, calcium and magnesium content. The regions that we chose were Icheon, Wonju, Yoeju, Ganghwa, Nonsan, Gochang, Gimje, Iksan, Muan and Haenam. The soil texture of Gimje, Iksan and Haenam were loam and the others were sandy loam. The regions which have sandy loam were consisted of sand (53~72%), silt (21~34%) and clay (6~18%). Result showed that, the pH of these areas were 5.3~7.2 and organic matter content was 3.2~16.8 g/kg which was lower than the other fields. As of the P_2O_5 content, it ranges from 72 to 221 mg/kg, Gochang (31 mg/kg) and Haenam (5 mg/kg) is tend to be lower than the other area. The T-N content varied from 0.02~0.08%. In regard of exchangeable cation, potassium content varied from 0.3~0.6 $cmol^+$/kg, where calcium and magnesium content were 1.8~8.8 $cmol^+$/kg and 1.1~8.0 $cmol^+$/kg, respectively. Icheon and Yeoju has the least content of exchange cation capacity (CEC) whose range was 7.4~8.9 $cmol^+$/kg and on the contrary, Haenam showed the most 13.1~14.5 $cmol^+$/kg.

(5340 - 3033) Physiological responses to differencial boron fertilization on soybean of brazilian Cerrado

Larissa Urzêdo Rodrigues[1]; Antônio Carlos Martins dos Santos[2]; Vitor de Laia Nascimento[2]; Fernando Machado Haesbaert[2]; Rubens Ribeiro da Silva[2]
Plant Production Graduate Program, Universidade Federal do Tocantins, Gurupi, Tocantins, Brazil[1]; Plant Production Graduate Program, Universidade Federal do Tocantins, Gurupi, Tocantins, Brazi[2]

Soybean is one of the main crops in Brazil and the Tocantins state comes every year increasing production and yield of this crop. A bottleneck for this increase is the management of macro and micronutrients in the Cerrado soil. Boron (B) is a micronutrient that has influence on plant physiology and growth, and one of the most demanded by the soybean. The strategies to complement the supply of B to crops are the fertilization via soil and the foliar application. Considering that soybean requires specific amounts of B for optimal yield and quality, it is necessary that ideal dose for each soil be established. The aim of this work was to use non-destructive physiological tools to evaluate the efficiency of B fertilization via soil and leaves in the soybean crop in the Tocantins Cerrado. The experiment was conducted in greenhouse with semi-automated irrigation system, plants grown in pots with 7.0 kg of soil (yellow latosol) and the experimental design was completely randomized in a 4x5 factorial scheme with four replications. The cultivar used was M8808Ipro. Treatments consisted of four doses of boric acid (the form that B is absorbed by plants) on soil (0; 2; 7; 40 kg ha^{-1}), done at the time of sowing, and five doses of boric acid on leaves (0; 0.5; 1.0; 1.5; and 2.0 kg ha^{-1}), applied during development. Here we analyzed photosynthetic pigments content (chlorophyll *a*, *b*, total, and *a*/*b* ratio, with ClorofiLOG®), as well as gas exchange (photosynthesis, transpiration, stomatal conductance, internal CO_2 concentration, and water use efficiency, with Infrared Gas Analyzer - IRGA), in two phenological stages, vegetative and reproductive. All variables presented interaction among the factors, demonstrating that these non-destructive physiological parameters are interesting tools in the study of micronutrient fertilization management. It is noteworthy that in the vegetative stage the low concentration of B via foliar application associated with low or none application of B in the soil were the best results of chlorophylls contents and photosynthetic rate demonstrating that high doses of B, even without presenting phytotoxicity, can be harmful to plant growth. Finally, for non-destructive physiological characteristics here analyzed, leaf fertilization presented better performance compared to soil fertilization. However, for the confirmation of these results it is necessary the growth and productivity analysis of the soybean at the end of the experiment.

(5646 - 1704) Potassium doses in the cultivation of tomato (Solanum lycopersicum) for the industry

Eli Pereira Jesus[1]; Bruno Bernardes de Andrade[1]
Centro Universitário de Patos de Minas - UNIPAM[1]

The tomato is one of the most consumed vegetable products in the world, whether in natura or industrialized (extracts, sauce and ketchup) and widely cultivated in Brazil, characterized as a very demanding nutrient culture where potassium is the most demanded, followed by nitrogen and calcium. In the Patos de Minas region, the cultivation of tomatoes destined to the processing occurs not only for commercial interest, but also as an alternative for soil nutrient cycling and reduction of pest and disease pressure in the region's crops. The supply of potassium to the plants, according to the literature, varies between 50 and 250 kg ha^{-1} of K_2O, which are lower than those used in Brazilian crops, which can be considered as lagged. The objective of this work was to evaluate the productivity of tomatoes as a function of different doses of potassium (378, 428, 478, 528, 578 kg ha^{-1} K_2O) using potassium chloride as the source. The experiment was carried out in May/17, in a pivotal pivot, located in Patos de Minas - MG, Brazil, using the hybrid HMX 7885 F1, with an experimental design in

a randomized complete block design (DBC) with five treatments and four replications. The leaves were collected randomly to determine the foliar content of potassium. The mean productivity (t ha^{-1}), mean fruit weight (kg), number of fruits per plant were also evaluated. The data averages were submitted to analysis of variance with the help of Sisvar software. There was no adjustment of the regression model indicating that there was no significant statistical difference for the K_2O doses on the characteristics studied. The results show that the dose of 378 kg ha^{-1} promoted higher productivity indexes (128.28 t ha^{-1}), a higher average number of fruits per plant (103.88), and it was possible to infer that this dose should serve as a delivery ceiling of potassium to the tomato. Although the increase in the potassium dose reduced the yield of the crop, all the treatments provided an average productivity higher than the national one. The leaf contents varied between 2.858 and 3.193% for the doses of 428 and 528 kg K_2O ha^{-1} respectively. The use of new genetic materials with high productive potential reinforces, as well as the results obtained in this work support the need in the development of studies to supply not only potassium but all nutrients for the tomato crop.

(9231 - 639) Potassium extracted by Ammonium acetate, Mehlich-3 and Sodium tetraphenylboron methods and their relationships with mineralogy in soils under agricultural systems in Uruguay

Marcelo G. Ferrando[1]; Mónica M. Barbazán[1]

Facultad de Agronomía, Universidad de la República[1]

Most methods of soil analysis to evaluate the supply of potassium (K) for the plants measure a proportion of the total exchangeable K of soil. The neutral 1 N ammonium acetate (NH_4OAc) is the conventional extractant, although other methods such as Mehlich-3 (M3) test, are being rapidly adopted, since they allow the simultaneous extraction of several elements in a single procedure. However, these methods do not estimate the nonexchangeable K held in the interlayers of the expandable clays minerals, which can be released to exchangeable or available forms in the medium and long term. The sodium tetraphenylboron ($NaBPh_4$) method has been proposed to improve the predictions of K available for the plants, since it estimates not only the exchangeable K, but also a proportion of that K held in the micas's interlayers. Were analyzed 412 soil samples from different agricultural soils in Uruguay, including a wide range of textural classes, different parent materials, history of K fertilization, K content and availability for plants. The K was extracted using NH_4OAc, M3 and $NaBPh_4$ (5-min extraction period). It was also analyzed the mineralogy of the clay fraction of most soils by X-ray diffraction analysis. Results showed a very strong correlation between the extraction of K with M3 and NH_4OAc (R^2=0,90), although the amounts extracted whit M3 were somewhat lower. The $NaBPh_4$ solution extracted between 1.5 and 2 times more K than the other solutions and allowed to groupe soils with different non-exchangeable K reserves, frequently associated with the presence of illite as the main clay fraction mineral.

(7055 - 2435) Potassium increases production and reduces the oxidative stress of Tanzania guinea grass used for cadmium phytoextraction

Ellen Cristina Alves de Anicésio[1]; Francisco Antonio Monteiro[1]

Escola Superior de Agricultura "Luiz de Queiroz" - ESALQ/USP[1]

Cadmium (Cd) is considered a serious environmental problem due to its high toxicity to living organisms. This metal induces oxidative stress causing negative impacts on plant growth and development. The potassium (K) supply is one strategy to increase the tolerance of tanzania guinea grass (*Panicum maximum* Jacq. cv. Tanzania) exposed to Cd toxicity. The aim of this study was to verify the influence of K on reducing the toxic effects of Cd in tanzania guinea grass used for phytoextraction of this metal. Plants were grown in a greenhouse, in a randomized complete block design, using a 3x4 factorial, with six replications. Three rates of K (0.4, 6.0 and 11.6 mmol L^{-1}) were combined with four rates of Cd (0.0, 0.5, 1.0 and 1.5 mmol L^{-1}) in nutrient solution. Two plant growth periods were evaluated. The first harvest was done at 35 days after seedlings transplanting to the pots and the second at 27 days after the first. In the second growth, Cd was not added in the nutrient solution. At the harvest, shoots were separated in recently fully expanded leaf laminae (LR) and other parts (DP). The Cd concentration in LR in both harvests and in the roots increased with the rate of Cd. In the second harvest, in medium to high Cd rates (0.5 to 1.5 mmol L^{-1}), the higher K supply favored the highest Cd concentration in the plant tissue. The increase of the K rates provided higher Cd accumulation in shoots collected in both harvests, increasing the Cd-phytoextraction potential of tanzania guinea grass. In the first harvest, the higher availability of cadmium (1.5 mmol L^{-1}) resulted in lower shoot dry mass production due to the increase (35%) in malondialdehyde (MDA) concentration in the DP. However, the K supply in plants exposed to Cd provided a reduction of the MDA concentration of the LR. In the second harvest, the higher K availability (11.6 mmol L^{-1}) provided higher shoot growth, under conditions of moderate toxicity (residual effect of Cd), due to the 26% reduction in MDA concentration of the DP. These results indicate that the K reduces oxidative stress of plants exposed to Cd toxicity, increasing shoot dry mass production. The increase in Cd concentration in plant tissues associated with higher production of dry mass indicate that the supply of K increases the Cd-phytoextraction potential of tanzania guinea grass.

(7956 - 758) Productive and nutritional characteristics of wheat cultivar brs 394, fertilized and irrigated with nitrogen and sulfur in the brazilian Cerrado

Edna Maria Bonfim-Silva[1]; Tonny Jose Araujo da Silva[1]; Thiago Henrique Ferreira Matos Castañon[1]; William Fenner2.[1]

UFMT[1]

Wheat (*Triticum aestivum* L.) is one of the main cereal cultivated in the world. In Brazil, wheat cultivation is concentrated in the southern region, characterized by mild temperatures and regular precipitation throughout the year. However, the Central-West region, in which the Cerrado biome is located, has great potential for wheat cultivation, in an irrigated regime during the off-season (months from April to September). Thus, the objective of this study was to evaluate the nitrogen concentration in the leaves and the number of wheat spikes cultivar BRS 394, irrigated and submitted to combinations of nitrogen and sulfur doses. The research was carried out in 2017 at the Federal University of Mato Grosso, Rondonópolis Mato Grosso, Brazil (16°27'54.98" S and 54°34'41.75" W). The soil of the area was classified as Oxisol. The experiment was in randomized block design in factorial scheme 5^2 fractionated with four replicates. The treatments were five nitrogen doses (0, 70, 140, 210 and 280 kg ha^{-1}) combined with five doses of sulfur (0, 25, 50, 75 and 100 kg ha^{-1}). The sources of fertilizers used were urea (45% N) and elemental sulfur (97% S). BRS 394 wheat cultivar is classified as early cycle. Irrigation was a self-propelled irrigation system with adapted irrigation bar. The evaluated

variables were nitrogen concentration in the diagnostic leaves (leaves +1 and +2) at 45 days after emergence of the plants and the number of spikes per m². The variables were significant only for nitrogen doses. The nitrogen concentration in the leaves was adjusted to the quadratic regression model, with the highest concentration (40 g kg^{-1}) at the nitrogen dose 280 kg ha^{-1}. The number of spikes was adjusted to the quadratic model of regression, with the largest number (387 spikes m^{-2}) in the nitrogen dose of 170 kg ha^{-1}. Nitrogen fertilization increases the nitrogen concentration in the leaf and the number of spikes of wheat. Sulfur does not influence the concentration of nitrogen in the leaves and the number of spikes when cultivated in Oxisol of the Brazilian Cerrado.

(5565 - 319) Productive components and yield of corn with *Azospiriilum brasilense* associated with silicon and nitrogen doses

Fernando Shintate Galindo[1]; Marcelo Carvalho Minhoto Teixeira Filho[1]; Salatiér Buzetti[1]; Willian Lima Rodrigues[1]; Eduardo Henrique Marcandalli Boleta[1]; José Mateus Kondo Santini[1]; Poliana Aparecida Leonel Rosa[1]; Rafaela Neris Gaspareto[1]
FEIS/UNESP[1]

Azospirillum brasilense is a bacterium that stands out for its biological nitrogen fixation (BNF) in corn crops. However, there is a lack of more comprehensive research defining how much mineral N can be applied as regards the efficiency of BNF to attain high, economically sustainable yields. Moreover, it would be interesting to investigate the use of silicon, which exerts numerous benefits on grasses, especially when the plants are subjected to biotic and abiotic stresses. The aim of this work was to study a synergistic effect between the inoculation with *A. brasilense* and the application of silicon, thus enabling a higher efficiency of nitrogen fertilization, evaluating the productive componentes (number of grains per spike, 100 grains mass, harvest index) and grain yield of irrigated corn. The experiment was conducted in Selvíria, MS, Brazil, which had been cultivated with annual crops for over 28 years, with the last 11 years under the no-till system, and the crops prior to corn were corn and wheat, respectively, on a Latossolo Vermelho distrófico (Oxisol) in 2015/2016 crop. The experiment was set up as a randomized block design with four replications, in a 2 × 5 × 2 factorial arrangement consisting of two soil corrective sources (dolomitic limestone PRNT = 80%, CaO = 28% and MgO = 20% and silicate of Ca and Mg as Si source PRNT = 88%, Ca = 25%, Mg = 6% and Si total = 10%); five doses of N (0, 50, 100, 150 and 200 kg ha^{-1}); with and without inoculation with *A. brasilense*. N doses influenced positively 100 grain mass and harvest index, with adjustment to the linear increasing function. The interaction between doses and inoculation was significant for the number of grains per spike and grain yield. The treatments without inoculation set to the linear increasing function, and the treatments with inoculation set to the quadratic funtion until the doses of 150 and 155 kg ha^{-1} of N for grains per spike and grain yield, respectively. At the dose of 200 kg ha^{-1}, the inoculated treatments promoted higher grain yield. The interaction between doses and sources of acidity correctives was also significant, with positive linear adjustment for dolomitic limestone and quadratic adjustment for Ca and Mg silicate until the dose of 138 kg ha^{-1}. At the dose of 200 kg ha^{-1}, the utilization of dolomitc limestone promoted higher grain yield.

(4677 - 2824) Productivity and nutritional status of maize grown under different dosages of nitrogen, phosphorus and potassium.

José Lucas Farias da Silva[1]; Renato Lemos dos Santos[1]; Maria José Alves de Moura[1]; Victor Hugo de Farias Guedes[1]; José de Arruda Barbosa[1]; Nayara Rose da Conceição Lopes[1]; Evaldo Barbosa de França Júnior[1]; Lyllian Brunelly dos Santos[1]; Larissa Grasiela de Arruda Ferreira Costa[1]; Diego Moura de Andrade Oliveira[1]; Wellisson José Maurício de Andrade[1]; Alisson Rodrigues Galvão da Silva[1]
IFPE[1]

The expression of the genetic potential of maize production requires adequate nutrition, which is usually favored by fertilization. However, the dosages traditionally recommended are outdated in relation to the need of the crop, and should be based on nutrient extraction. The objective of this work was to evaluate the effect of N, P and K dosages on nutritional status and biomass production of the maize. The experiment was developed at Fazenda Cipoal, in Passira-PE, from September to December 2017. The hybrid maize genotype AG 8677 VT PRO 3 was submitted to five treatments, varying dosages, in kg ha^{-1}, de N, P_2O_5 e K_2O, as follows: 200, 104 and 120, T1; 200, 104 and 240, T2; 200, 50 and 240, T3; 240, 104 and 280, T4; and 240, 50 and 280, T5. The experiment was a randomized block design, with four replications. Each plot is 39.2 m², with five plants per m². At 65 days after planting (DAP), index leaves were collected to evaluate the nutritional status of the crop, determining the N, P, K, Ca and S content. The nutritional evaluation was performed using the range of sufficiency. For the evaluation of the fresh matter production of the aerial part (MFPA), at the 70 DAP the cutting and the weighing of the plants were performed. The product of the number of plants per meter and the fresh mass of the plants estimated the production of the crop. The data were submitted to analysis of variance by the F test ($p < 0.05$), when observed significant effect, was applied or Scott-Knott's test ($p < 0.05$). When using the sufficiency range, it was observed that in all treatments maize was fed N, K and Ca, and the P content was below the sufficiency range. S levels did not present within the sufficiency range, only when T2 treatment was received. In general, T4 provided levels above the target stipulated by the sufficiency range for the crop. At 70 DAP, the highest productivity of MFPA was observed in T4, 68.87 Mg ha^{-1}, a value above the crop yield average of 45 Mg ha^{-1}. T1 presented the lowest productivity among treatments. The production of MFPA between treatments T2, T3 and T5, was intermediate to treatments T1 and T4, but similar to each other. The application of 240 kg ha^{-1} of N, 104 kg ha^{-1} of P_2O_5 and 280 kg ha^{-1} of K_2O, based on the extraction and the K/N ratio, provided the maize with better nutrition, resulting in higher productivity of aerial biomass.

(6655 - 2877) Productivity of the sugar cane in the second cycle, cultivated under nitrogen and molybdenum fertilization

Wellisson José Maurío De Andrade[1]; Renato Lemos Dos Santos[1]; Diego Moura De Andrade Oliveira[1]; José De Arruda Barbosa[1]; Maria José Alves De Moura[1]; Nayara Rose Da Conceição Lopes[1]; Victor Hugo De Farias Guedes[1]; Larissa Grasiela De Arruda Ferreira Costa[1]; Lyllian Brunelly Dos Santos[1]; Lluan Dos Santos Costa Ataide[1]; Monalisa Barbosa Da Costa[2]; José Lucas Farias Da Silva[1]

IFPE[1]; UFPE[2]

The production of sugarcane in Brazil stands out with most of the sugar marketed worldwide. Nitrogen (N) is one of the nutrients most absorbed by the crop. Reductions in their availability and absorption lead to loss of productivity. Molybdenum (Mo) is a micronutrient, of extreme importance for sugarcane, because it acts in the assimilation and fixation of the N, promoting greater absorption of the nutrient, raising productivity. The objective of this work was to evaluate the effect of nitrogen and molybdenum fertilization on yield of stalks and sugar in the second cycle of sugarcane. Methodology – The experiment was conducted at the Plant of the JB Group, located in rural area of the city of Vitória de Santo Antão-PE. It was started in March 2017, in the second cycle of the crop. The variety used was SP 933094. It was submitted to four doses of Mo (0, 100, 200 and 400 g ha^{-1}) and three doses of N (0, 60 and 120 kg ha^{-1}), using four repetitions, arranged casually in blocks. 300 days after the cut (DAC) was evaluated the yield of stalk (TCH), estimated by the mass of three stalks per plot and the number of plants per meter in each plot. In the stalk was determined the Pol of the corrected sugarcane (PCC), according to the methodology of CONSECANA (2006). The ton of Pol per hectare (TPH) was estimated by the equation: TPH = TCH × PCC/100, according to LIMA NETO ET AL. (2013). Data were submitted to analysis of variance (Test F, $p < 0.05$). When a significant effect of Mo was observed, regression analysis was performed. Results and discussions – At 300 DAC, the application of 120 kg ha^{-1} of N, in the absence of Mo, promoted increase in stalks, differentiating from the other N availability situations. However, when the Mo dose was maximal, the values were close, and no difference was observed. The TPH value was higher with the application of N, until approximately the dose of 200 g ha^{-1} of Mo. In the absence of molybdenum fertilization, the application of 120 kg ha^{-1} of N promoted an average increment of 8% in Pol productivity. Mo doses increased the Pol productivity. In situations of lower N availability, TPH was maximal with the dose of 200 g ha^{-1} of Mo. When 120 kg ha^{-1} of N was applied, TPH was maximal with the highest dose of Mo. Conclusions – TCH and TPH had gains with molybdenum fertilization. Therefore, it is recommended to use molybdenum fertilization, regardless of the dose of N, to promote increases in agricultural productivity.

(4465 - 347) Quantification of carbon, phosphorus and potassium in a red nitosols under succession of cultures with different historical

Ericles Marques Ribeiro[1]; Vitor Hugo Terrenas Carvalho[1]; Felipe Gasparello Luccas[1]; Wesley Machado[1]; Thadeu Rodrigues de Melo[1]; Maria de Fátima Guimarães[1]; Pedro Vendrame Siqueira[1]
Universidade Norte do Paraná[1]

Nowadays, with the advent of no-till, we support the idea of soil and water conservation, consequently, the preservation of natural resources, through the pillars that support the technique, but this isn't the reality we are. The objective was to quantify the levels of carbono (C), phosphorus (P) and potassium (K) in crop succession areas, with different historical. Trenches were opened for pedological classification and samples collection from 0-10, 10-20 and 20-40cm. For chemical analysis, a composite sample of each deep was made. Tukey's test was performed at 5% significance. Both trenches were classified as Red Nitosol due to the presence of B-Nithic horizon, with clay accumulation and presence of cerosity. The first analyzed area (A1), was in succession of cultures 20 years ago, however, in no-tillage, being previously, destined to pasture. While the second (A2), was in succession for 42 years, being the first 20 years conventional management. The C results at all deeps of A1 were higher than A2, with emphasis on 0-10 cm layer, with 23.4 g kg^{-1} organic matter (OM), since A2 had 19.2 g kg^{-1} of OM. This is because the conservation of C stocks over the time due to non-rotation and the presence of highly productive and doesn't degrade pasture, which has been able to increase C until the succession implantation, although the absence of rotation, got to hold the stocks in relation to A2. The P contents were only higher in the 0-10cm layer of A1 when compared to A2, in the other layers the A2 stood out. The highest levels of P in the first layer are due to the positive correlation with the OM content. In the 10-20cm layer the A2 was 4.16 $mg.dm^{-3}$, while the A1 was 1.58 $mg.dm^{-3}$. In the 20-40cm layers, A2 was also higher, differing from A1 in 1.54 $mg.dm^{-3}$. This is due to the intense soil revolving, resulting in the incorporation of P in deep, since it's an immobile element. The K contents didn't differ statistically in the two studied areas, being in A1 of: 0.77; 0.38 and 0.21 $cmolc.dm^{-3}$, respectively in the deeps: 0-10,10-20 and 20-40 cm, while in A2, in the same deeps was found 0.79; 0.46 and 0.31 $cmolc.dm^{-3}$. Because K is a mobile element, it easily translocates in the soil profile, resulting in the same proportion of the element in the two areas observed. The history of the area directly influences the management to be accomplished, and the intense revolving favors only the incorporation of immobile elements, degrading the C.

(4481 - 290) Silicon fertilization is an alternative tool against the water deficit effects in sugarcane

Monica Sartori de Camargo[1]; Breno Kennedy Lima Bezerra[2]; Marcelo de Almeida Silva[2]
APTA Polo Centro Sul[1]; UNESP/FCA[2]

Sugarcane is planted in sandy soils with silicon (Si) low soluble contents and low water storage capacity, which is a problem during water deficit periods. The increased of Si uptake by Si fertilization could decrease negative effects in sugarcane, but information is scarce. This study evaluated the effects of Si fertilization on macronutrients and Si concentration in the leaves, and morphological and physiological aspects of sugarcane cultivars after water deficit. A completely randomized factorial design with four replications, two cultivars (RB86-7515 and RB85-5536), two Si rates (equivalent to 0 and 600 kg ha^{-1} Si, Si- and Si+), and without (well-watered, WW) and with water deficit (water deficit, WD) was used. Pots (100 L) were filled with samples of Quartizpsament with equal quantities of Ca and Mg, using silicate (274 g kg^{-1} Ca; 481 g kg^{-1} Mg;108 g kg^{-1} Si) in +Si treatment, and lime (343 g kg^{-1} Ca; 96 g kg^{-1} Mg), and $MgCl_2$ (12% Mg) in –Si treatment. WD (55% of field capacity of soil) was imposed in 4 months-old plants (May, 2014) and WW treatment was kept close to 100%. Evaluations were done in the top visible dewlap leaves after 30 and 60 days after stress (DAS). Treatments did not influenced macronutrients concentrations, and number of green leaves. Si concentrations increased by fertilization in both evaluations and RB85-5536 showed the highest values only after 30 DAS. WD decreased Si concentrations only after 60 DAS. Plant height was superior to RB86-7515 and WD reduced 9% it after both periods. Number of tillers per plant was reduced by Si after 60 DAS for RB85-5536, no effect was found for RB86-7515. RB86-7515 showed higher RWC in both evaluations and B85-5536 showed higher EL after 30 DAS. Si application decreased electrolyte leakage (EL) after 30 DAS and increase Ψw at pre-dawn after both periods. Si fertilization is useful to alleviate the effects of WD in sugarcane, leading to sustainable agriculture.

(1881 - 2196) Silicon foliar in development and sugarcane production

Gelza Carliane Marques Teixeira[1]; Luiz Cláudio Nascimento dos Santos[1]; Ramon César dos Santos Pinto[1]; Antonio Márcio Souza Rocha[1]; Marcilene Machado dos Santos Sarah[1]; Renato de Mello Prado[1]

Paulista State University[1]

Silicon (Si) is a beneficial element and has shown an effect on the increase in sugarcane production. The Si has low mobility in the plants, thus, the leaf silicates can be considered sources of interesting Si, to favor the use of this element by plants. The objective of this research was to discover viable Si fertilization alternatives through the use of smaller quantities that could supply Si plants or to stimulate their beneficial effects. The work was developed in a greenhouse of UNESP / FCAV, Campûs de Jaboticabal - SP. The experimental design was a randomized complete block design with four replicates, arranged in a 4 x 5 factorial scheme, four Si sources and five concentrations (0, 0.25, 0.5, 0.75 and 1.0 mmol L -1). The Si sources used were nanosilica (77 g L-1 Si), acid silicate (14 g L-1 Si), stabilized alkali silicate (107 g L-1 Si) and potassium silicate (128 g L-1 Si). Four leaf applications of Si were performed at 41, 54, 68 and 84 days after transplanting. The highest Si accumulations were obtained in the acid silicate and alkali silicate sources, with 89.8 and 87.86 mg plant, in the concentrations of 0.61 and 0.52 mmol L-1, respectively. The results for the green color index followed the same pattern of element accumulation. In the angle of insertion of the first fully expanded leaf, the plants with Si presented lower insertion angles, an important characteristic, since the smaller insertion angle can give the plant a greater photosynthetic efficiency by the improvement in the capitation of the light energy, higher plant growth, which can be observed from increases in plant height, especially in the sources of acid silicate and alkali silicate. The highest internode lengths were obtained in the sources of silicate, alkali silicate and potassium silicate, being 13.04 cm, 13.25 cm and 11.69 cm in the concentrations of 0.52; 0.58 and 0.51 mmol L-1 respectively. The shoot yield was also increased by the application of foliar Si, reaching 2.52; 2.71 and 2.58 kg of stem per pot at concentrations of 0.59; 0.81 and 0.63 mmol L -1 of Si for the acid, alkaline and potassium silicate sources, respectively.

(4945 - 1870) Soil characteristics in a long-term liming abandoned agricultural land and the adjacent mixed pine plantation in central Taiwan

Chuang-Wen pai[1]; Chiu Ching-An[2]; Chiou-Pin Chen[1]

the Experimental Forest, National Taiwan University[1]; National Chung Hsing University[2]

An abandoned agricultural land next to the Formosan landlocked salmon refuge in Shei-Pa National Park, central Taiwan, had been continuously cultivated by local farmers, and the seedlings growth was found retarded after afforesting. In order to investigate the effects of cultivation on soil characteristics and the possible reasons causing plant growth retardation, soil properties and nutrient conditions in this abandoned land were determined. Except the agricultural land, soils under the adjacent mixed pine forest (Taiwanese red pine (*Pinus taiwanensis*), red cypress (*Chamaecyparis formosensis*), Formosan China-fir (*Cumminghamia konishii*)) were also determined as the reference. Comparing to the mixed pine plantation, the abandoned agricultural land showed the higher bulk density, soil pH, electrical conductivity, total phosphorus, available phosphorus, exchangeable Ca, K, Mg, Na but lower soil organic matter, cation exchangeable capacity and total nitrogen. The higher levels of soil pH (7.2-7.44) and exchangeable Ca (4208-5104 mg kg^{-1}) in the abandoned agricultural land showed the significant effects of long term liming. The lower levels of available Fe (21.4-30.71 mg kg^{-1}) and Mn (33.4-40.4 mg kg^{-1}) was suspected to contribute to plant growth retardation since the high soil pH could reduce the solubility of Fe and Mn and the large amount of Ca could also reduce the availability of Fe and Mn. However, the exact reasons for plant growth retardation still need to be investigated through plant analysis in the future.

(7998 - 467) The VIUSID agro as an alternative in the nutrition of radish (Raphanus sativus L.) and beet (Beta vulgaris L.)

Kolima Peña Calzada[1]; Juan Carlos Rodríguez[1]; Dilier Olivera Viciedo[2]; Jorge Meléndrez[3]

University of Sancti Spíritus José Martí[1]; University (Unesp), School of Agriculture and Veterinary Sciences, Jaboticabal, SP- Brazil.[2]; Universyti of Sancti spiritus José Martí[3]

To evaluate the effect of the VIUSID agro on the radish and beet culture, two randomized block experiments were designed with five treatments and three replications. The variants were: dose 0.2; 0.5; 0.7 and 1.0 L ha-1 of the growth promoter and a control. Among the evaluated indicators was the fresh and dry mass of the plant as well as its organs individually. In addition, the polar and equatorial diameter of the stem and fleshy root, the physiological growth rates, the foliar, productive efficiency and the agricultural yield were evaluated. The results showed a significant increase ($p \leq 0.05$) of the fresh mass of the plant when the VIUSID was used and the increments with respect to the control on average were 12.13 g in the radish and 65.88 g in the beet. In the final evaluation dry mass, all VIUSID treatments differed significantly from the control and exceeded it on average by 35.43% in the radish and over 40% in beet. In the fresh and dry mass of the stems, last evaluation, the 0.7 L ha-1 dose was the one with the best behavior in radish and that of 1.0 L ha-1 in beet. The net assimilation rate was significantly higher with the mentioned dose. The highest productive efficiency was achieved with the variants (0.5, 0.7 and 1.0 L ha-1) and the best performance in the performance with significant differences ($p \leq 0.05$) of the rest of the treatments was dose 0.7 and 1.0 L ha-1. For this reason, the VIUSID agro positively influenced the morphophysiological and productive indicators of the cultivation of radish and beet.

(1598 - 2792) Tolerance potential of *Eugenia dysenterica* DC to aluminum

Arthur Almeida Rodrigues[1]; Sebastião Carvalho Vasconcelos Filho[1]; Douglas Almeida Rodrigues[1]; Caroline Müller[1]; Cássia Lino Rodrigues[1]; Joiran Luiz Magalhães[1]

Goiano Federal Institute of Education, Science and Technology (IFGoiano), Campus Rio Verde[1]

Aluminum (Al) is highly phytotoxic for several crops in general, however, some native Cerrado species that occur on acid soils have developed or inherited strategies that allow them to survive in high concentrations of this element. The aim of this study was to evaluate the morphological and fluorescence characteristics of chlorophyll a and *Eugenia dysenterica* as indicative of species tolerance markers for Al stress. The variables were analyzed based on the evaluation of root growth and fluorescence of chlorophyll a in seedlings (0.1 mM $CaCl_2$, pH 4.0) with low ionic strength with Al at the concentrations of (0, 200,

400, 600 and 800 µmol L^{-1}) in the form of sulfate ($Al_2(SO_4)_3 \cdot 18H_2O$). The PSII (Fv / Fm) quantum yield potential of Al, which was not affected by the growth of the alloys at 400, 600 and 800 µmol L^{-1}, thermal energy dissipation efficiency in the antenna system (Fv'/Fm'), non-photochemical quenching (qN) and non-photochemical dissipation (NPQ) were not affected with increasing doses of Al. For *Eugenia dysenterica* aluminum is not toxic and can be beneficial for the better development of the plant.
Keywords: Al-tolerant; cagaita; cerrado; growth stimulus.

(5272 - 1543) Use of inverse vulcanization for the production of multifunctional sulfur FERTILIZERs

Stella Fortuna do Valle[1]; Amanda Soares Giroto[1]; Caue Ribeiro[2]
Federal University of São Carlos[1]; Embrapa Instrumentation[2]

Sulfur (S) is an important macronutrient for vegetable development and its deficiency in soils has been a concern in several agricultural regions nowadays. Elemental sulfur (S_8) stands out amidst conventional sulfur-based fertilizers due to its higher sulfur content and lack of leaching problems. However, in order to be assimilated by plants it needs first to be biologically oxidized to sulfate (SO_4^{2-}), a slow rate process that strongly depends on the fertilizer's characteristics. The aim of this study is to develop a fertilizer in which elemental sulfur's structure is more accessible to the microorganisms that promote the element's oxidation, and thus investigate if this structural modification can increase the oxidation rate. Ring opening polymerization (ROP) of S_8 occurs when the compound is heated above 159ºC, a reversible reaction that leads to depolymerization of the product back into cyclic species when cooled down. The recently developed inverse vulcanization technique addresses this issue by stabilizing the terminal sulfur radicals with low amounts of dienes, producing materials with chemically stable polymeric sulfur chains and enhanced processability. The materials proposed in the present work were obtained by performing the inverse vulcanization method, selecting vegetable oil as a cheap, renewable alkene for the reaction. A detailed physical-chemical characterization of the products was conducted by infrared spectroscopy (FTIR), X-ray diffraction (XRD), scanning electron microscopy (SEM), thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC). Sulfate release experiments were also carried out, both in soil and in cultivation under submerged fermentation (SmF). The results confirmed the successful conversion of reagents and the formation of homogeneous functional materials with great potential to be applied as a multifunctional sulfur fertilizer.
Keywords: Inverse Vulcanization; Sulfur; Fertilizer.

(7656 - 1770) Vegetal cover of soil in grazing under recovery in response to wood ash doses

João Vitor Dourado Soares[1]; Jean Carlos Costa Couto[1]; Helon Hébano De Freitas Sousa[1]; Edna Maria Bonfim-Silva[1]; Tonny José Araújo Da Silva[1]
Universidade Federal De Mato Grosso[1]

Wood ash can be a way to potentiate and to recover the productivity of pastures, since it can act as fertilizer and corrective of acidity. So, the objective was to evaluate the effects on soil cover of Brachiaria brizantha cv. Marandu in response to wood ash doses and forms of application in Entisol. The experiment was carried out in the field, in its third year of execution, from December 2016 to April 2017, in the municipality of Rondonópolis, Mato Grosso, at the experimental farm of the Mato-grossense Institute of Cotton (IMAmt). The design was randomized blocks in a 6x2 factorial scheme, in bands, with four replications. Six doses of wood ash (0, 3, 6, 9, 12 and 15 t ha^{-1}) were used in the plots and two treatments of application (incorporated and not incorporated) in the subplots. The application of ash was carried out manually. Nitrogen fertilization was performed at 100 kg ha^{-1} in all subplots, using urea as source. Four evaluations were performed before the programmed cuts, with intervals of 30 days between them, using "Line Transect Method". The results were submitted to analysis of variance up to 5% probability and, when significant, the averages for the application form were compared by the Tukey test. For the wood ash dose factor, regression analysis was applied at the 5% probability level, using the SISVAR statistical program. There was a significant effect on the levels of wood ash for vegetation cover in the four evaluations. In the first, the data were adjusted to the linear regression model, with the maximum result obtained in the highest dose. In the second, third and fourth cuts, the data adjusted to the quadratic regression model, reaching the maximum coverage of 44.17, 30.07 and 39.58% for the doses of 10.8, 11.05 and 9.98 Mg ha^{-1} respectively. Regarding the form of application, there was a significant difference in the first three evaluations. The unincorporated form presented better results, with coverage percentage of 49.86, 40.51 and 36.97% against 25.52, 32.03 and 30.87% of the application of incorporated form, in the 1st, 2nd and 3rd cuts, respectively. The application of vegetal ash influences the soil cover of the soil cultivated with Brachiaria brizantha cv. Marandu, the effect can be observed from small doses, but reaches the maximum around 10 Mg ha^{-1}. The unincorporated form provides greater vegetative cover.

(1511 - 641) Vegetative development of the safflower under doses of wood ash and levels of bulk density

Tulio Martinez Santos[1]; Edna Maria Bonfim-Silva[1]; Tonny José Araújo da Silva[1]; Luana Glaup de Araújo Dourado[1]
UFMT[1]

Due to the increase in mechanized areas and inadequate soil management, problems such as compaction grow exponentially in agricultural crops, as well as the generation of residues such as ash, from the processing and storage of products of agricultural origin. The objective of this study was evaluate the effect of combined ash wood doses at bulk density levels on the initial development of safflower crop cultivated in Brazilian Cerrado Oxisol. The experiment was conducted in a greenhouse under a randomized block design with five doses of wood ash (0, 8, 16, 24, 32 g dm^{-3}) combined at five levels of bulk density (1.0, 1, 2, 1.4, 1.6 and 1.8 Mg m^{-3}), with four replicates. Each experimental plot was composed of polyvinyl polychloride cylindrical vessels containing 9.4 dm^3 of soil, composed of three isometric rings of 100 mm height each, the intermediate ring being compacted, with the aid of hydraulic press model Bovenau P15ST. After the soil was collected, the ash doses were applied according to the treatments and after 30 days the pots were made. Nitrogen fertilization was performed with 150 mg dm^{-3}, divided into three applications (40, 55 and 55 mg dm^{-3}), at 15, 30 and 45 days after sowing, respectively. The soil water tension was maintained above 20 kPa with the aid of Irrigas® irrigation flag. Three heights were measured at 15, 30 and 45 days after sowing. The results were submitted to analysis of variance and regression test, both at 5% significance using the software SISVAR 5.6. The linear effect for the

ash doses applied when evaluated at 15 days. For the 30 days after the emergence of the plants a significant difference was observed only for the doses of vegetal ash, with maximum height point estimated when applied 25.08 g dm^{-3} and maximum of 42 cm. For the 45 days both sources of variation had quadratic behavior, the optimum dose estimated of ash is 24.59 g dm^{-3} and the compaction favoring the highest growth was 1.2 Mg m^{-3}. Fertilization with vegetal ash and soil compaction levels influence the growth of safflower plants cultivated in Cerrado Oxisol.

(3430 - 873) Water use efficiency in safflower crop under soil moisture maintenance methods

Tonny José Araújo da Silva[1]; Julyane Vieira Fontenelli[2]; Edna Maria Bonfim-Silva[1]; William Fenner[1]
UFMT[1]; UNICAMP[2]

Adequate water supply is essential to ensure maximum plant growth and development, since water is the major limiting factor to plant development. However, in agricultural experimentation, especially under controlled conditions, such as greenhouses, several methods of soil moisture maintenance are used, which may constitute sources of experimental errors. Thus, the objective of this study was to test soil moisture maintenance methods in a greenhouse, evaluating the water use efficiency (WUE) in safflower crop, cultivar IMA 0213. Therefore, an experiment was carried out in a greenhouse at the Rondonópolis Campus of the Federal University of Mato Grosso, in a completely randomized design, with four moisture maintenance methods: Gravimetric; Irrigas; Tensiometer and Self-irrigation, with 8 repetitions. The experimental units were composed of plastic vessels with a capacity of 3.18 dm^3, which were filled with Oxisol from a Cerrado native vegetation area collected in the 0 - 0.2 m layer, incubated for 30 days after liming to correct the acidity and increase the base saturation at 60%. Were incorporated into the soil 150 and 100 mg dm^{-3} of P_2O_5 and K_2O, using simple superphosphate and potassium chloride, respectively. Were also applied 200 mg dm^{-3} of N in form of urea at 10, 20 and 40 days after emergence and 15 mg dm^{-3} of FTE BR 12 to meet the demand for micronutrients. To monitoring soil moisture, the soil water retention characteristic curve was used, and humidity equivalent to 80% of the field capacity was considered for water replacement in all treatments except the Self-irrigation. For the Gravimetric method the humidity was determined by mass difference, each vessel being weighed individually. In the Irrigas system replacement occurred when the ground tension reached 20 kPa. For the Tensiometer the considered value was 5 kPa and 3 kPa for the Self-irrigation. The readings were performed daily at 7 and 14 h. The plants were harvested 69 days after emergence and the WUE was determined considering the dry mass production of chapters (g $plant^{-1}$) and the water consumption (L $plant^{-1}$) expressed in g L^{-1}. Data were submitted to ANOVA and Tukey's test at 5% probability. The Gravimetric, Irrigas and Self-irrigation methods differed significantly in relation to the Tensiometer with greater WUE in the dry mass of chapters of the safflower crop

C3.3.4 - Greenhouse gases emissions associated with fertilizer use

(8110 - 576) Assessment of Nitrous Oxide Emission Factors from Barley Cropland under Land Application of Biosolids

Carmen Cecilia Roman Perez[1]; Guillermo Hernandez Ramirez[1]; Germar Lohstraeter[2]; Len Kryzanowski[2]
Department of Renewable Resources, Faculty of ALES, University of Alberta[1]; Agri-Environmental Innovation Unit, Environmental Strategy and Research Section, Alberta Agriculture and Forestry[2]

Agriculture is responsible for more than 60% of anthropogenic global N_2O emissions mainly due to the application of synthetic nitrogen-based fertilizers. Biosolids (BS) are byproducts from municipal wastewater treatment plants that can have beneficial uses in agriculture, forestry and land reclamation. Canada still uses the emission factors from the IPCC 2006 (Tier 1) to estimate N_2O emissions from land application of BS, which assumes that 1% of mineral N applied to soils is lost as N_2O. The objective of this study was to estimate the N_2O emission factors from a cropland fertilized using different biosolids and placement. To determine N_2O emissions, 15 nutrient management treatments (including a control) were evaluated growing barley for silage (*Hordeum vulgare*). For organic amendments, liquid mesophilic anaerobic digested (B_{lmad}), alkaline stabilized (B_{as}) and composted (B_c) biosolid were applied, while urea was applied as mineral fertilizer. Treatments with a mix of BS and urea in a proportion of 50%-50% were also evaluated. Regarding to fertilizer placement, the treatments were evaluated under surface and incorporation methods. Treatments were arranged in a randomized complete block design with 4 replications. Aboveground biomass of barley yield was quantified at the end of the growing season in dry matter basis production. Emission factors (EF) were calculated on the basis of area and yield. Results indicated that barley biomass was typically higher in treatments that combined BS with urea and with incorporation of the nutrient sources. Incorporation also increased N_2O fluxes typically by 2-21 times compared to surface application. Treatments with B_{lmad} showed higher N_2O cumulative emissions. These findings were mirrored by the $EF_{area\text{-}based}$ values, where treatments with B_{lmad} and under incorporation exhibited the highest $EF_{area\text{-}based}$ (1.57%). This $EF_{area\text{-}based}$ was 4 to 17 times higher than treatments with other types of nutrient sources and using surface application (0.41%-urea and 0.09%-B_c). Regarding the results for $EF_{yield\text{-}based}$, a similar behavior was observed; incorporated Blmad was the highest (0.74 $gN_2O\text{-}N\ kg^{-1}$ biomass dry matter) and 8 to 37 times higher the treatments using surface application (e.g., B_c was 0.02 $gN_2O\text{-}N\ kg^{-1}$ barley dry matter). For most treatments, the $EF_{area\text{-}based}$ were below the IPCC Tier 1 (0.09 - 0.73%); only 2 treatments that used BS incorporation (B_{lmad}-1.57%, and B_{lmad} + 50% urea-1.14%) exceeded the IPCC EF of 1%.

(6294 - 2918) Carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) fluxes from potato production system (solanum phureja) under traditional fertilizer and k- carrageenan -coated fertilizer management

M. Camila Morales-Pulido[1]; Carmen Alicia Parrado[1]
Universidad Jorge Tadeo Lozano[1]

Environmental impact associated with greenhouse gas emissions (GHG) from agricultural soils is linked to N fertilizer overuse. A worldwide leading strategy to diminish the impact is the use of controlled release fertilizers that deploy nutrients into the soil continuously reducing time-spatial asynchrony thus reducing GHG

emissions. However, in Colombia, a country where traditional management prevails, the use of these fertilizers is not a common practice due to costs and low research in the subject. We studied the effect of a controlled release fertilizer (coated with *k-carrageenan*) on carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) fluxes and their interaction with associated microbiological processes (N-mineralization, potential denitrification rates) in a potato (*Solanum phureja*) production system in Cundinamaca, Colombia. Using a traditional N fertilizer, the average fluxes were 103.765 µg C-CO_2 m^{-2} hr^{-1}, -0.017 µg C-CH_4 m^{-2} hr^{-1} and 1.828 µg N-N_2O m^{-2} hr^{-1}, the average N-mineralization rate was 3.34 µg N-NH_4 g^{-1} h^{-1} and the potential denitrification rate was 0.3342 µg N g^{-1} hr^{-1}. Meanwhile, using a controlled release fertilizer the average fluxes were 98.530 µg C-CO_2 m^{-2} hr^{-1}, -0.019 µg C-CH_4 m^{-2} hr^{-1} and 0.872 µg N-N_2O m^{-2} hr^{-1}, the N-mineralization rate was 3.53 µg N-NH_4 g^{-1} hr^{-1} and the potential denitrification rate was 0.286 µg N g^{-1} hr^{-1}. Results showed lower GHG emissions and lower potential denitrification rate as well as higher N mineralization rate in soils managed with the *k-carrageenan* controlled release fertilizer than those managed with the traditional one. Even though fluxes were not significantly lower than traditional N fertilizer values, the CH_4, CO_2 and N_2O fluxes and N mineralization rate showed to be driven by the amount of N in the soil.

(5747 - 1074) Comparison of greenhouse gas emissions with application of organic fertilizers (manure, slurry and digested slurry) in a managed grassland in Southern Hokkaido, Japan

Kaho Yasuda[1]; Arata Nagatake[1]; Chiho Sugiyama[1]; Masahito Kawai[2]; Ryusuke Hatano[1]
Soil Science Lab. Hokkaido University[1]; Field Science Centre for Northern Biosphere Hokkaido University[2]

A field experiment was conducted at a managed grassland in southern Hokkaido, Japan to evaluate effects of application of organic fertilizers on greenhouse gases (CO_2, CH_4 and N_2O) emissions and carbon (C) budget. Fertilized plots (chemical fertilizer (F), manure (M), slurry (S) and digested slurry (D)) and no-fertilizer plot (NF) were established in the middle of May, 2017. Due to high concentration of potassium in the organic fertilizers, their application rates were limited to the recommended level of potassium in this region, and deficits of nitrogen (N) and phosphorus were supplied by chemical fertilizers. Soil CO_2 (RH), CH_4 and N_2O emissions, above- and below-ground net primary production (ANPP and BNPP, respectively) and harvest were measured in all plots from May 14 to Sep 20, 2017, and used to calculate EF N_2O, net biome production (NBP=NPP-RH-Harvest+C input), and global warming potential (GWP=GWPCO_2+GWPCH_4+GWPN_2O, GWPCO_2 was calculated using -NBP). Inputs of C and N in M, S and D were 797, 152, 914 kg C ha^{-1} and 28, 21, 109 kg N ha^{-1}, respectively. There was no significant difference in harvest among the treatments despite a tendency higher in fertilized plots than NF. RH was not different but lower in organic fertilizer plots than F and NF. NBP was negative in all plots, however, significantly higher in M, S and D than F and NF (-3.39, -4.40, -3.30, -5.65, -5.56 Mg C ha^{-1}, respectively). Cumulative N_2O emission was significantly higher in fertilized plots (2.97, 5.61, 4.15 and 4.50 kg N ha^{-1} in M, S, D and F, respectively) than NF (0.59 kg N ha^{-1}). The EF N_2O was 3.92% for chemical fertilizer, while it was higher for slurry (6.5%), lower for digested slurry (0.9 %) and negative for manure (-4.7 %). Cumulative CH_4 emission was very small and had no tendency among the treatments, although its flux peaked when soil was wet. GWP was significantly lower in M and D than S, F and NF (14.66, 14.95, 19.58, 24.12, 22.40 Mg CO_2eq ha^{-1}, respectively), and GWP CO_2 contributed to more than 88% of GWP, but GWP CH_4 did less than 0.2 %. GWP CO_2 significantly decreased in M and D where C input was large, and GWP N_2O also tended to be smaller in M and D than S and F. The results clearly showed that each organic fertilizer had different effects on greenhouse gas emissions and C budget, manure and digested slurry may perform better to mitigate global warming than slurry.

(5805 - 2535) Effect of fertilizers on CH_4 production and emission from paddy soil

Takashi Nagasawa[1]; Zanyang Wang[1]; Kazuyuki Inubushi[1]
Chiba University[1]

Over the last decade, the greenhouse gas concentration in the atmosphere has been constantly increasing because of anthropogenic activities. One of the greenhouse gases, CH_4, contributes to global warming and paddy field is one of important source as estimated to be about 18% among total CH_4 emission. The trend of atmospheric CH_4 concentration has been continued to increase, so mitigation to prevent this increase is very imperative. A steel-making slag, a by-product of the steel industry, has been used as silicate fertilizer and a possible mitigation to reduce CH_4 from paddy fields. This study aimed to show how the effects of this fertilizer and organic fertilizer (Bokashi) on CH_4 emission from paddy soil and rice growth. The soil from farmer's paddy field in Tokamachi, Niigata Prefecture, central Japan, was used for incubation experiment and pot experiment. Incubation experiment was designed with 4 treatments as; slag fertilizer, bokashi, bokashi+slag fertilizer, and the soil only as a control; all with three replications. The soil (10g) was placed in a glass bottle containing about 20 ml of distilled water to give a standing above water layer. Bottles were covered with lids and incubated at 30°C for 16 weeks to measure CH_4 production. In the pot experiment, 3 kg soil was placed into plastic pots (1/5000a), the steel-making slag was added to the pots at the rate of 2 g, equivalent to 1 ton ha^{-1}, and the other pots were treated with NPK fertilizer 1g, 0.5 ton ha^{-1} then transplanted with rice. CH_4 flux from the pot and soil Eh were measured from April to September, 2016. In the incubation experiment, CH_4 production increased 9 % by Bokashi, but decreased 2 % by slag fertilizer. In the pot experiment, the steel-making slag treatments showed higher Eh values compared with the control. CH_4 emission during the cultivation period was reduced about 38 % by steel-making slag, and the rice growth was better than the control.

(5714 - 1784) Emission of greenhouse gases (N_2O, CO_2 and CH_4) of sandy loam Mollisol, under maize—cover crop rotation and nitrogen fertilization

Daniela Mallitasig[1]; Jorge F. Perez-Quezada[2]; David Aguilera-Riquelme[2]; Osvaldo Salazar[3]
Programa de Magíster en Manejo de Suelos y Aguas, Universidad de

Chile, Casilla 8820808, Santiago, Chile[1]; Departamento de Ciencias Ambientales y Recursos Naturales, Facultad de Ciencias Agronómicas, Universidad de Chile, Casilla 1004, Santiago, Chile[2]; Departamento de Ingeniería y Suelos, Facultad de Ciencias Agronómicas, Universidad de Chile, Casilla 8820808, Santiago, Chile[3]

Information about the effects of greenhouse gases (GHG) (N_2O, CO_2 and CH_4) emissions from soils in Chilean crops systems is limited. It is known that cover crops (CC) reduce GHG emissions such as nitrous oxide (N_2O), carbon dioxide (CO_2), while methane (NH_4) emissions increase under anaerobic conditions with high soil moisture content. In this study, we analyzed the inclusion of cover crops (*Fabaceae and / or Poaceae*) and nitrogen (N) fertilization on maize and its effect on GHG emission in a sandy loam soil (Entic Haploxeroll) in the Mediterranean climatic region of Chile. The experiment was done at the Antumapu Experimental Station located in Santiago, Chile (33 ° 34'S, 70 ° 38'W), where 4 plots were established: i) Zea mays – $fallow_{250}$, ii) Zea mays – $fallow_{400}$, iii) *Zea mays-L. multiflorum*$_{250}$ and iv) *Zea mays-T. repens*$_{250}$ (x 3 replicates) where the two subscript indicate two different doses of N (250 or 400 kg N ha^{-1}). The first measurements (performed between 4 and 15 January 2018) confirm that the GHC emissions increase proportionally with the dose of N, but the properly control of water supply by irrigation prevent differences in N_2O emissions between treatments. In the present season, we continue studying the effect of the cover crop type (*Fabaceae* vs *Poaceae*). This information will help to understand the dynamics of N and C emissions from soils and the environmental and agronomic effects that are associated with the CC in the maize production in central Chile.

(8950 - 2052) Flow of Greenhouse Gases in the Summer Period in a System of Integrated Crop-Livestock with Nitrogenous System Fertilization

Jonatas Thiago Piva[1]; Priscila Grella Moretti[1]; Felipe Bratti[1]; Jorge Luiz Locatelli[1]; Guilherme Seiki Iwasaki[2]; Ricardo Henrique Ribeiro[2]; Kelen Cristina Basso[1]; Claudia Aparecida Guginski-Piva[3]; Cimélio Bayer[4]
UFSC_Curitibanos[1]; UFPR[2]; UNOESC_Campos Novos[3]; UFRGS[4]

Nitrous oxide (N_2O) and methane (CH_4) are the main greenhouse gases (GHG), a fact that is related, among other factors, to the intensification of activities carried out in the agricultural sector. When properly managed Integrated Crop-Livestock Systems (ICLS) have a great potential for mitigation in the emission of these gases. The objective of this work was to evaluate the emissions of N_2O and CH_4 due nitrogen system fertilization (summer), and residual pasture heights during the development of maize crop in ICLS. The experiment was conducted at the Federal University of Santa Catarina (UFSC), Curitibanos-SC, in a Cfb climate, with an average annual rainfall of 1500 mm, and an average temperature of 15ºC. The soil is classified as Clayey Cambissolo Háplico. The experimental design was randomized blocks, in sub-subdivided plots. The main plot corresponded to nitrogen (N) rates (0, 75, 150 kg ha^{-1}), and the subplot, in winter, as residual pasture heights (7 and 15 cm) in the *Avena strigosa* crop, in rotational grazing by calves. For the sub-subplot, N rates (0, 75, 150 Kg ha^{-1}) were applied in the summer crop (*Zea mays*). The air samples were collected during the summer period, by the static chamber method, at 0, 15 and 30 minutes and were submitted to gas chromatographic analysis. A peak in N_2O emission was observed in the treatment with 150 kg ha^{-1} and grazing intensity of 7 cm in winter, even at 0 kg of N ha^{-1} in the summer. This may be related to the higher soil bulk density in the superficial layer, caused mainly by the animal trampling, the high soil moisture and the presence of mineral N available in the soil, which are substrate for the denitrification processes, resulting in N_2O production. Treatment with 0 kg of N ha^{-1} grazing at 15 cm in winter and 75 kg N ha^{-1} in summer also showed a peak emission, mainly after nitrogen fertilization. In general, the soil presented as CH_4 absorption during the maize cycle, with a greater sink in the treatment without N in summer and winter, with a 15 cm residual pasture height. Higher GHG fluxes were observed after N application, coinciding with periods of high rainfall, favouring the anaerobic environment of the soil, which allowed higher production of N_2O and CH_4. The higher pasture management (15 cm) influenced positively the soil properties, showing that it is the best option in the mitigation of GHG emissions. The use of a systems fertilization with applications of N in pasture, tend to reduce GHG emissions.

(8390 - 1774) Methanotrophic activity of isolated bacteria from dairy manure used as fertilizer

Valentina García[1]; Homero Urrutia[2]; Erick Zagal[3]; Cristina Muñoz[3]
University of Concepción, Campus Chillán, Avenue Vicente Méndez 595, Chillán, 3812120, Chile (valentinagarcia@udec.cl)[1]; Biotechnology Center, Barrio Universitario s/n Building Biotechnology Center, Concepción, 4070386, Chile.[2]; University of Concepción, Campus Chillán, Avenue Vicente Méndez 595, Chillán, 3812120, Chile[3]

The climate change is produce by a progressive increase in the greenhouse gases emissions, damaging the Chilean farming activity, which directly affects its economy. Methane (CH_4) is the second most relevant greenhouse gas, it stays on the atmosphere around 9 to 15 years and whose power of heat retention is 25 times more powerful than CO_2's. This gas is mainly produced during the processes of enteric fermentation and manure handling. The liquid manure, a mix of feces, urine, and wastewater coming from washing and rainwater in the dairy industry, is high in nitrogen, potassium oxide, and phosphorus oxide, which makes it widely used as an organic fertilizer; however, its handling and, mainly, its storage in manure pits, reduces the airing process which generates partial oxidation products such as CH_4. An alternative for mitigating this gas are the methanotrophic microorganism, bacteria that use this and other small carbon compounds as a source of energy, due to the presence of the enzyme methane monooxygenase, which produces methanol as an intermediary to the aerobic oxidation of CH_4. These microorganisms live in environments that have an interface between aerobic and anaerobic processes, this means that they can be found in manure, whose identifying process is a challenge and a search of mechanism to strengthen its action on manure and reduce the CH_4 emissions in agriculture.

Keywords: Methane; manure; methanotrophic microorganism

(7594 - 1673) Mitigation alternatives of the soil nitrous oxide emission associated with eucalyptus nitrogen fertilization

Mariana Alves Ibarr[1]; Josiléia Acordi Zanatta[2]; Jeferson Dieckow[1]; Marcos Fernando Gluck Rachwal[2]; Rosana Clara Victoria Higa[2]
Universidade Federal Do Paraná[1]; Embrapa Florestas[2]

The enhanced-efficcieny nitrogen fertilizers (EENFs) are an alternative to mitigate the nitrous oxide (N_2O) from fertilized soils, since they act

by slowly releasing the nitrogen in the soil and/or inhibiting the enzymes responsible for the N_2O emission, in both cases allowing greater utilization by the cultivated plants. The study aimed to evaluate the EEFNs potential in reduces the soil N_2O emission under eucalyptus. The study was carried out in a greenhouse, with clayley dystrophic Red Oxisol. The treatments consisted of control (C); urea (U); urea with urease inhibitor (U-NBPT); urea with nitrification inhibitor (U-DCD); urea with urease and nitrification inhibitors (U-NBPT-DCD); polymer-coated urea (U-P); ammonium sulfate (AS); ammonium sulfate with nitrification inhibitor (AS-DCD) and polymer-coated ammonium sulphate (AS-P), in a 13.6 kg N ha^{-1} rate, applied at 10 days after *Eucalyptus urograndis* (I144) seedlings planting. The air sampling for N_2O flux evaluation was performed by the closed static chamber method, with four chambers per pot and three replicates per treatment. The cumulative emission was calculated to the 90 days period after fertilization. The soil N_2O flux remained low up to 50 days after planting (dap), when it increased, reaching more than 900 µg m^{-2} h^{-1} at 78 dap in the urea treatment, which together with U-NBPT, U- NBPT-DCD and UP presented the highest soil N_2O fluxes (on average 215.1 µg m^{-2} h^{-1}). The U-DCD presented fluxes equivalent to the control, with low fluxes (on average 16 µg m^{-2} h^{-1}) throughout the evaluation period. As consequence, the lowest accumulated emissions were observed in the soil of the U-DCD treatment (average of 0.15 kg N-N_2O ha^{-1}), and the highest losses occurred in U and U-NBPT treatments (on average 4.38 kg N-N_2O ha^{-1}). Only the DCD addition to the nitrogen fertilizer was able to reduce soil N_2O losses, possibly due to the monooxygenase enzyme inhibition, thus reducing the nitrification rate and consequent N_2O emission. The enhanced-efficcieny nitrogen fertilizers by the DCD addition represented technically viable alternatives to mitigate N_2O emission from the soil under eucalyptus.

Keywords: greenhouse gas; forest system; enhanced-efficieny nitrogen fertilizers.

(2886 - 1045) Mitigation of nitrous oxide emissions from soils by coconut coir application

Yutaka Shiratori[1]; Haoyang Shen[2]; Sayuri Ota[1]; Keishi Senoo[2]
Niigata Agricultural Research Institute[1]; The University of Tokyo[2]

Nitrous oxide (N_2O) emissions from soils are widely accepted to be mainly resulted from denitrifications and nitrifications of soil bacteria. However, recent evidences suggest that fungal denitrifications also play important roles in mediating the N_2O production from soils in certain ecosystems. In our previous research, N_2O emissions after organic fertilizer application were demonstrated to be mainly resulted from fungal denitrifications. Therefore, suppressing the growth of fungal denitrifiers could be a strategy to mitigate N_2O emissions from organic fertilizer applied soils. In recent years, the antifungal property of coconut coir has been reported by an increasing number of researches. Coconut coir, as a natural material made from the husk of coconut, is with low environmental risk and low-cost. This makes it worthwhile to test the possibility to use coconut coir for suppressing N_2O-producing fungi in agricultural soils. In this study, the effect of coconut coir on the mitigation of N_2O emissions from agricultural soils was tested based on a microcosm experiment and two times of field experiments. In the microcosm experiment, 200 g of Andisol was applied with 5 g of surface granular organic fertilizer and with/ without 1 g of air-dried coconut coir. N_2O emissions were decreased by 30% in microcosms amended with coconut coir compared to non-amended control. The field experiment in the spring of 2016 was performed on an upland field (Andisol) planted with sweet corns. A 50 g/ m^2 of air-dried coconut coir application resulted in a 53% of mitigation of N_2O emissions in the 2.5 months after granular organic fertilizer application. Furthermore, there was no significant impact on sweet corn yields from the coconut coir application. In the field experiment in the autumn of 2016, a 50 g/ m^2 of air-dried coconut fiber was applied to an upland field (Andisol) with no plant. Soil and granular fertilizer samples were sampled during the N_2O emitting period. DNA extraction and quantitative PCR targeting fungal 18S rRNA genes were performed accordingly. As a result, N_2O emissions were decreased by 39% in plots amended with coconut coir compared to non-amended plots. In addition, quantitative PCR revealed lower copy numbers of fungal 18S rRNA genes in plots amended with coconut coir. These results suggest that it is effective and practical to use coconut coir for the mitigation of N_2O emissions from agricultural soils after organic fertilizer application.

Keywords: Coconut coir, Fungal denitrification, Nitrous oxide, Organic fertilizer

(6810 - 1956) N_2O emissions from soil subjected to a history application of organic sources application

Rodrigo Otavio Schneider Souza[1]; Alessandra Bacca[1]; Wagner Squizani de Arruda[1]; Jacson Hindersmann[1]; Letícia Morsch[1]; Gustavo Brunetto[1]; Beatriz Batissini Vito[1]; Lucas Telles[2]; Cledimar Rogério Lourenzi[3]; Carlos Alberto Ceretta[1]
UFSM[1]; UFRGS[2]; UFSC[3]

Successive applications of animal manures can increase N accumulation in the soil organic pool. It is expected an increase of NO_3^-content with the mineralization of organic N, which might intensify the emissions of nitrous oxide (N_2O), especially in soils subjected to applications of animal manures with high concentrations of organic N. The aim of the study was to evaluate N_2O emissions from a soil subjected to 17 and 18 applications of types of animal manures, in sandy soil under no-tillage system. The experiment was installed in 2004 at the experimental area of the UFSM Soil Department, souther Brazil. The N_2O emissions were analyzed during the cultivation of black-oat and corn in 2015/2016. The experiment was set in a randomized block design with four replications. The treatments consisted of a control, mineral fertilization (MF), pig slurry (PS), dairy slurry (DS), and pig deep-litter (PL). The collections of N_2O initiated the day after the application of treatments to the crops, and were sustained along the crop cycles. The gases were kept in static chamber in each plot and collections were performed by using a 20 mL-polypropylene syringe at 0, 15, 30, and 45 minutes. The concentration of N_2O was analyzed by gas chromatography. The application of animal manures showed the highest N_2O emissions, highlighting the DS treatment. This is explained by the fact that the DS were derived from grazing cows, whose wastes had partiallymdigested forage with high concentration of organic N. Thus, the successive application of DS might have favored the accumulation of N in a more labile soil pool, augmenting the mineralization and, consequently, the denitrification. Although the PS presented higher concentration of mineral N and soluble C, there were fewer emissions in relation to other treatments. Even if it is expected that higher emissions occur from animal manures like PS, there was a significant increase in N_2O emissions in treatments DS and PL, which contained the highest organic matter and organic C

content. The contents of mineral N remained high since the beginning of the evaluations. The successive application of animal manures with high contents of organic N and a not-so-high C/N ratio can increase the rate of N_2O emissions by promoting changes in the N dynamics in these areas.

(6532 - 3081) Nitrous Oxide and Ammonia Emissions from N-Fertilization of Maize and Common Bean in the Brazilian Cerrado

Maria da Conceição Santana Carvalho[1]; Nelson Horowitz[2]; Adriano Stephan Nascente1[1]; Paulo César Teixeira[1]

EMBRAPA[1]; Yara Brasil[2]

The Cerrado region is responsible for more than 50% of maize (*Zea mays* L.) and common bean (*Phaseolus vulgaris* L.) produced in Brazil. These crops are large consumers of synthetic N-fertilizers in Brazil, which is an agricultural practice of growing environmental concern as one important source of Greenhouse Gas Emissions (GEE). During three growing seasons, we quantified N_2O emissions and NH_3 volatilization from three fertilizers applied on maize and on common bean grown in a clayey Oxisol in the State of Goiás, Brazil. The fertilizers evaluated were calcium ammonium nitrate - CAN, urea, and ammonium sulfate. The rates of N applied were 150 kg ha^{-1} (maize in 2013/14 growing season), 100 kg ha^{-1} (maize in 2014/15, 2015/16, and 2016/17 growing season), and 80 kg ha^{-1} (common bean in 2015/16 growing season). We also evaluated the GEE emissions from a control treatment, without N application. The treatments were arranged in a randomized block design with five replications. The N fertilization increased the N_2O emissions due to the increasing of soil nitrogen availability. The high peaks occurred within the first week after fertilizers application. The calcium ammonium nitrate promoted the higher N_2O emissions in all growing season, which were clearly associated with high soil NO_3^--N availability, interacting with high soil moisture (WFPS > 50%). The N_2O-N emission factor ranged from 0.07% to 0.59 for ammonium sulfate, from 0.17% to 0.49% for urea, and from 0.46% to 0.84% for CAN, depending on the growing season and on the N rate. As we expected, urea presented the highest NH_3-N emissions in all growing seasons. The main losses occur within the first four days after N application. The cumulative N loss as NH_3 volatilized ranged from 3.4% (common bean, 2015/16 growing season) to 38% (maize, 2014/15 growing season) for urea, from 0.7% to 2.4% for ammonium sulfate, from 0.53% to 2.0% for CAN. Considering the total N losses (N_2O + NH_3) per grain yield, urea was the less efficient fertilizer.

(3012 - 557) Nitrous oxide and methane in integrated crop-livestock system with nitrogenated fertilization

Felipe Bratti[1]; Jorge Luiz Locatelli[1]; Luiz Gustavo do Prado[1]; Guilherme Romani de Mello[1]; Maria Luiza Camargo Magnani[1]; Guilherme Seiki Iwasaki[2]; Ricardo Henrique Ribeiro[2]; Kelen Cristina Basso[1]; Jonatas Thiago Piva[1]; Cimélio Bayer[3]

Universidade Federal de Santa Catarina[1]; Universidade Federal do Paraná[2]; Universidade Federal do Rio Grande do Sul[3]

The agricultural sector has adopted strategies for reduction of greenhouse gases (GHG) emissions, mainly nitrous oxide (N_2O) and methane (CH_4). In this aspect the Integrated Crop-Livestock System (ICLS) emerges as a model of adequacy environmental, social and economic adaptation to the current productive system. The objective of this work was to evaluate N_2O and CH_4 emissions in an ICLS with residual management of winter black oat pasture and nitrogen (N) rates. The experiment was conducted at the Federal University of Santa Catarina (UFSC), campus Curitibanos, under a clayey Cambissolo Háplico in Cfb climate. The experimental design was a randomized blocks in a factorial scheme. The main plot was three N rates (0, 75 and 150 kg of N ha^{-1}) and in subplot was two heights of residual management of oats (7 and 15 cm) and one control without grazing. Gas sampling was performed by the method of closed static chambers. The samples were analyzd by gas chromatography to determine the concentration of N_2O and CH_4. At the same sampling dates, soil was collected to determine the moisture and N-mineral content at 0,0-0,20 m layer. The treatments 75 and 150 kg of N ha^{-1} both with residual of 7 cm and 150 kg of N ha^{-1} with residual of 15 cm obtained the highest rates of CH_4 emissions, after the N fertilization. These higher emission peaks are associated with higher soil moisture and N-mineral content. In addition, the animals management and consequently of the soil, influence the methane oxidation, enhancing methanotrophic bacteria activity that uses CH_4 as energy source. The highest emissions of N_2O were observed in the treatments with 75 kg of N ha^{-1} and residual of 7 and 15 cm, observing a constant flow in most of the evaluations dates, mainly after N fertilization. The animals management in the area may have contributed with emissions, due to deposition of manure and urine. In general, the treatments with residual of 15 cm, due to the greater contribution of biomass, behaved like a sink, due to the greater soil coverage and smaller physical impact generated on the soil. The without grazing resulted in the lowest emission rates, regardless of the N rate, which may be related to the short development time of the experiment (3 years), as well as absence of animal excreta on the soil. The fertilization with 150 kg of N ha^{-1} in the pasture in an ICLS alongside with residual pasture management of 15 cm was the best option to GHG mitigation.

(4450 - 1521) Nitrous oxide emission from soil with urea and biochar

Julia Gonçalves Dias Fonseca Ferreira[1]; Jeferson Dieckow[2]; Josiléia Acordi Zanatta[3]; Cláudia Maria Branco de Freitas Maia[3]; Caroline Amadori[2]; Priscila Luzia Simon[2]; Mariana Alves Ibarr[2]; Bruna Ramalho[2]; Cimélio Bayer[4]

Universidade Federal do Rio Grande do Sul[1]; Universidade Federal do Paraná[2]; EMBRAPA Florestas[3]; Universidade Federal do Rio Grande Sul[4]

Biochar (Bc) is able to reduce nitrous oxide (N_2O) emissions from the soil, as it affects nitrogen (N) availability, reducing the substrate of the nitrification and denitrification reactions. In addition, the conditioned soil with biochar can increase the reducing activity provided by the functional groups of the biochar, which favors the emission of nitrogen gas. However, much of the work involving biochar and N_2O was performed under controlled conditions. Therefore, the aim of the study was to evaluate the potential of biochar in mitigating N_2O emissions from nitrogen associated fertilizer, aiming at the applicability of these inputs to field in summer and winter grain crops. The study was carried out at the Universidade Federal do Paraná Experimental Station located in the city of Pinhais - PR, the first upland of Paraná. Two field experiments were carried out to evaluate the potential of biochar in mitigating N_2O emissions. The first one, tested methods of applying urea in sidedress, broadcast or in the furrow,

with and without biochar in maize (*Zea mays* L.) and the second, rates of biochar in oats (*Avena strigosa* Schreb.) Gas samples were collected by the closed static chamber method and analyzed by gas chromatography. In the experiment with maize, the application of biochar reduced the emission of N_2O by 43%, which occurred mainly by denitrification. The highest flow occurred at 18 days after application, and the gas emission range from 17.2 to 542 mg N m^{-2} h^{-1}. However, when the inputs were applied broadcast, there was no effect of the treatments. In the experiment with oats, N_2O flow was due to nitrification, a process that was not influenced by the different doses of biochar, 0; 2 and 10 Mg Bc ha^{-1}. The emission peak was recorded three days after application, with the highest gas emission rate 119 µg N m^{-2} h^{-1} by the treatment with the intermediate dose of biochar. It was concluded that the biochar reduces the N_2O emission associated with nitrogenous sidedress fertilization, when the inputs are applied together in the furrow.

Keywords: Biochar. Greenhouse gases. Application methods. Rates.

(2075 - 243) Nitrous oxide emissions from a soybean-corn succession under conventional and no-tillage systems

Rafael Cassador Monteiro[1]; Julio C. Franchini[2]; Robert M. Boddey[3]; Claudia P. Jantalia[3]; Segundo Urquiaga[3]; Bruno J. R. Alves[3]
UFRRJ[1]; Embrapa Soja[2]; Embrapa Agrobiologia[3]

No-tillage based systems are considered strategic to control soil erosion while preserving soil carbon, contributing to the mitigation of greenhouse gas emissions. However, the concentration of nutrients and labile carbon at the soil surface and the preservation of soil moisture due to soil mulching may potentially increase N_2O emissions from no-tilled soils after N fertilization, limiting the mitigation potential of the system. Hence, this study aimed at comparing N_2O emissions of a soybean – corn succession under conventional and no-tillage. In addition, a relationship between emissions and some soil variables was evaluated. The experiment was carried out at Embrapa Soybean experimental station at Londrina, Paraná state, Brazil. The studied area has been managed under the tillage systems for 21 years. The treatments imposed to the area were conventional tillage with (CT+N) and without (CT) N fertilization (90 kg N ha^{-1}) and no-tillage with (NT+N) and without (NT) N fertilization. Nitrogen fertilization was applied to the corn cycle only. Six static-closed chambers were used per treatment to monitor N_2O fluxes. Gas monitoring lasted from corn seeding, in April 2015, to soybean harvest in March 2016. During this time, soil samples were taken to determine moisture, mineral nitrogen and soluble carbon. Integrated N_2O emissions for CT and NT areas were not statistically different from each other in both crop cycles. Emissions of N_2O from corn growing on CT+N and NT+N soils were greater and statistically different from those without N fertilization even though no differences were observed during soybean crop. Baseline N_2O emissions rarely exceed 20 mg N m^{-2} h^{-1} irrespective of treatments, but the largest N_2O fluxes after N fertilization in corn reached 486 µg N m^{-2} h^{-1} in CT+N and 364 µg N m^{-2} h^{-1} in NT+N. Soil mineral N content seemed to be the major soil variable regulating N_2O emissions in corn cycle. None of the variables were significantly correlated with N_2O fluxes in soybean cycle. Approximately, 0.58 kg N ha^{-1} were emitted as N_2O on average during soybean cycle under CT or NT. Similarly, the soil under unfertilized corn emitted 0.65 kg N ha^{-1} as an average of CT and NT areas, but the N fertilization raised it up to 1.79 kg N-N_2O ha^{-1} in CT+N and to 1.31 kg N-N_2O ha^{-1} in NT+N. Considering the corn-soybean cropping year, N_2O losses were equivalent to 0.62% and 0.36% of the fertilizer N added to corn, respectively to CT and NT areas.

(6355 - 1032) Nitrous Oxide Fluxes, Sources and Processes in an Temperate Agricultural Soil: Moisture and N Addition Effects

E.M.S.K.Thilakarathna[1]; G. Hernandez-Ramirez[1]
University of Alberta[1]

Fertilized soils in agricultural lands have become a major source of nitrous oxide (N_2O) emissions, yet the relative contributions of sources and processes on N_2O emissions are still uncertain. A laboratory soil incubation study was conducted to investigate the effect of regular fertilizers and inhibitors on N_2O emission at different moisture contents. Soils from wheat fields of Central Alberta, Canada were collected in the mid spring and fertilized with 6.67 mg N g^{-1} soil (equivalent to a rate of 100 kg N ha^{-1}) of regular urea or ^{15}N labelled urea in order to establish five N fertilizer treatments; (1) untreated control, (2) unlabeled urea, (3) ^{15}N labeled urea at 5 atom%, (4) ^{15}N urea with nitrification inhibitor (nitrapyrin additive), and (5) ^{15}N urea with two urease inhibitors; N-(N-butyl) thiophosphoric triamide (NBPT) and N-(2-nitrophenyl) phosphoric triamide (NPPT). Under room temperature, soils were pre-incubated for 2-day followed by a 30-day incubation period at five different water-filled pore spaces (WFPS): 38%, 50%, 65%, 80%, and 95%. The fluxes and source-partitioning were derived from concentrations and isotopic N composition of N_2O measured using a quantum cascade laser spectroscopy analyzer (Aerodyne™) with flow-through recirculation. Cumulative mean N_2O emissions of N treatments were not significantly different at the level of p=0.05. Based our N-N_2O isotope analyses using Keeling plots, 75 % of the emitted N_2O from wetter treatments during peak emission was derived from the added urea, and the rest of the N_2O production was attributed to the soil N pool. The N_2O emissions increased with increasing soil moisture content; the cumulative N_2O emissions of 95 % WFPS treatment was significantly greater than the other moisture content treatments ($P < 0.05$), confirming that soil moisture content has a triggering effect on N_2O fluxes. Results from ^{15}N-N_2O site preference analysis will also be discussed and interpreted to identify the partitioning and relative contributions of microbial processes (nitrification versus denitrification) to N_2O fluxes. Findings of this study will be used to improve prediction ability and develop best management practices to mitigate N_2O emissions from croplands.

(7728 - 1649) Relationships between nitrous oxide emission and soil microbial activity under different irrigation modes and nitrogen treatments

Fusheng Li[1]; Yan Zeng[1]
Guangxi University[1]

Irrigation and fertilization affect soil microbial population and enzyme activity related to nitrogen transformation, which impacts nitrous oxide (N_2O) emission from paddy fields, therefore the objective of this

study was to study how N_2O emissions from paddy field are influenced by the change in soil microbial activity under different irrigation methods and N treatments. Field experiments of late rice and early rice were conducted with three irrigation methods (CIR conventional irrigation, TIR "thin-shallow-wet-dry" irrigation, DIR alternate wetting and drying irrigation) and two nitrogen treatments (FM1 100% urea-N, FM2 50% urea-N and 50% pig manure-N). Results show that DIR had higher cumulative N_2O emission than CIR. Compared to CIR, TIR augmented nitrifying bacteria population (NB) but decreased denitrifying bacteria number (DNB) at the milky stage, and DIR enhanced ammonia-oxidizing bacteria population (AOB) and NB, and hydroxylamine reductase activity (HyR) at the tillering, booting and milky stages, but reduced DNB and nitrate- and nitrite-reductase activities. FM1 had lower cumulative N_2O emission than FM2. Compared with FM1, FM2 enhanced AOB at the other growth stages except at the tillering stage under CIR, HyR at the milky and ripening stages under TIR, and NB at the milky and ripening stages and DNB at the mid-late stage under DIR. Correlation analysis shows that N_2O emission flux had significantly positive correlations with AOB, NB and HyR. Thus the change in AOB, NB and HyR influenced N_2O emission flux under different irrigation methods and N treatments.

(4060 - 2419) Simulating soil organic carbon and nitrous oxide fluxes after pig deep litter addition in annual crops using DayCent model

Getúlio Elias Pilecco[1]; Douglas Adams Weiler[1]; Carlos Alberto Ceretta[1]; Alessandra Bacca[1]; Rafael Bick[1]; Roberta Lago Giovelli[1]; Sandro José Giacomini[1]

Universidade Federal de Santa Maria[1]

Several studies have been conducted with the DayCent model around the world, but only a few evaluate the model´s ability to simulate organic fertilizers application into annual crops. In this study, we used DayCent model to simulate an oat/corn system successively fertilized with pig deep litter (PDL) or mineral fertilizer (MF). A 2-year dataset was used to DayCent calibration and an independent dataset from a 12-year experiment was used to model validation. Both studies were carried out in Santa Maria, Brazil. We also tested alternative scenarios (2016-2046) to simulate the new technical recommendation to PDL in Southern Brazil, which reduced PDL N efficiency index (NEI) from 0.5 to 0.2. The effects of PDL and the combination of PDL and MF on SOC and N_2O emission were evaluated. The model performance was evaluated using the following statistical criteria: correlation coefficient (r), root mean square error (RMSE) and mean difference (M) with t test. DayCent model was able to reproduce the system with addition of organic residues, indicating a higher SOC and N_2O emission in the treatment with organic fertilization than control and mineral fertilization. Statistical model performance was the following: r: 0.97; RMSE: 1.10 Mg C ha^{-1} and M: 0.39 Mg C ha^{-1} for SOC; and r values range from 0.02 to 0.35, RMSE and M (g N-N_2O ha^{-1} day^{-1}) range from 4.29 to 121.9 and -1.16 to 32.3, respectively, for N_2O. DayCent model simulated daily N_2O fluxes fairly well after fertilizer addition, but was not able to reproduce the same magnitude of some events. The model slightly underestimate N_2O emissions by 0.4 and 0.9 kg N-N_2O ha^{-1} yr^{-1} to control and PDL, respectively, but with no significant bias. Annual N_2O emissions of MF treatment simulated by DayCent were close to observed values (3.13 *vs* 3.06 kg N-N_2O ha^{-1}, respectively). DayCent model indicated an increase on SOC when PDL was used as an N source for oat and corn, at rate of 0.24 and 0.87 Mg C ha^{-1} yr^{-1} to 0.5 and 0.2 NEI, respectively. The amount of PDL recommended for 0.2 NEI increases annual N_2O emissions by 45% compared to 0.5 NEI. DayCent simulations shows that the continued application of PDL increase SOC, but also N_2O emissions. The combination of PDL and mineral fertilizer may be a strategy to increase SOC associated with intermediate N_2O emissions.

(5686 - 2309) Variation of nitrous oxide emission from combined organic and synthetic fertilizer in *Citrus unshiu* field in Southwestern Japan.

Yo Toma[1]; Takeshi Higuchi[1]; Osamu Nagata[2]; Seiichi Nishimura[3]; Hideto Ueno[1]

Graduate school of Agriculture, Ehime University[1]; NARO Tohoku Agricultural Research Center[2]; NARO Hokkaido Agricultural Research Center[3]

Nitrous oxide (N_2O) is one of the important greenhouse gas emitted from agricultural field. We measured N_2O emission for 5 years to investigate the emission N_2O emission from combined organic and synthetic fertilizer in citrus orchard. Two treatments, fertilized (F) and unfertilized (NF) plots, were set up in Ehime prefecture, southwestern Japan from January 2013 to December 2017. Combined organic and synthetic fertilizer was applied in every January and March at each 96 kg N ha^{-1}. N_2O fluxes were measured under the tree crown of *Citrus unshiu* by closed chamber technique. Differences in those gas emissions between in F and NF were defined as the emission from applied fertilizer N. Cumulative N_2O emission were calculated in the period after basal (F1) and supplemental (F2) fertilizations, summer (S), and the other period. Emission factor (EF) of N_2O induced by the applied fertilizer N was also calculated. Annual N_2O emissions were varied from 1.89 to 8.28 kg N ha^{-1} (Ave. 3.61 kg N ha^{-1}) in F and from 0.58 to 2.60 kg N ha^{-1} (Ave. 1.19 kg N ha^{-1}) in NF. Significant differences in annual N_2O emission among treatment and year indicate that organic and synthetic fertilizer application increase annual N_2O emission and annual N_2O emission was yearly varied. EF was ranged from 0.31 to 2.95% (Ave. 1.25%; 95% confidence interval 0.01-2.49%). Observed significant difference in EF in each year suggested that environmental factors controlled N_2O production from applied fertilizer N. Cumulative N_2O emission from fertilizer N in F1 and F2 increased with increasing N_2O emission for two weeks and maximum N_2O flux after the fertilization. Moreover, the maximum N_2O flux was positively correlated with mean air temperature after the fertilization. On the other hand, days after fertilization until observed maximum N_2O flux increased with increasing precipitation during that period. Those suggested that N_2O production was enhanced under warm and dry condition. Because precipitation may delay activity of N_2O production, N_2O emission can be increased due to increase of temperature after the rainfall. Consequently, in citrus orchard, N_2O emission from combined organic and synthetic fertilizer can be decreased when the fertilizer is applied based on weather forecast at the cool and dry weather condition.

(6300 - 1116) Various types of biochar effect on reducing greenhouse gas emission

Sunil Lee[1]; Eunjung Choi[1]; Jongsik Lee[1]; Hyuncheol Jung[1]; Gunyeob Kim[1]

National Institute of Agricultural Sciences[1]

Biochar is a carbon-rich solid product obtained by pyrolysis of biomass. It has been suggested to mitigate climate change through reduction of greenhouse gas emission. However, the biochar has a wide range of natural physical and chemical properties depending on the feedstock. The objective of this study was to evaluate carbon dioxide (CO2) and nitrous oxide (N2O) emissions from soil after addition of various types of biochars. The biochars were made from a pyrolyzer, which a reactor was operated about 400~500℃ for 5 hours. The treatments were consisted of a control and four biochars (pear branch, rice hull, soybean stalk, woodchip) addition treatment. Emissions of CO2 and N2O from soil were determined using closed chamber for 60 days at 25℃ of incubation temperature. Soil pH, total carbon and total nitrogen were significantly influenced by biochar type. Soil pH for all treatments ranged from 7.3 to 7.8. Alkaline biochars (pear branch, rice hull, soybean stalk) increased soil pH, while acidic biochar (woodchip) decreased pH. The concentration of total carbon and total nitrogen were significantly higher biochar treatment than control. Soil nitrate was significantly influenced by biochar type, whereas ammonium was not different between biochar treatments and control. The concentration of nitrate was significantly lower in control (191~512 μg g?1) than in biochar treatments (235~1,446 μg g?1). The cumulative N2O emissions over the 60 day incubation were significantly lower in all biochar treatments by 82~87% compared to the control, but they were not significantly different from biochar treatments. While no significant differences were CO2 emissions. The biochar from crop byproducts could suppress the soil N2O emission. The results from the study imply that biochar can be utilized to reduce greenhouse gases emission from the cropland.

Keywords: Biochar, Greenhouse gases, Incubation, Nitrous oxide

C3.3.5 - Soils for mitigating global warming: greenhouse gas emission reduction and/or enhancing carbon sequestration

(3883 - 1436) Annual methane emissions of production systems in lowlands of Rio Grande do Sul

Walkyria Bueno Scivittaro[1]; Thaís Murias Jardim[2]; Miguel David Fuentes Guevara[2]; Lillian Medeiros Barros[3]; Renata Abreu Rodrigues[3]; Rogério Oliveira de Sousa[2]; Rosa Maria Vargas Castilhos[2]

Embrapa Temperate Agriculture[1]; Federal University of Pelotas[2]; Instituto Federal Sul-Rio-Grandense[3]

Irrigated rice cultivation, the main productive activity of the lowlands of Rio Grande do Sul, Brazil, constitutes a major anthropogenic source of methane (CH_4) to the atmosphere, contributing to global warming. The production and emission of CH_4 occurs only in a reduced environment, being also associated with the amount of organic carbon (C) available in the soil. Thus, the production systems influence the potential of C incorporation and, therefore, CH_4 emissions from the soil. The objective of this work was to evaluate annual CH_4 emissions in representative production systems of the Rio Grande do Sul lowlands and in a natural area. The study was conducted in a Planossolo (Typic Albaqualf) in Capão do Leão, State of Rio Grande do Sul, Brazil. CH_4 emissions evaluations were performed from June 2015 to May 2016. Three production systems (irrigated rice/fallow, soybean/ryegrass/corn and improved pasture) and a natural area were evaluated. In each area, three greenhouse gas collectors systems (closed static chamber) were distributed, constituting the replications of the treatments. CH_4 fluxes and CH_4 total emissions were measured seasonally (fall/winter period - 2015 and spring/summer period 2015/2016 (summer season)) and throughout the year. During the fall/winter period, there were practically no CH_4 emissions from the soil, regardless of the production system. It was observed alternation between low intensity fluxes and influxes of CH_4. During the summer season, the area cultivated with irrigated rice presented several high peaks of CH_4 emission, due to the anaerobic condition established by soil flood irrigation. The other production systems and the natural area did not presented significant CH_4 emissions during the summer season; the emissions were characterized by low intensity fluxes alternated by eventual CH_4 absorption events. Total CH_4 emissions during the fall/winter period were low for all treatments (irrigated rice/fallow: 7.6 kg CH_4 ha^{-1}; natural area: 6.8 kg CH_4 ha^{-1}; improved pasture: 1.5 kg CH_4 ha^{-1} and soybean/ryegrass/corn: 0.3 kg CH_4 ha^{-1}). During the summer season, CH_4 emissions from the irrigated rice/fallow system (339.3 kg CH_4 ha^{-1}) were higher than the other systems (natural area: 3.2 kg CH_4 ha^{-1}; soybean/ryegrass/maize: 1.3 kg CH_4 ha^{-1} and improved pasture: 0.8 kg CH_4 ha^{-1}). Irrigated rice/fallow system presents higher annual CH_4 emission than the other production systems mainly due to emissions associated with irrigated rice.

Soil microbial biomass Carbon (MBC) and Nitrogen (MBN) are indicative of the changes caused by different systems of land use and soil management. The evaluation of biological quality of soil is a strategy that aims to define appropriate systems for maintaining and improving the sustainability of agricultural enterprises. This research aimed to determine the levels of MBC and MBN of the soil microbial biomass in six agricultural management systems. Soil samples were collected within each system/management, at Muniz Farm, in the municipality of Pindaré-Mirim – MA, in a Haplic Plintosol, at 0-0.1 m depth, during the rainy season of 2017, in 4 replications, in all systems. The evaluated systems were (T1) corn intercropped with *brachiaria* grass and double rows of eucalyptus every 28 m implanted in 2016; (T2) corn intercropped with *massai* grass; (T3) corn intercropped with *massai* grass and double rows of *sabiá* tree (Mimosa *caesalpiniaefolia*) every 30 m implanted in 2017; (T4) corn intercropped with *massai* grass and babassu (native palm); (T5) corn intercropped with *massai* grass, babassu and double rows of *sabiá* tree every 30 m implanted in 2017; and (T6) *brachiaria* grass pasture (reference treatment). In each soil sample, the levels of MBC and MBN were determined. The analysis of variance of the data was performed by the F test. The averages were compared by the Tukey test. The MBC variable from T6 area (637

mg kg^{-1} of soil) was higher in relation to T1 (343 mg kg^{-1} soil), T2 (238 mg kg^{-1} of soil), T4 (210 mg kg^{-1} of soil) and T5 (203 mg kg^{-1} soil). However, T6 did not differ from T3 (433 mg kg^{-1} of soil). The highest concentration of MBN was observed in T6 (2.4 mg kg^{-1} of soil). In general, the biological attributes of soil were significantly affected as a function of the soil management. The *brachiaria* grass pasture presented the highest activity when compared to other silviagricultural systems evaluated in 2017.

(2390 - 2292) Carbon of humics fractions in latossolo (oxisoil) under different forms of use in Cerrado

Adilson Alves Costa[1]; Bruno de Oliveira Dias[1]; Tales Emanuel Duarte Santos[1]; Vandayse Abades Rosa[2]; Daniel Ferreira de Lima Eliziário[1]
Federal University of Paraíba[1]; Federal University of Bahia[2]

The change in land use, due to anthropogenic action, has a significant effect of altering the soil organic matter dynamics, thus modifying the carbon contents in its different compartments. In this scenario, the use of conservation practices, such as no-tillage, can promote higher soil quality. The objective of this work was to evaluate the carbon content of humic substances in areas under conventional tillage and no - tillage in the Cerrado. The geographical coordinates of the study site are 11 ° 51'8 "S and 45 ° 37'50" W and 763 m altitude, located in Luís Eduardo Magalhães municipality, Bahia, Brazil. The soil was classified as Latossolo Amarelo distrófico típico (Oxisoil), with a clay-loamy texture. Soil samples were collected in layers of 0-0.5 cm and 0.5-10.0 cm in three areas in different forms of land use, and area under native vegetation sensu stricto Cerrado the area under cultivation with cotton and conventional area under no-tillage five years of implementation, with current soybean crop. Carbon content in the fulvic acid fraction (C-FAF), humic acid (C-FHA) and humin (C-FHU) was determined. The carbon of humic substances (C-HS) was also obtained through the sum of C-FHA and C-FAF. Among the different humic fractions, it is observed that the C-FAF content under conventional tillage was similar to the area under native Cerrado, however, both being larger than the samples collected under no-tillage system at 0-0.5 cm depth. On the other hand, the C-FHA was higher in the area under conventional planting in relation to the other areas. For many authors the elevation of C-FHA may be related to the increase of the biological activity that promotes the synthesis of the humic substances. The no-tillage system presented lower values of C-HS when compared to the other areas evaluated, in the 0-0.5cm depth with a 59% reduction, thus demonstrating lower mineralization rates of organic matter in the soil. The C-HUM increased up to 21% in the area under no-tillage compared to the area under tillage at the surface depth of up to 0-0.5 cm and 39% in the depth of 0.5-10 cm. It can be concluded that area under tillage favored an increase of C-FAF and C-HS for the 0-0.5 cm depth, while no-till improved C-HUM, regardless of depth studied.

(1809 - 2638) Chemical carbon fractioning in different land uses

José Rafael Vásquez Polo[1]; Felipe Macías Vásquez[2]
Universidad del Magdalena[1]; Universidad Santiago de Compostela[2]

Land use change and management can affect the soil's ability to capture carbon; the magnitude of these changes is unknown in the Caribbean region. For this reason, we studied the relationship of the different land uses to contents and forms of carbon in six soil and climate zones in northern Magdalena, Colombia, with altitudes between 5 and 956 m, average temperatures between 24 and 30 °C, and average rainfall between 663 and 2000 mm. In each area, two sites were sampled: tropical crops and forests (Humid and Dry Tropical). Four samples consisting of ten random subsamples per site were taken. In each subsample, we determined total C (Ct), oxidizable C total (Cox), hidrolizable C with 6N HCl (Ch), C linked to humic material (Cp) by extraction with sodium pyrophosphate, rust free C (Cnox) or recalcitrant C calculated as the difference between Ct-Cox, total stored C (Cta) per unit of surface area, which is calculated by taking into account bulk density (Da) and sampling depth. Statistically signif icant differences were found for the effect of area; the highest percentages of Nt (0.32), Ct (3.90), Cox (3.85), Ch (2.05) and Cp (1.15) and Cta (109 Mg ha^{-1}) were found in soils of humid forest zone 1 with the highest altitude (956 m), precipitation (2000 mm) and the lowest temperature (24 ºC). Land uses showed significant differences only for NT, CT, Cox, and Ch; in general, the values of the more stable forms of C of forest soils exceeded those of crop soils. Cox and Cnox accounted for 95% and 5% of Ct, respectively, for the different land uses; an average loss of 26% of Ct was observed in cultivated soils as compared with forest soils.

(8779 - 579) Contribution of microbial biomass carbon to below-ground biomass carbon budget in an agricultural field in Southern Hokkaido, Japan

Yuma Michinobu[1]; Putri Okutariani[1]; Ryusuke Hatano[1]
Hokkaido university[1]

Below-ground biomasses, plant roots and soil microbes, are important components controlling terrestrial carbon budget. However, the contribution of microbial biomass carbon (MBC) is not fully evaluated yet. Therefore, this study aimed to investigate the dynamics of MBC and the factors of MBC change at an agricultural field on Mollic Andisol in Southern Hokkaido, Japan (42°24'N, 142°28'E), for three years. The field was used as cornfield. After the corn harvest at September 2015, the field was converted to fallow until grass seeding at September 2016. After the seeding, the field was managed as grassland. Chemical fertilizer plot (F plot) and manure and chemical fertilizer plot (MF plot) were established in both cornfield and grassland. Fertilizer and tillage managements followed the regional recommendation were conducted. CO_2 flux, climate and soil environmental variables were monitored every 1-4 weeks. At the same time, soil samples were taken from 0-5 cm depth to measure MBC by the fumigation-extraction method, and to calculate MBC budget (MBCB. In MF plot, plant biomass was sampled to obtain above- and below-ground net primary production (ANPP and BNPP, respectively). The ratio of MBCB/BBCB (below-ground biomass C budget: BNPP + MBCB) indicated the contribution of MBC to below-ground biomass carbon. Mean MBC was significantly different among the landuses (cornfield < grassland < fallow: $p<0.001$) and there was no significant difference between MF and F plots. Root biomass was significantly higher in grassland than cornfield ($p<0.001$). Result of Pearson's test showed that, in entire term, MBC has significant positive correlation with soil moisture content and pH. In fallow, MBC has significant positive correlation with soil temperature and soil moisture content. In grassland, MBC has significant positive correlation with soil moisture content and negative with soil temperature. In cornfield, there are no significant correlations with the environmental variables. Those results indicated that MBC was mainly controlled by soil moisture content, and root biomass might be a factor affecting MBC change. In MF plots of cornfield and grassland, ANPP was 8.34±0.87 and 6.52±0.50 Mg C ha^{-1}, respectively, BNPP was 0.40±0.92 and 0.73±0.56 Mg C ha^{-1}, respectively, MBCB was 0.22±0.12 and -0.20±0.03 Mg C ha^{-1}, respectively, and MBCB/BBCB was 0.35 and -0.38, respectively. Those result suggested that MBC

contributed greatly to below-ground carbon and the carbon budget.

(1375 - 973) Developing an unmanned air vehicle deployed sensor platform for studying atmospheric emissions of soil carbon dioxide

Leandro Boari Naves Silva[1]; Marx Leandro Naves Silva[2]; Pedro Velloso Gomes Batista[2]; Danilo Alves de Lima[1]; Arthur de Miranda Neto[1]
UFLA/DEG[1]; UFLA/DCS[2]

Carbon dioxide emissions from vegetal biomass burning, deforestation, and inadequate soil management cause relevant alterations on soil carbon stocks. New technologies such as Unmanned Air Vehicles (UAVs) are a potential tool for the enhancement of methodologies and the development of innovative solutions for monitoring the earth surface, especially considering the use of deployed sensors. Hence, the objective of this study was to develop an on-board sensor platform for UAVs in order to measure spatially referenced data of carbon dioxide emissions (CO2), relative air humidity (RAH), and atmospheric temperature (AT). Such data will be used for the continuous monitoring of environmental changes caused by land use and soil management on agricultural systems. An on-board platform of the electronic systems used for the automated measurements, data storage and interfacing, was dimensioned based on a DJI Phantom 3 four rotor UAV (quadcopter) (ANAC registration number PP-11111110 – series P76DDC18B271). A microcontroller Atmega 328P – Arduino Nano V3 was used as the electronic prototyping platform for data input and output. A module MG811 was used for CO2 detection and DHT22 for measuring RAH and AT. Data is sampled at a two second temporal resolution, which is georeferenced by a NEO-6 U-Blox GPS module. A recording module stores the measured data in a Micro SD memory card after each flight. Weighting 200g, the platform and couplings did not interfere with the UAV flight stability. The DHT22 module has a maximum energy consumption of 2.5 mA during use and takes AT measurements between -40 °C and 80°C, with a precision of ±0.5 °C. RAH is measured between 0 and 100 % with a ± 2.0 % precision. The MG811 module has an energy consumption of 3.0 mA during use and takes CO2 measurements between 0 and 10,000 ppm. Initial tests indicate that the platform is efficient for data collection and information recording. Next steps will be focused on developing an interface for extraction, visualization, storage, and analysis of the sampled data, as well as on the examination of precision and accuracy of the sensor measurements.

(9327 - 2408) Dynamics of methane and nitrous oxide emissions in lowland production systems.

Miguel David Fuentes Guevara[1]; Thaís Murias Jardim[1]; Walkyria Bueno Scivittaro[2]; Lillian Medeiros Barros[3]; Renata Abreu Rodrigues[3]; Cristiano Weinert[1]; Thaís Antolini Veçozzi[1]; Anderson Dias Silveira[1]; Rogério Oliveira de Sousa[1]; Jaqueline Trombetta da Silva[1]
Universidade Federal de Pelotas[1]; Embrapa Clima Temperado[2]; Instituto Federal Sul-Riograndense[3]

The main greenhouse gases (GHG) associated with agricultural activity are methane (CH_4) and nitrous oxide (N_2O), providing significant emissions when expressed in carbon dioxide (CO_2) equivalent, as they have the capacity to absorb infrared radiation 25 and 298 fold higher than CO_2, respectively. The objective of this work was to evaluate CH_4 and N_2O emissions in representative production systems of the Rio Grande do Sul lowlands. The study was developed at an Embrapa Temperate Agriculture experimental area, in Capão do Leão, State of Rio Grande do Sul, Brazil, during 2016/2017 summer season. Three production systems (native pasture with extensive livestock, irrigated rice/fallow and soybean/corn rotation under no-tillage system - cultivating corn during the evaluation period) and a natural area, used as a reference. Gas collection was performed using closed static chambers with three replicates per treatment. The fluxes and total emissions of CH_4 and N_2O were determined. Significant CH_4 emissions were found only in irrigated rice system; the maximum CH_4 emission peak occurred on the 60th day after sowing (2,048.04 g CH_4 ha^{-1} h^{-1}), being attributed to the anaerobic condition promoted by flooded soil. On the other hand, higher N_2O emissions were observed in the soybean/corn rotation system, which presented high magnitude peaks at the 19th, 40th and 63rd day after sowing, corresponding to 800.08; 11,980.5 and 25,832.7 mg N_2O ha^{-1} h^{-1}, that were associated to topdressing nitrogen fertilization and to the variation in the conditions of soil oxidation, conditioning nitrification and denitrification processes, promoted by rainfall events. The irrigated rice system provided higher total CH_4 emission (803.83 kg ha^{-1}), followed by soybean/corn rotation (4.35 kg ha^{-1}), native pasture (0.97 kg ha^{-1}) and the natural area (0.82 kg ha^{-1}); while the highest total N_2O emission was determined for the soybean/corn rotation (10.92 kg ha^{-1}). The emission of methane and nitrous oxide from the lowland production systems is greater than in the natural area.

(1371 - 1820) Effect of different soil bulk density and temperature on soil CO_2 emission from tropical peatland

Nur Azima Busman[1]; Nagamitsu Maie[2]; Che Fauziah Ishak'[3]; Muhammad Firdaus Sulaiman[3]; Lulie Melling[4]
1. Sarawak Tropical Peat Research Institute, Lot 6035, Kota Samarahan Expressway, 94300 Kota Samarahan, Sarawak, Malaysia 2.3Department of Land Management, Faculty of Agriculture, Universiti Putra Malaysia, 43400, Serdang, Selangor, Malaysia[1]; School of Veterinary Medicine, Kitasato University, Towada, Aomori 034-8628, Japan[2]; Department of Land Management, Faculty of Agriculture, Universiti Putra Malaysia, 43400, Serdang, Selangor, Malaysia[3]; Sarawak Tropical Peat Research Institute, Lot 6035, Kota Samarahan Expressway, 94300 Kota Samarahan, Sarawak, Malaysia[4]

Tropical peatland store 68.5 Gt of C and since 1990s, ca. 25% of the tropical peatland area in Malaysia has been converted for oil palm plantation where drainage, compaction, and groundwater table (GWT) control are pre-requisites. However, the information on the simultaneous effect of soil compaction and rise in temperature on soil CO_2 emission from tropical region is scarce. Soil compaction causes the reduction of the pore size, increase in soil bulk density (BD) which eventually affects the soil moisture content. Nonetheless, the effect of soil BD, GWT, and rise in temperature as a whole towards the production of CO_2 are ambiguous. Therefore, the objective of this study is to examine the effect of soil BD and temperature on CO_2 emission from tropical peat soils. Soil samples (50–70cm depth) collected from a Mixed Peat Swamp forest in Sarawak, Malaysia were packed and compacted in a PVC pipe to four different BD; 0.14 g cm^{-3}, 0.18 g cm^{-3}, 0.22 g cm^{-3}, and 0.24 g cm^{-3} and incubated in a laboratory condition under two temperature regimes, 25°C and 35°C. Soil CO_2 fluxes and redox potential (E_h) were measured weekly for three

months. It was found that CO_2 emission from soil with a different BD shows similar trend in 25°C and 35°C, with soil CO_2 emission from BD 0.24 g cm^{-3} was significantly lower than other soil BD ($P < 0.05$) throughout the incubation period. Meanwhile no significant differences were observed between soil BD 0.14 g cm^{-3}, 0.18 g cm^{-3} and 0.22 g cm^{-3}, possibly due to the sufficient presence of O_2 in the soil, when the E_h value recorded during incubation period was high. The effect of soil BD was insignificant towards CO_2 production rate when sufficient amount of O_2 is available. However, greater soil compaction to a BD 0.24 g cm^{-3} resulted in prolonged water saturation in the soil pore space, cause the reduction in the O_2 diffusion rate into the soil throughout the incubation period, thus lowering the soil CO_2 flux. The low O_2 level is represent by E_h values ranging between +400 to -300 mV (Pezeshkiez & DeLaune 2012). E_h value recorded from BD 0.24 g cm^{-3} ranges between 170 to 367 mV and 180 to 272 mV at temperature 25°C and 35°C, respectively. Overall, soil CO_2 emission is higher at temperature 35°C compared to 25°C ($P < 0.05$). CO_2 emission from soil BD 0.14 g cm^{-3} and 0.18 g cm^{-3} were significantly higher at temperature 35°C, but no significant difference was observed from soil compacted to BD, 0.22 g cm^{-3}, and 0.24 g cm^{-3}.

(7988 - 851) Effect of the endogenous and exogenous minerals on the stability of biochar

Ke SUN[1]; Yan YANG[1]; Haoran SUN[1]; Baoshan XING[2]
State Key Laboratory of Water Environment Simulation, School of Environment, Beijing Normal University, Beijing 100875, China[1]; Stockbridge School of Agriculture, University of Massachusetts, Amherst, MA 01003, USA[2]

The stability of biochar is a major determinant of its potential for carbon sequestration. In previous studies, the biochar stability was evaluated by analyzing the oxidation resistance property of biochar, for which, $K_2Cr_2O_7/H_2O_2$ oxidation and thermogravimetric analysis (TGA) were widely used to measure the high oxidation resistance of biochars. In this study, rice straw (RI)- and swine manure (SW)-derived biochars produced at different heating treatment temperatures (HTTs) and their corresponding de-ashed biochars and iron-biochars were selected to investigate the effect of minerals on these biochars stability. There was a significantly positive correlation between carbon remaining values (CRVs) obtained after $K_2Cr_2O_7/H_2O_2$ oxidation and ash (mineral) contents of biochars ($p < 0.05$). Moreover, the decreasing CRVs of most biochars were observed after de-ashing treatment. These $K_2Cr_2O_7/H_2O_2$ oxidation results indicated that endogenous minerals in biochars can protect biochars from chemical oxidation. On the other hand, the R_{50} (C recalcitrance index) values of iron-biochars (33.3−57.4%) were lower than those of corresponding biochars (38.6−60.8%), indicating that Fe-bearing mineral formed in biochars can promote the thermal decomposition of biochars. In H_2O_2 oxidation, the different change trend of CRVs between biochars produced at 450 °C and biochars produced at 600 °C after iron mineral treatment showed that the effect of exogenous Fe-bearing mineral on biochar stability was related to biochar category regulated by HTTs. This study indicated that endogenous minerals could increase biochar stability, and exogenous Fe-bearing minerals had dissimilar effects on different kinds of biochars, which critically regulates the potential of biochar for long-term carbon sequestration. Our findings will help understand the stability of biochars and provide a theoretical basis for efficient use of biochars in environment as a carbon sink.

(8514 - 702) Effect of tillage method and timing in grassland renovation on soil greenhouse gas emissions

Arata Nagatake[1]; Vecky dwi[2]; Sota[3]; Kaho[4]; Hiromichi[5]; Yuma[6]; Chiho[7]; Masahito[8]; Ryusuke[9]
Hokkiado University[1]; Kuswandra[2]; Nishi[3]; Yasuda[4]; Takahashi[5]; Michinobu[6]; Sugiyama[7]; Kawai[8]; Hatano[9]

Managed grassland is occasionally renovated to improve grass yield by plowing and reseeding, and different plowing depth and renovation season may affect soil organic matter decomposition and plant growth. We conducted field experiment in grassland on a Mollic Andosol in Southern Hokkaido, Japan to assess the effect of tillage method and timing of grassland renovation on greenhouse gas emissions. Split tillage (ST) every 10 cm interval to 10 cm depth, 15 cm and 30 cm inversion tillage (T15 and T30) were conducted in autumn renovation (AR) and spring renovation (SR). Timothy grass seed and chemical fertilizer were applied in each treatment in rate of recommended level in this region. CO_2, N_2O, CH_4 fluxes were measured by closed chamber method at three replicates, and root-excluded plot was set up to estimate heterotrophic respiration (RH). Carbon (C) balance was estimated as net biome production (NBP), and calculated as difference between C inputs (net primary production (NPP) and plant residue) and C outputs (harvested C and RH). Global warming potential (GWP) was estimated as the sum of CO_2 equivalents of CH_4, N_2O and NBP. Greenhouse gas intensity (GHGI) is estimated as GWP divided by grass yield. This experiment was repeated in 2015-2016 and 2016-2017. RH and net C loss (–NBP) were higher in T30 and T15 than in ST ($p < 0.05$) except 2016-AR which was conducted after typhoon. N_2O and CH_4 emissions were not significantly different across tillage methods and renovation seasons, but N_2O emissions in T30 were tended to be lower than ST and T15. There was negative correlation between CO_2 fluxes and water filled pore space (WFPS)($p < 0.01$), and WFPS in T30 and T15 were lower than ST ($p < 0.01$). This indicates that soil organic C decomposition was stimulated under better soil aeration due to tillage in T15 and T30. N_2O emission showed positive week correlation ($p = 0.053$) with plant residue N decomposition estimated by litter bag method, but not with chemical fertilizer input. This might indicates that dissolved organic matter and mineral nitrogen from residue is a driving factor of N_2O emission. Contribution of NBP and N_2O emission to GWP were 60~92% and 7~40%, respectively, and contribution of CH_4 emission was less than 4%. There were no significant differences in net GWP between tillage methods and renovation season. Grass yield was not different among tillage method, but AR showed significantly lager yield than SR. Therefore AR more decreased GHGI than SR.

(7087 - 844) Effects of Elevated Atmospheric CO_2 on Soil Organic Carbon in Rice Paddy Field

Jianguo ZHU[1]
Institute of Soil Science, CAS[1]

This research was carried out on China FACE (Free-air Carbon-dioxide Enrichment) experimental platform with the concentrations of carbon dioxide in the atmosphere as main treatments and the levels of nitrogen fertilizer as sub-treatments. A split plot design was used in the experiment. The carbon dioxide concentration treatments had two levels, i.e. Ambient (atmospheric carbon dioxide concentration) and FACE (Ambient + 200 ppm). The nitrogen application rates were

LN (low nitrogen application rate, 125 kg ha^{-1}) and NN (normal nitrogen application rate, 250 kg ha^{-1}). After nine years, SOC at plow layer (0-15 cm) increased significantly (9.95 %, $p<0.05$), about 1.1 % per year under medium to long-term atmospheric [CO_2] enrichment condition. The storage of SOC in microaggregates (250-53 µm) increased about 15.1 % ($p<0.05$) and the storage of SOC in small macroaggregates (2000-250 µm) decreased about 6.4 % ($p<0.05$). Elevated [CO_2] had a trend to increase the turnover of two macroaggregates (>250 µm) of the 0-5 cm soil, as a result more quantity ($p<0.05$) and SOC of microaggregates were found under elevated [CO_2]; elevated [CO_2] didn't change the composition of the 5-15 cm soil, but it had significant negative effects ($p<0.05$) on SOC of macroaggregates. It also showed that normal level of nitrogen fertilizer (NN) decreased the quantity and SOC of large macroaggregates (>2000 µm) at 5-15 cm soil depth. iPOM-C was about 17.8-33.7 % of total SOC. Elevated [CO_2] significantly increased mSOC and iPOM-C in aggregates at 0-5 cm soil depths ($p<0.05$), however it had no effect on concentrations of iPOM-C at 5-15 cm soil depth. Elevated [CO_2] has no effect on SOC of light-fraction (LF-C) and LF-C was only 4.0-8.5 % of total SOC. In conclusion, elevated [CO_2] increased soil organic carbon by allotting them in microagggregates in the form of mineral associated organic carbon mainly.

(5517 - 1397) Effects of rice straw field burial on methanogenesis: a laboratory assessment

M.Carreras[1]; B.Fernández[1]; M. Martínez-Eixarch[1]; F. X. Prenafeta-Boldú[1]; M.Viñas[1]

IRTA[1]

Rice paddy fields are one of the major sources of greenhouse gas (GHG) emissions, being the main source of anthropogenic methane emissions (CH_4) (20%). The project LIFE EBRO-ADMICLIM is evaluating the annual pattern of CH_4 emissions in the rice paddy fields in the Ebre Delta. Ebre Delta is one of the main wetland of western Mediterranean and Biosphere's reserve. It's main anthropogenic activity is the rice cultivation, being the 65% of the total surface. It represents the 1% of the Europe's rice paddy. Annual CH_4 emissions in the Ebre Delta displayed a bimodal pattern, with a peak of 70% of the methane produced during the post-harvest season. Preliminary results revealed that both the incorporation of rice straw into the soil, and the water management at the end of the harvest, were the main factors contributing to the annual GHG emissions in rice paddy fields. Two mechanisms of methane emission has been proposed so far: i) the capacity to massively detach the methane accumulated beneath the sediment during the crop season, and ii) the higher bioavailability of organic's matter in the soil, still wet, when the tillage incorporate the straw at the beginning of the post-harvest season. The aim of the study is to gain insight on the potential contribution of mixing rice straw in the sediments in the rice paddy fields of Ebro's Delta during the postharvest season. Microbial key players linked to methane emissions and strategies to diminish methanogenesis has also been assessed. Although, the strong influence of the straw's incorporation on the CH4 emissions has been previously described, there is limited information about the type, quality and dose of straw and its effects on boosting methane emissions from natural sediments, and regarding the microbial populations implied in the fermentative and methanogenic activities. The present shows the results of different in-vitro methanogenic batch assays containing sediment and surface water from Ebre Delta to study i) the direct influence of growing amounts of rice straw in the sediment; ii) and the potential effect of different methanogenic inhibitors based on the inhibition of HMG CoA reductase in Archaea linked to membrane lipid biosynthesis pathway to decrease methane emissions. Molecular microbial assessment of total and metabolically active microbial populations has been performed throughout incubation time to identify those microbial key players that are contributing to methane emission in the sediments.

(6724 - 2048) Effects of soybean expansion on soil chemical indicators in the matopiba region, brazilian savanna

Marcos Siqueira-Neto[1]; Gustavo Vicentini Popin[2]; Maurício Rogério Cherubin[2]; Isabela Gomes Pires[2]; Tiago Osório Ferreira[2]; Edmilson Igor Bernardo Almeida[1]; Gregori da Encarnação Ferrão[1]

UFMA[1]; USP[2]

The savanna biome in Maranhão State represents a large ecotone between Caatinga-Savanna-Amazon biomes. This region has been focus of land use change (LUC) to soybean expansion in Brazilian savanna, and currently one of the biggest grain producers in the world. Our objective was to quantify the effects of time after LUC (from native vegetation to soybean) on soil chemical indicators (SCI) in the MATOPIBA Savanna. Soil samples (0-30 cm) was collected in a Xanthic Ferralsols Dystric cohesive located in the municipality of Chapadinha (MA, Brazil) in areas under soybean over 1, 8 and 15 year and an area under native vegetation (NV-reference). The selects SCI evaluated were: active acid (pHCaCl2), bulk density (BD), carbon (SOC), nitrogen (TN), available-phosphorus (P), potassium (K), base (BS%) and aluminum saturation (m%). Overall, LUC from NV to soybean reduced one-third of original SOC (from 12 to 7.5 g kg-1), while TN not showed changes (0.6 g kg-1), as well as BD (1.46 g cm-3). However others SCI as soil pH increased from 3.9 to 5.0; base saturation increased more than four times (from 10 to 45%); aluminum saturation reduced from 57 to ~10%. The potassium content increased 40% (from 13 to 20 mg kg-1), while available-P showed drastically increased between seven to eighteen times (from 0.5 to 9.3 after 15 yr). These results indicated that due the lower natural fertility, LUC had the capacity to improve soil chemical indicators, however, the SOC depletion can be to consider a high cost-effectiveness to ecosystem soil service.

(1144 - 2812) Emission factor of nitrous oxide from urine cattle and dicyandiamide use as a mitigation strategy in a subtropical Brazilian grass.

Ezequias Cloy Ferreira[1]; Priscila Luzia Simon[1]; Bruna Ramalho[1]; Mariana Alves Ibarr[1]; Ricardo Henrique Ribeiro[1]; Caroline Amadori[1]; Bruno da Silva Pereira[1]; Jeferson Dieckow[1]; Josiléia Acordi Zanatta[2]

Federal University of Parana, Rua dos Funcionarios 1540, Curitiba, 80035-050, Brazil[1]; Empresa Brasileira de Pesquisa Agropecuária (EMBRAPA), Centro Nacional de Pesquisa em Floresta 83411- 000, Colombo, PR, Brazil[2]

Searching for a conservationist production system, the Brazilian agriculture sector has been concerned in adopting strategies to smooth greenhouse gas emissions, mainly nitrous oxide (N_2O) from cattle urine, responsible for 41% of national N_2O gas emission. The proposals of this work were to evaluate the dicyandiamide efficiency (DCD), a nitrification inhibitor, on N_2O emission reduction, and to compare the emission factor from cattle urine with 2% default

suggested by Intergovernmental Panel on Climate Change (IPCC). The study was carried out at the experimental farm of the Federal University of Parana, Pinhais-PR, Brazil under an Inceptisol and subtropical climate. The trial design was in randomized block with three treatments of cattle urine application over aries grass (*Panicum maximum cv. Aries*) and four replicates. The treatments were: soil without urine application (control), urine application and urine + DCD application. The urine application was done in a single portion, simulating one animal urination, by means of dosage equal to 103 g N m^{-2}. The air samplings were performed by the static chamber method and analysed by gas chromatography. The data was submitted to analysis of variance and applied Tukey´s test ($p < 0.10$). There was a considerable positive effect of DCD use on N_2O emissions reduction, with a cumulative emission of 726 mg N m^{-2} compared to urine application (1436 mg N m^{-2}) and a total of 49% reduction. The effects of DCD are related to its action in the first step of the nitrification process, inhibiting the ammonia monooxygenase enzyme, responsible for oxidizing ammonia to nitrite, which is the substrate to N cycling and thus N_2O production. The lower temperatures in subtropical regions are most likely one of the major reasons of the high efficiency of DCD in our study, and thus, being an effective alternative to reduce N_2O emissions. The emission factor of N_2O from cattle urine obtained was 1.33%, which suggests a revision to the 2% IPCC default for subtropical regions.

(2088 - 1646) Emissions of biogenic greenhouse gases in grasslands and croplands of the Chiloé Island, Chile.

Patricia Ibaceta[1]; Mauricio Galleguillos[2]; Bruce Osborne[3]; Jorge F. Pérez-Quezada[2]
Programa de Magíster en Manejo de Suelos y Aguas, Universidad de Chile, Casilla 1004, Santiago, Chile[1]; Departamento de Ciencias Ambientales y Recursos Naturales, Facultad de Ciencias Agronómicas, Universidad de Chile, Casilla 1004, Santiago, Chile[2]; School of Biology and Environmental Science, University College Dublin, Belfield, Dublin 4, Irlanda[3]

Soil is a critical regulator of the global balance of carbon (C) and nitrogen (N) through their storage, capture and emission mechanisms. Both elements interact between the soil and the atmosphere through the biogeochemical cycles that involve their transformation to greenhouse gases (GHG) such as carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O). This is especially important in southern Chile, due to the increasing conversion of natural ecosystems into croplands and grasslands, whose effects have been poorly documented. Our study is a pioneer assessment of biogenic GHG emissions in a native forest and two typical agroecosystems of the Chiloé Island: 1) potato crops and 2) grazed grasslands mainly by sheep, with predominance of perennial herbaceous plants, such as *Dactylis glomerata*, *Holcus lanatus*, *Lolium perenne* and *Trifolium repens*, which were sampled in three locations (41°53' S, 73°39' W; 42°0' S, 73°53' W; 42°15' S, 73°38' W) or replicates. To measure these GHGs we used at field level a portable closed chamber system with an infrared gas analyzer (model LI-840A, LI-COR) for CO_2 and the cavity ring-down spectroscopy technology (model G2308, Picarro Inc.) for CH_4 and N_2O, along a day of each month and during six months. The daily GHG fluxes were modeled using continuously recorded environmental variables, such as soil (Andisol) water content, photosynthetically active radiation, soil, air and canopy temperature. When comparing the GHG balance in agroecosystems with the GHG balance previously obtained for a native forest of Chiloé (-660.1 g CO_2-eq m^{-2} $year^{-1}$), we found that the managed ecosystems release more C to the atmosphere (in form of CO_2 or CH_4) than natural ecosystems, thus showing the effect of forest conversion to agricultural systems.

(9573 - 2466) Emissions of nitrous oxide and methane in vitro influenced by soil management systems of a long-term field experiment from the south of Brazil

Anaí Sangiovo Ottonelli[1]; Murilo Gomes Veloso[1]; Cimelio Bayer[1]
Universidade Federal do Rio Grande do Sul[1]

Greenhouse gas (GHG) emissions are linked to the dynamics of C and N in different management systems of soil. The objective of this study was to validate the influence of tillage and culture system on GHG emissions in disturbed and undisturbed samples in soils from long term experiments. The study was performed in soil samples were collected in an experiment installed in 1985 located at the Agronomical Experimental Station of the Federal University of Rio Grande do Sul. The experiment consisted of a combination of two tillage systems: conventional tillage (CT) and no-tillage (NT). Each tillage system was associated to three cultures systems: oat/maize (O/M), vetch/maize (V/M) and oat + vetch /maize + cowpea (OV/MC). The soil was classified as an Ultisol. In laboratory, the emissions of N_2O and CH_4 were validated as undisturbed and disturbed samples of incubation determined by gas chromatography. The C and N contents were analyzed by dry combustion. The disturbed samples reported N_2O emissions of about twice as much as the undisturbed samples of the management systems. Overall, disturbed samples reported efflux of CH_4 while undisturbed samples reported influx of this gas. The undisturbed samples approached closer to the results obtained in field. Also, the undisturbed samples were more appropriate the regulatory processes of GHG emissions. It was verified that the accumulated emissions of CH_4 in laboratory the soil in NT and with crop cover legumes favored the consumption of CH_4., which probably occurred due to the improvement of structure of the soil and the recovery of the metanotrofic population. The soil there were observed more emission of N_2O on the system covered by legumes, which was probably related to the increase in mineralization of N during decomposition of residual. Moreover, the no-tillage with insertion of legume cover crops was the one with more vegetal residual contribution due the highest stocks of C and N on the soil for 0-20 cm. The undisturbed samples were more consistent to the field performance. Such data agree with the data obtained on field all the management systems, it was observed that only aerobic environments reported low or influx of CH_4. Also, the highest emission of N_2O of soil occurred with the presence of cover crop legumes, were counterbalanced with most sequester of C in the no-tillage and cover crops legumes systems of soil, when it is estimated the global warning potential.

(7366 - 1475) Grazing management contributions to global warming potential in Pampa Biome.

Janquieli Schirmann[1]; Diego Fernandes Bastos[2]; Douglas Adams Weiler[1]; Paulo Cesar de Faccio Carvalho[2]; Cimélio Bayer[2]
Universidade Federal de Santa Maria[1]; Universidade Federal do Rio Grande do Sul[2]

Pampa is recognized as the most important forage source to livestock production in South America. The impacts of Pampa grazing management on net global warming potential are still unknown. The study was performed to quantify the global warming potential (GWP) of four forage allowance in a native grassland: 4, 8, 12 and 16% (kg dry matter 100 kg animal live weight^{-1} day^{-1}). Experimental site was located in UFRGS Experimental Station in Rio Grande do Sul State, Brazil. Native grassland has been managed with four forage allowance for 30 years. Experimental design was randomized blocks, with two replicates. Soil methane (CH_4) and nitrous oxide (N_2O) emissions were measuring with static chamber method during two years. Soil samples to evaluate organic carbon concentration and stocks were collected in stratified layers up to 100 cm deep in four trenches per replicate. Soil carbon sequestration was calculated taken 4% forage allowance as reference. GWP was calculated for each forage allowance treatment as the sum of emitted CO_2 equivalents from three factors: carbon sequestration, CH_4 emission from soil and enteric fermentation, and N_2O emission from soil and bovine excreta (urine and dung). Soil carbon stock in 0-100 cm in the 8% forage allowance (135.7 Mg C ha^{-1}) was 20 Mg C ha^{-1} higher than in 4%, but did not differing from the 12% (124.2 Mg C ha^{-1}) and 16% (122,2 Mg C ha^{-1}). Cumulative N_2O (0.19 kg N ha^{-1}) and CH_4 (1.53 kg C ha^{-1}) emissions were low, with no difference among forage allowance on 2-year average. The 8% forage allowance showed the lowest GWP (-442 kg CO_2eq ha^{-1} yr^{-1}) and the lowest GHG intensity (-3.5 kg CO_2eq kg animal live weight^{-1}). GWP were predominantly determined by CH_4 production from enteric fermentation and carbon sequestration rates. Results suggests that 8% forage allowance may promote an increase in soil carbon stock in native Pampa grassland compared to 4% forage allowance. Forage allowance of 8% associated animal production and low GHG emissions, featuring environmental benefits for livestock production on native grassland in Pampa biome.

(3212 - 2904) Greenhouse gases fluxes as affected by water potential in soils under sclerophyllous vegetation of Central Chile

Juan-Pablo Fuentes-Espoz[1]; Horacio Bown[1]; Amanda Martínez[1]; Daniela Celedón[1]; María-Andrea Díaz[1]; Jorge Pérez-Quezada[2]
University of Chile, Faculty of Forestry Sciences and Nature Conservation[1]; University of Chile, Faculty of Agronomy[2]

In natural systems, most of the greenhouse gases (GHG) are sequestered or emitted by soils. The fate of CO_2, CH_4, and N_2O is mostly biologically mediated, hence soil properties affecting microbiota play a key role. Soil water content (swc) affect aerobic and anaerobic microorganisms, inducing shifts in the fluxes of GHG. Most studies of soil GHG fluxes use swc as an explanatory variable. However, microorganisms can have different responses to similar swc, particularly when comparing different soils. Consequently, the use of soil water potential (P_T) could be a good surrogate variable. We determined the effects of P_T on GHG fluxes in soils under 4 sclerophyllous plant species of Chile. Soil samples (0-10 cm depth) were obtained under *Quillaja saponaria* (QUI), *Lithraea caustica* (LIT), *Colliguaja odorifera* (COY), and *Acacia caven* (ESP), all growing in the same landscape area. Soil samples (50 g) were brought to swc equivalent to saturated (P_T= 0 MPa), near saturated (P_T ~0.005 MPa) and field capacity (P_T =0.01 MPa), and then incubated at 23°C in 1L jars for 3 days (n=5 per plant species and P_T). GHG fluxes were measured using a Cavity Ring Down Spectrometer (G2308, Picarro Inc., USA). CO_2 fluxes were affected by P_T ($p<0.001$) and plant species ($p<0.05$). Higher P_T (Y_T *= 0 and 0.005)* caused a decrease in CO_2 fluxes of about 50% as compared to the lower P_T (0.45-0.78 and 1.95 umol m^2 sec^{-1}, respectively). ESP had 3.5 times lower fluxes as compared to QUI (0.45 and 1.56 umol m^2 sec^{-1}, respectively). Such difference might be caused by soil organic carbon availability. In contrast, P_T and plant species did not affect CH_4 fluxes, which were very variable, particularly for P_T=0.01 (-0.0227 to 0.6361 nmol m^2 sec^{-1}), showing either emission or sequestration patterns. Mean values of CH_4 fluxes were positive, suggesting that saturated and near saturated conditions, and even lower P_T, create conditions for methanogenesis. N_2O fluxes were affected by Pt ($p<0.001$) but not plant species. N_2O emissions were greater with near saturated and saturated conditions (176.65 and 93.58 nmol m^2 sec^{-1}, respectively) as compared to the lower P_T (2.81nmol m^2 sec^{-1}). Our findings suggest that, under saturated and near saturated conditions, methanogenesis and denitrification start shortly after water saturation. Emissions of CH_4 and N_2O at lower P_T, suggest that production of these GHG in sclerophyllous soils can occur despite aerobic conditions.

(9745 - 1947) Impact of *Eucalyptus* Harvest Residues Management on Soil Carbon Storage and Greenhouse Gas Emission (GHG) in sandy soil in southern Brazil

Jackson Freitas Brilhante de São José[1]; Cimélio Bayer[1]; Andressa Classer Bender[1]; Juscilaine Gomes Martins[1]; Deborah Pinheiro Dick[2]; Elias Frank de Araújo[3]; Renato de Aragão Ribeiro Rodrigues[4]; Eduardo Carniel[1]; Daniela Ulian da Silva[1]
Department of Soil Science and Graduate Program on Soil Science, Faculty of Agronomy, Federal University of Rio Grande do Sul; Porto Alegre, RS; Brazil[1]; Department of Physical-Chemistry, Institute of Chemistry, Federal University of Rio Grande do Sul; Porto Alegre, RS; Brazil[2]; Technology and Forestry Development, CMPC Celulose Riograndense, Guaíba, RS; Brazil[3]; Researcher Climate Change, EMBRAPA Soils, Brazilian Agriculture Research Corporation, Rio de Janeiro/RJ; Brazil[4]

In the last years, Brazilian companies in the forestry sector have discussed the use of waste left by the forest harvest residues for energy generation as an alternative to the use of fossil fuels. These residues are basically composed of leaves, branches, bark and parts of wood, and are usually left in the field, thus maintaining soil organic matter contents and forest productivity. In Brazil, studies on the impact of harvest residues (HR) on GHG emissions (N_2O, CH_4 and CO_2) and soil organic matter are scarce. We investigated the GHG emissions in an eucalyptus plantation in function of five alternative strategies for management of HR: (i) SRCS- all forest residues from the previous rotation were removed; (ii) CRC- bark, leaves and litter layer from the previous rotation were maintained on the soil; (iii) CRG- branches, leaves and litter layer from the previous rotation were left in the soil; (iv) CR- presence of all harvest residues (leaves, branches, bark, + litter); and (v) SRSS- all forest residues were removed and litter from the new plantations were also removed. These treatments were installed in plots of 900 m^2, using a randomized block design with four replications. The experiment was conducted in the forest Park of the company CMPC, located in the county of Barra do Ribeiro/RS, Brazil in sandy entisol. In each plot, one trenche was opened up to 100 cm

depth, and soil samples were collected in two sides of the trenche and soil carbon was analyzed by dry combustion (Shimadzu TOC-VCSH analyzer). Annual campaign of GHG colletion was performed by method of closed chamber where air samples were collected each three weeks, and analyzed in regarding the contents of N_2O and CH_4 contents by gas chromatography. The maintenance of HR of eucalyptus CR led to an increment of 8 Mg ha^{-1} of soil C storage in 0-100 cm mineral soil compared to SRSS. Soil N_2O fluxes were very low under all HR management.The highest accumulated emissions of N_2O were obtained in CR, with 0.45 kg ha^{-1}. There was a predominance of CH_4 influx in practically all treatments. Similarly to N_2O, CR also showed higher cumulative annual emissions influx of CH_4 reaching 5.7 kg ha^{-1}. All HR managements presented negative GWP values, showing the potential of forest plantations as drainage for GHG. Our results indicated that the maintenance of eucalyptus HR is an environmentally interesting strategy with the greatest potential to mitigate GHG emissions, as it promotes greater soil carbon retention.

(2648 - 1067) Influence of irrigation on photosynthetic carbon inputs under ryegrass-white clover pasture in New Zealand

C.R. Medina[1]; S. R. McNally[2]; T. Clough[1]; M.H. Beare[2]; J. E. Hunt[3]; C.S. Tregurtha[2]
Department of Soil and Physical Sciences, Faculty of Agriculture and Life Sciences. Lincoln University, Lincoln 7647, New Zealand.[1]; Sustainable Production Portfolio, New Zealand Institute for Plant and Food Research Limited, Private Bag 4704, Christchurch 8140, New Zealand[2]; Landcare Research, P.O. Box 69040, Lincoln 7640, New Zealand[3]

Carbon (C) stocks under grazed pasture in New Zealand represent ~50% of the national soil C inventory. The use of irrigation is increasing to improve dry matter production (DMP). However, it is not clear whether irrigated pastures act as a sink or a source of atmospheric CO_2. Our objective was to study the effects of irrigation on the allocation of photosynthetic-C in a plant-soil system under a perennial ryegrass (*Lolium perenne L.*) and white clover (*Trifolium repens L.)* pasture. The experiment consisted of two treatments (dryland [37-80 % of field capacity] and irrigated [69-92% of field capacity] pasture) applied to pots (15 cm dia x 25 cm deep) with soil (0-15cm, sieved <6 mm) from a non-irrigated site. Well established ryegrass-clover pasture was continuously pulse labelled with $^{13}CO_2$ (10 atom %) over three months. A further set of pots were maintained at natural abundance CO_2. After labelling, the allocation of fixed-C to plant-soil compartments was determined by harvesting 8 pots/treatment. The soil organic C derived from the newly fixed-C at the end of the labelling phase was calculated using a two-pool mixing model. During the labelling period, DMP was greater under irrigated (65 ± 1 kg ha^{-1} d^{-1}) than dryland conditions (55 ± 1 kg ha^{-1} d^{-1}). Total annual DMP was also higher for irrigated (17400 ± 370 kg ha^{-1}) than dryland pasture (14700 ± 380 kg ha^{-1}). The total DMP of the dryland system was higher than would typically be expected under field conditions. After labelling, approximately 76% of the added ^{13}C was recovered in the herbage, 8% in above-ground residue, 7% in roots, 5% in the bulk soil and 1% in the rhizosphere soil. The allocation of ^{13}C into these respective compartments was similar between the irrigated and dryland systems. The C input to bulk soil was 1479 ± 144 kg ha^{-1} and 1433 ± 85 kg ha^{-1} (0–15 cm) and 750 ± 131 kg ha^{-1} and 557 ± 72 kg ha^{-1} (15–25 cm) for irrigated and dryland systems, respectively. There was no significant effect of the irrigation treatments. These results show that despite greater aboveground production there was not an increase of C inputs to the soil under irrigated pasture. However, the effects of more extreme differences in soil moisture on pasture production and belowground C allocation under irrigated and dryland conditions are not know and require further study. On-going work is also investigating the longer term stability of new pasture-fixed soil C under both irrigated and dryland conditions.

(7570 - 977) Legume cover crops favour soil organo-mineral formation through microbial products

Murilo Veloso[1]; Denis Angers[2]; Martin Chantigny[2]; Janaína Costa[3]; Deborah Dick[1]; Cimélio Bayer[1]
UFRGS[1]; AAFC Canada[2]; UFGRS[3]

The implementation of no-till coupled with legume cover crops results in high carbon sequestration rates in subtropical soils of Southern Brazil. We hypothesized that this effect is due to the accumulation of organo-mineral associations enriched in microbial products induced triggered by the absence of tillage and the high-quality of legume biomass. We sampled soil in a 30-yrs old field experiment and used density and particle size fractionation in combination with carbohydrate and *n*-alkane analyses to compare the effect of conventional tillage (CT) vs. NT, combined or not with legume cover cropping, and combined or not with mineral N fertilization. In general, the amount of microbe-derived carbohydrates (galactose, manose, fucose and rhamnose) exceeded plant-derived carbohydrates (arabinose and xylose), especially in clay fraction of 20-30 and 75-100 cm layers (microbe-derived-to-plant-derived carbohydrate ratio of 1.9 and 2.2, respectively). Due to the large abundance of LF-C in the 0-5 cm soil layer, leading an overwhelming contribution of plant-derived carbohydrates, the relative contribution of microbial residues was lower than from microbial-derived, but still dominant. In 20-30 and 75-100 cm, the contribution of microbial over plant-derived carbohydrates in the clay fraction was 19 and 7%, respectively, greater with than without legume cover-crops. These findings were in good agreement with the assessment of *n*-alkanes biomarkers: Short *n*-alkanes chains (15-25) instead of long chains (25-35) were favoured by legumes under NT in clay fraction of superficial and deeper soil layers, indicating predominance of microbial residues. The nitrogen fertilization favoured the increase only in LF-C but not in clay-C due to increase of maize input. This result suggests that the high lability of legume residues might be the main driver to C accumulation in organomineral association. This study confirmed our hypothesis that carbon accumulating in organomineral associations is dominated by microbial-derived carbohydrates, and that legume cover crops under NT further favour the dominance of microbial over plant-derived residues, and consequently the SOC accumulation.

(4572 - 1450) Liming increases carbon sequestration in tropical cropping systems

Murilo de Souza[1]; Danilo Silva Almeida[1]; Kassiano Felipe Rocha[1]; Gustavo Prestes Gomes[1]; Ciro Antonio Rosolem[1]
School of Agricultural Sciences, Sao Paulo State University[1]

Lime application for soil-acidity amelioration has been considered a

practice contributing to CO_2 emissions to the atmosphere, not only by C loss during its dissolution, but also due to a priming effect resulting from raising soil pH. On the other hand, improvements in soil fertility by liming increase grain yields and biomass production, and in the long term, can raise soil carbon. Our hypothesis is that C sequestration due to liming overcomes emissions to the atmosphere, and so liming is an environmentally sound practice. The objective of this work was to evaluate soil carbon accumulation due to applications of acid-neutralizing amendments to the soil. Two experiments were conducted from 2012 to 2016, one under no-till (NT) and other under conventional-tillage (CT), in Botucatu, SP, Brazil. The treatments consisted of lime (3.7 Mg ha^{-1}), silicate (6.7 Mg ha^{-1}), lime + gypsum (3.7 + 2.0 Mg ha^{-1}), silicate + gypsum (6.7 + 2.0 Mg ha^{-1}) and a control treatment with no amendment. In the CT system, the plots were disk-plowed every year from 2012 to 2015 in the summer, five days before soybean (*Glycine max*) planting. NT and CT experiments were carried out with soybean as summer crop, followed by Maize (*Zea mays*) intercropped with ruzigras (*Urochloa ruziziensis*) in 2013 and 2015, and pearl millet (*Pennisetum glaucum*) intercropped with ruzigrass in 2014. Soil pH amelioration and Al neutralization increased both root and shoot plant biomass, resulting in a greater soil organic matter content in the soil. Soil C down to 0.60 m was increased by 1.7 and 2.75 Mg $year^{-1}$ on average under CT and NT systems, respectively, compared with the control. The total grain yield from 2012 to 2015 was increased with both by lime and silicate application, by 2.6 Mg $year^{-1}$ under CT and 3.3 Mg $year^{-1}$ under NT, on average. There was no difference between lime and silicate as to soil C accumulation. Therefore, the priming effect of lime and the increased C emission are not significant under field conditions, because the correction of the exchangeable acidity results in improved soil fertility for root and plant growth and, thus, increased yields. Despite a peak of C emission right after liming, the results on the long term show that soil acidity amelioration promotes soil carbon sequestration by improving plant root growth, grain and biomass yields. The rate of C sequestration with liming or silicate application is higher in systems under no-till as compared with conventional tillage.

(1742 - 3001) Linking vegetation and litter-soil profile properties reveal pathways of soil carbon storage

Fernando Vieira Cesário[1]; Fabiano de Carvalho Balieiro[2]; Masha van der Sande[3]; Marcel Hoosbeek[3]; Lucas Mazzei[2]

Universidade federal do Rio de Janeiro[1]; Embrapa[2]; Wageningen University[3]

Tropical forests contain ~25% of the carbon in the terrestrial biosphere (Bonan 2008), which is divided into different pools, such as vegetation and litter-soil (Grace et al. 2014). Between these pools, the soil carbon stock represents a significant part (~ 2000 Gt) (Stockmann et al. 2013), and therefore even a small release may increase the atmospheric greenhouse gases (Lehmann and Kleber 2015). Hence, soil carbon in tropical forest plays an important role in regulating climate change (Malhi 2012, Crowther et al. 2016). However, much uncertainty still exists about which factors drive soil carbon stabilization in forest tropical ecosystems. To disentangle the direct and indirect effects of the vegetation and litter-soil profile attributes on soil carbon, here we used a structural equation model that links the vegetation (i.e., species diversity, functional traits, aboveground biomass) through the litter-soil profile (i.e., litter quality, enzyme activity, soil texture) to estimate soil carbon using 44 plots in a high diversity tropical Amazon forest. We expect that (i) functional traits will increase aboveground biomass (AGB) since a high abundance of species with high nitrogen leaf would increase photosynthetic rates; (ii) diversity enhances niche complementarity (Tilman 1999) increasing total AGB; (iii) AGB gain would increase root turnover enhancing belowground carbon; (iv) functional traits affect litter quality, a high nutrient in leaves may decrease litter quality because speed up decomposition; (v) litter quality can increase or decrease the decomposition process, a recalcitrant litter (i.e., high C:N) slow down litter decomposition increasing soil carbon; (vi) a recalcitrant litter may increase the microbial production of enzymes; (vii) enzyme activity could increase soil carbon through organic matter breakdown and mineralization; (viii) soil texture can increase both enzyme activity and carbon stock via stabilization and protection with the mineral phase. We find that high nutrient content in the leaves was associated with high C:N in a litter, which in turn increase soil carbon. Suggesting a microbial N preference in early decomposition stages and a litter quality control in later stages. Additionally, diversity increase AGB, which in turn enhance soil carbon. Indicating species richness control in forest growth that leads to accumulating carbon. This study has shown that we can better predict soil carbon connecting vegetation via litter-soil.

(1503 - 2966) Magnetism of the Archaeological Black Earth as an agricultural and environmental indicator

Ivanildo Amorim de Oliveira[1]; Ludmila de Freitas[1]; José Marques Júnior[2]; Milton César Costa Campos[3]; Diego Silva Siqueira[2]; Renato Eleotério de Aquino[2]; Daniel Teixeira de Bortoli[2]; Laércio Santos Silva[2]

Instituto Federal do Pará[1]; Universidade Estadual de São Paulo[2]; Universidade Federal do Amazonas[3]

The Amazon region presents a great diversity of soils, especially those with anthropic horizon known as Indian Black Earth (IBE) or Archaeological Black Earth (ABE), which are of great economic importance to the region and to the world. The aim of this work is to understand the spatial variability of environmental attributes (soil CO_2 emission), and agricultural (related to physics and fertility) attributes, using a methodology to understand the sustainability of soil with Indian Black Earth in the Amazon, using magnetic susceptibility as an agricultural and environmental indicator, relating these attributes to the mineralogical composition of this soil, located in the southern region of Amazonas, Brazil. The study was realized in Argissolo Vermelho (Ultisol) whit anthropic horizon or Archaeological Black Earth. In the área grids of 70 × 70 m were established, and the soil was sampled in regular spacing of 10 m in the depth of 0.0-0.20 m. Was determination of chemical properties (pH in water, organic matter, phosphorus, sum of bases (SB), cation exchange capacity, base saturation (V%), organic carbon (OC), stock of organic carbon (STOC)), iron forms (oxide free extracted with dithionite–citrate–bicarbonate (Fe_d) and low crystallinity oxide extracted by ammonium oxalate (Fe_o)) physical properties (texture, and bulk density, magnetic susceptibility and CO_2 flux of soil (FCO_2).To characterize the variability, descriptive and geostatistical statistics were performed through the use of scaled semivariograms to evaluate the spatial relationship between magnetic susceptibility and physical, chemical, iron and FCO_2 attributes. The SM can be used to understand the variability of some agricultural and environmental attributes in Indian Black Earth.The high values of SM can be associated with the presence of maghemite found in the soils and in the ceramic fragments present in the Indian Black Earth.Magnetic susceptibility presents a pattern of spatial variability similar to the CO_2 flux, with the same semivariogram adjustments, presenting a positive spatial correlation between FCO_2 and χfd and negative spatial correlation between FCO_2 and SMbf.

Sites with higher magnetic susceptibility (4.7 to 5.1 × 10^{-6} m^3 kg^{-1}) presented 1.2 times more CTC and emitted 1.4 times less CO_2 compared to areas with lower magnetic values (3.5 to 3.9 × 10^{-6} m^3 kg^{-1}).

Keywords: magnetic susceptibility, spatial variability, CO2 flux of soil.

(9182 - 790) Manure type affects manure degradation rate, soil biogeochemistry, and greenhouse gas emissions

Tien Weber[1]; Scott Chang[2]; Xiying Hao[3]; Karen Beauchemin[3]
University of Alberta & Agriculture and Agri-Food Canada[1]; University of Alberta[2]; Agriculture and Agri-Food Canada[3]

Reducing greenhouse gas (GHG) emissions from agriculture is an important way to mitigate climate change. Diet manipulation influences enteric fermentation and has the potential to reduce GHG emissions; however, few studies have examined the effect of diet composition on GHG emissions after manure is applied to the soil. We conducted a 70-day lab incubation experiment to investigate this knowledge gap and analyze how different manure types affect soil biogeochemical cycling and GHG emissions. Soil samples from three sites in Alberta, Canada were treated with manure from beef cattle fed corn or barley, and no manure was applied. The flux of nitrous oxide (N_2O), carbon dioxide (CO_2), and methane (CH_4) was measured. Nitrogen (N) mineralization to ammonium (NH_4^+) under 60% water filled pore space (WFPS) conditions and the nitrification and denitrification roles of N_2O under 80% WFPS conditions were tested using soil incubations. Ammonium (NH_4^+) and nitrate (NO_3^-), microbial biomass, carbon (C) to N ratio, and the activity of β -1,4-Glucosidase (N cycling) and β-1,4-N-acetyl-glucosaminidase (C cycling) were measured to better understand the relationships between soil biogeochemical cycling and GHG emissions. We hypothesize that manure from corn diets reduces GHG emissions correlated to lower levels of nitrification and denitrification due to lower levels of nitrogen excretion from the animal. The results of this study will be used to develop best manure management practices for current and future feeding practices in the beef industry.

(9584 - 2492) Multifunctional agroecosystems in the semi-arid environment to mitigate the impacts of climate change

Vanderlise Giongo[1]; Maria do Socorro Conceição de Freitas[2]; Monica da Silva Santana[3]; Alessandra Monteiro Salviano[1]; Tony Jarbas Ferreira Cunha[1]
Embrapa Semiárido[1]; IFSertão[2]; Universidade Federal do Ceará[3]

The governments of the world have been concerned about climate change and how they can ensure access to sufficient food, water and energy resources to safeguard human wellbeing. The Brazilian semi-arid, covering approximately 969.589 km^2, has 21 million people and 1.6 million of agricultural establishments of which 95% are classified as family farms. The typical agricultural systems are characterized by high grazing density, slash and burn practices and fruits and legumes irrigated monocultures. Consequently, soil degradation occurs due unsustainable soil management, decreasing soil carbon stock and the biodiversity. The aim of the work was to design sustainable multifunctional agroecosystems adapted to the soil and climatic conditions and that deal with climate change through carbon sequestration. The study was carried out in two long-term experiments with mango trees (*Mangifera indica* L.), implanted in 2008, and melon crop (*Cucumis melo* L.), implanted in 2012, in Ultisol, located in Pernambuco, Brazil, latitude 09 °09'S, longitude 40°22'W and altitude 365,5m. Experimental areas contemplate models of multifunctional agroecosystems that include two phytomass management systems as main plots (tillage and no-tillage) and three types of plant mixture (PM), as subplots, two of which are composed of 14 species of green manure in different proportions of grasses, oilseeds and legumes (PM1- 75% leguminous + 25% grass and oilseeds; PM2 - 25% legumes + 75% grasses and oilseeds) and one with spontaneous species (PM3), between the lines or in succession, in a randomized complete block design, with four replications. The phytomass production and changes in soil carbon stocks were evaluated over time. The green manures, regardless of the soil management system, promoted significantly higher production of phytomass (PM1= 7,87±0,44 Mg ha^{-1} and PM2= 7,63 ± 0,53 Mg ha^{-1}) than spontaneous vegetation (PM3= 4,00 ±0,34 Mg ha^{-1}). The cultivation of plant mixtures with no-tillage were the agroecosystems more efficient in increasing the soil carbon stocks (0,6 Mg ha^{-1} $year^{-1}$) than agroecosystems with spontaneous vegetation and or soil tillage (0,09 Mg $ha^{-1}year^{-1}$), in first layer (0-5 cm). Multifunctional agroecosystems designs that contemplate the use of green manures and no tillage are efficient in increasing the carbon stock in irrigated semiarid environments, composing a technological strategy to mitigate the impacts of climate change.

Keywords: Green manure, no tillage, dryland.

(2243 - 1234) Nitrogen stock in latosolo (oxisoil) under different forms of use in Cerrado

Adilson Alves Costa[1]; Bruno de Oliveira Dias[1]; Belchior Oliveira Trigueiro da Silva[1]; Erlane Souza de Jesus[2]; Liliane da Silva Soares[1]
Federal University of Paraíba[1]; State University of Bahia[2]

Soil represents an important component in the biogeochemical cycle of nitrogen and other elements. However, the activity of land use change in biomes, such as the Cerrado, has been highlighting the reduction of nitrogen stocks. The objective of this work was to evaluate the nitrogen stocks in Cerrado soils under different forms of land use. The study was carried out in commercial areas located in the municipality of Luís Eduardo Magalhães, West of Bahia, Brazil (12 ° 33'50 '' South and 46 ° 23'35 '' West, altitude 763 m) under Cerrado biome. The soil was classified as Latossolo Amarelo distrófico típico (Oxisoil), with medium texture. Soil samples were collected in the 0-5, 5-10, 10-15, 15-20, 20-30, 30-40 and 40-60 cm layers in three areas under different forms of soil use: area under vegetation native of Cerrado (ACN), no-till area with four years (APD) and area under Eucalyptus plantation with eight years (AEU). The total nitrogen contents and, consequently, the nitrogen stocks were calculated, whose correction of the mass was made by the equivalent mass of the soil. With the data, the analysis of variance was done and the means were submitted to a Tukey average test at 5% of probability. Regarding the total soil nitrogen results, it was observed that there was no difference between AEU and ACN up to the depth of 10 cm and that APD obtained the lowest values in all depths evaluated. The increase of the nitrogen in the first depths in the AEU was due to the time of implantation of the crop of eight years, occurring in this period greater biomass production, which increased the organic matter content of the soil and, consequently, greater nitrogen storage. There were changes in the stocks, where the AEU was similar to the soil under Cerrado at depth of up to 20 cm. The APD presented the lowest stocks in all depths, due to the fact that the implementation time of four years, insufficient to consolidate the system in Cerrado areas. Considering the 0-60 cm depth, it was observed that by replacing ACN (9.25 Mg N ha^{-1}) with AEU (7.49 Mg N ha^{-1}) there was a reduction of

19% in nitrogen and APD stocks (3.79 Mg N ha^{-1}) there was a 41% reduction. It can be concluded that the cultivation of eucalyptus increased in the nitrogen content, contributing with the increase in the nitrogen stocks over the years in the superficial depth.

(5436 - 773) Nitrous oxide emission from urine and dung patches in subtropical Brazil and its reduction by the nitrification inhibitor dicyandiamide

Priscila Luzia Simon[1]; Jeferson Dieckow[1]; Cecile A. M. de Klein[2]; Josileia Acordi Zanatta[3]; Tony van der Weerden[2]; Bruna Ramalho[1]; Cimélio Bayer[4]

Universidade Federal do Parana[1]; AgResearch Invermay Agricultural Centre[2]; Embrapa Florestas[3]; Universidade Federal do Rio Grande do Sul[4]

The Brazilian cattle herd exceeds 200 million heads and its excreta contribute with 41% of the national emission of nitrous oxide (N_2O). This study aimed at (i) determining the N_2O emission factor (EF) for cattle urine and dung in subtropical condition, and comparing it with the IPCC default EF of 2%; (ii) evaluating the efficiency of the nitrification inhibitor dicyandiamide (DCD) at reducing N_2O emission from urine and dung patches; and (iii) evaluating the efficiency of DCD at curbing emissions when sprayed over excreta patches. Field experiment was conducted in in a kikuyu grass (*Pennisetum clandestinum*) over a haplic Cambissol, in Pinhais-PR, Brazil. Urine and fresh dung of Frisian dairy cows, at volume equivalent to one urination and mass equivalent to one defecation, were deposited in circular microplots of 0.083 m^2. Excreta were combined with or without application of DCD; and when applied, DCD was dissolved into the excreta before its application or was sprayed on the excreta patch after its application. Treatments were applied four times during the year 2014, once per each season (in different spots). After excreta application, N_2O fluxes were monitored in 10 air sampling sessions over 63-68 days, by using closed static chambers. Urine and dung were important sources of N_2O, with an average EF of 0.34% for urine and 0.11% for dung; what urges the investigation and establishment of corresponding mitigation strategies for livestock production. Yet, those emission factors were not as high as the default EF of 2% that the IPCC recommend for national greenhouse gas inventories, what suggest that this default value should be revised for the subtropical region. And revised separately for urine and for dung, which emits less; so that each excreta type has its own emission factor. As a mitigation strategy in subtropical pastures, the use of DCD had a potential to curb N_2O emission from urine patches, particularly in the cooler seasons of autumn and winter, when it significantly reduced the emission by 60-82% after being dissolved in urine. However, improvements on the application method of DCD are still needed, once the most common application method of spraying DCD reduced N_2O emission only in autumn, and by 46%; hence less efficient than when dissolved in urine. With respect to dung, there is no clear evidence that N_2O emission from this excreta is mitigated by DCD, either dissolved into the dung mass or sprayed over the dung pat.

(5533 - 2451) Nitrous oxide emissions of production systems in lowlands of Rio Grande do Sul

Thaís Murias Jardim[1]; Walkyria Bueno Scivittaro[2]; Miguel David Fuentes Guevara[1]; Lillian Medeiros Barros[3]; Renata Abreu Rodrigues[3]; Rogério Oliveira de Sousa[1]

Universidade Federal de Pelotas, Campus Universitário, s/n, Capão do Leão, RS, 96160-000, Brazil (thais.murias@hotmail.com)[1]; Embrapa Clima Temperado, Caixa Postal 403, Pelotas, RS, Brasil, CEP 96010-971[2]; Instituto Federal Sul-Rio-Grandense, Praça 20 de setembro, 455, Pelotas, RS, Brasil, CEP 96015-360[3]

The lowlands of Rio Grande do Sul, Brazil, are mainly used for irrigated rice cultivation, being an important source of methane (CH_4) to the atmosphere, due to the establishment of anaerobic environment by flood irrigation of the soil. However, nitrous oxide (N_2O) emissions may also be relevant, especially for production systems involving crop rotations or grazing crop, that require the application of high amounts of nitrogen fertilizers. The objective of this work was to evaluate N_2O emissions in representative production systems of the Rio Grande do Sul lowlands and in a natural area. The study was conducted in a Planossolo (Typic Albaqualf) in Capão do Leão, State of Rio Grande do Sul, Brazil. N_2O emissions evaluations were performed from June 2015 to May 2016. Three production systems (irrigated rice/fallow, soybean/ryegrass/corn and improved pasture) and a natural area were evaluated. In each area, three greenhouse gas collectors systems (closed static chamber) were distributed, constituting the replications of the treatments. N_2O fluxes and N_2O total emissions were measured seasonally (fall/winter period - 2015 and spring/summer period 2015/2016 (summer season)) and throughout the year. During fall/winter period, N_2O emissions were generally low, except for improved pasture system, which presented several high emission peaks associated with the application of nitrogen fertilizer and the deposition of feces and urine of grazing animals. The natural area provided small N_2O absorption in both periods (fall/winter: -0.04 kg N_2O ha^{-1} and summer season: -0.29 kg N_2O ha^{-1}). During the summer season, N_2O emissions were higher than in fall/winter period for all production systems, decreasing from improved pasture (22.8 kg N_2O ha^{-1}) > soybean/ryegrass/corn (10.8 kg N_2O ha^{-1}) > irrigated rice/fallow (2.5 kg N_2O ha^{-1}). The sum of emissions from fall/winter period and summer season shows that the soybean/ryegrass/corn and improved pasture systems provide greater annual emission of N_2O than irrigated rice/fallow system and natural area. Thus, the irrigated rice/fallow system, contrary to CH_4, presents low N_2O emission potential. On the other hand, production systems involving rainfed and pasture crops increase the emission of N_2O.

(8333 - 391) Organic carbon stock in Haplic Cambisol under winter cover crops and corn in summer

Jorge Luiz Locatelli[1]; Eduardo Brancaleoni[1]; Felipe Bratti[1]; Luiz Gustavo do Prado[1]; Priscila Grella Moretti[1]; Ricardo Henrique Ribeiro[2]; Jonatas Thiago Piva[1]

Universidade Federal de Santa Catarina[1]; Universidade Federal do Paraná[2]

Soil organic carbon is an indication of the quality of management that is used in the system. Although it is a variable strongly influenced by environmental factors, agricultural practices are determinant for the establishment of a conservationist system. The objective was to evaluate the carbon stock in the 0-0,6 m layer, in the succession of corn (*Zea mays*) in the summer, with seven winter coverage crops, a consortium and fallow, under no-tillage in a temperate climate. The

experiment was implemented in 2013 at the experimental farm of the Universidade Federal de Santa Catarina, located in the city of Curitibanos-SC, in a Cfb-temperate climate, with an annual average rainfall of 1500 mm, and an average temperature of 15 °C. The soil is classified as a Haplic Cambisol of clayey texture, 550 g kg^{-1} of clay. In the summer the corn crop (*Zea mays*) was cultivated, and in winter the different cover crops, *Avena sativa*, *Avena strigosa*, *Lolium multiflorum*, *Brassica napus*, *Vicia craca*, *Raphanus sativus*, *Trifolium pratense*, the consortium between *Avena strigosa* and *Vicia craca* and a fallow, in plots 4 x 4 m. During the summer crops, no nitrogen (N) fertilization was used, only potassium and phosphate fertilization was applied. In winter, in addition to potassic and phosphate fertilization, the cover plants received 30 kg ha^{-1} of N in topdress. The soil samples were collected by the excavation method, 4 years after the implantation of the experiment, in the depths of 0-0,05, 0,05-0,10, 0,10-0,20, 0,20-0,30, 0,30-0,45 and 0,45-0,60 meters. The determination of the soil organic carbon content was carried out by the wet combustion method. Data were submitted to analysis of variance and the Scott-Knott test was applied to 5%. The carbon stock for the 0-0,60 layer did not show variation under different cropping systems, which may be justified by the short period of experiment conduction, since the carbon dynamics in soil is slow, and influenced by several environmental and anthropic factors, mainly in a temperate climate. Among the evaluated depths, the succession of *Zea mays* + *Vicia craca*, and *Zea mays* + *Avena strigosa* was superior to the other treatments in the layer of 0,45-0,60 meters, which may be related to the greater dry matter addition provided by these crops, and also by the root system growth in depth. The establishment of a high-quality cropping system acts positively, increasing soil quality and mitigating environmental effects.

(6054 - 920) Organo-mineral interaction is the main stabilization mechanism of C from animal manures in a subtropical sandy Acrisol under no-tillage

Lucas Antonio Telles Rodrigues[1]; Roque Junior Sartori Bellinaso[2]; Matheus Severo de Souza Kulmann[2]; Rodrigo Knevitz Hammerschmitt[2]; Isac Aires de Castro[2]; Rodrigo Otávio Schneider Souza[2]; Cimélio Bayer[1]; Carlos Alberto Ceretta[2]

Universidade Federal do Rio Grande do Sul[1]; Universidade Federal de Santa Maria[2]

Establishing the long-term effect of different types of manure (animal species, solid or liquid) on soil organic matter fractions (SOMF) has high agronomic and environmental importance. In addition, are scarce long-term field trials comparing the effect of different types of manure (in comparison to mineral fertilizer) on labile and stable fractions of soil organic matter (SOM), mainly in subtropical regions. This study aimed to evaluate the impact of successive applications of pig slurry (PS), cattle slurry (CS), pig litter (PL) and mineral fertilizer (MF) for 12 years on physical fractions of SOM (free and occluded light fractions and sand and silt+clay-size heavy fraction) within a 0-20 cm layer of a sandy Acrisol (~ 100 g kg^{-1}clay). The quantity of manures and MF were applied according to local recommendations to maize on summer, in succession to black oat or wild radish or Wheat on winter, cultivated under no-tillage system. Animal manures (PL and CS) provided higher increases in C in all SOMF compared to PS and MF up to 10 cm. We verified greatest accumulation of C in the silt+clay-size heavy fraction with application of PL (50.5%) in relation to control (19.62 Mg C ha^{-1}), followed by CS (25.6%), PS (15.0%) and MF (6.8%) (non-significant) in the 0-20 cm soil layer (sum of 0-4, 4-10 and 10-20 cm). It was possibly due to the high amount of C added and possibly to differences in its constitution. In the PL, further to C plants residues input there were C from the rice husk used as litter in pig breeding. In addition, the digestive system of cattle and swine and diet of both species is also distinct (cattle - rich in fiber vs. swine - rich in grains). On free and occluded light fractions, the high C accumulation were verified with PL (346 and 316%, respectively), and CS (154 and 47%, respectively) application in relation to control (0.329 Mg C ha $^{-1}$), while PS and MF did not or had little effect, which may be linked to an insufficient C input to offset a possible PS-induced priming effect on soil OC mineralization. Twelve years of PL and CS applications improve soil C accumulations in all soil SOMF up to 10 cm soil layer. On the other hand, PS an MF had little effect on the C pools, which was possibly related to their small content of C and or the PS-induced priming effect. Application of PL as fertilizer to plants by long time stood out because improve soil organic carbon occlusion in aggregates and its stabilization in organo-mineral complexes.

(1396 - 2778) Participatory technology demonstrations for enhancing climate resilience in varied agro-ecologies across India

A.K. Singh[1]; Y.G. Prasad[2]

ICAR[1]; ICAR-ATARI, Hyderabad[2]

Participatory technology demonstrations for climate resilience in agriculture are in progress since 2012 in diverse agro-ecological situations spread across 121 climatically vulnerable districts in India under the National Innovations in Climate Resilient Agriculture (NICRA) project implemented by Farm Science Centres, locally known as KrishiVigyanKendras (KVKs), of the Indian Council of Agricultural Research (ICAR). Transplanted paddy is largely cultivated in irrigated tracts of delta areas across the country. However, facing erratic rainfall onset and distribution and depleting groundwater resources, farmers in recent years, have shown more acceptance for direct seeded rice cultivation. Direct seeding with drum seeder in puddled conditions and line sowing in un-puddled conditions along with effective weed management was more widely adopted in demonstration areas. Direct seeding not only saved water, reduced cost of cultivation but also contributed to reduction in methane emissions. Soil test based nutrient application in rice crop reduced use of nitrogenous fertilizer. In rainfed agro-ecologies (<750 mm rainfall), *ex-situ* rainwater harvesting technologies and *in situ* soil moisture conservation practices such as bunding, conservation furrows, planting across slope, practice of mulching, manuring, choice of crops/ crop combinations and short duration varieties depending on onset of rainfall enhanced coping ability of farmers in the semi-arid tracts.In rainfed areas with higher rainfall (>1000 mm), promising resource conservation practices included planting of rainy season crops such as soybean and pulses adopting ridge-furrow/ raised bed systems in vertisols, zero till planting of post rainy season crops such as wheat, maize, oilseeds and pulses along with adoption of mulching techniques. Potential of a wide range of climate resilient practices and technologies was demonstrated and evidences generated across the country for sustainable use of natural resources. Efforts to integrate identified practices in the local adaptation plans for enhancing coping with climate variability are underway in a number of states across the country.

(5196 - 1966) Passive mineral carbonation as a potential atmospheric C sink: exploratory samples from Brazil.

Antonio Carlos de Azevedo[1]; David A. C. Manning[2]; Marcos Canto Machado[1]; Marcos Yassuo Kamogawa[1]

USP-ESALQ[1]; New Castle University[2]

Calcium (Ca) and magnesium (Mg) in solution may react with carbonate anions to precipitate Ca- and Mg-carbonates. This process relates to the CO_2 concentration in the atmosphere over geological timescales by producing pedogenic and marine carbonates. Establishing the conditions for this process to occur in natural or constructed soils will contribute as a carbon sink to atmospheric CO_2. Mineral carbonation in batch reactors is extensively studied, but there are few studies about passive carbonation in open systems such as mining stockpiles or construction debris. The objective of the EPSRC-funded SUCCESS Program was to evaluate the potential of carbon capture by mineral carbonation in terrestrial, particularly urban, environments. A combination of chemical and stable isotope analysis (C, O) has been used to identify recent, biogenic, carbonate products. This showed removal of up to 85 T CO_2 per hectare annually in a soil dominated by demolition materials at Science Central, Newcastle, UK. A set of three samples from construction debris recycling facilities in the Piracicaba region, Brazil, was submitted for preliminary analysis by this method. The results showed delta ^{18}O and delta ^{13}C ratios similar to the samples collected from Science Central site, indicating that the same process of capture of atmospheric CO_2 takes place in Brazil. These preliminary results encourage further investigation on the potential of passive mineral carbonation as a carbon sink in tropical conditions in Brazil and elsewhere, especially in urban soils.

(8593 - 2794) pH modulation of microbial communities driving the methane cycle in the Amazon Forest-to-Pasture conversion

Leandro Fonseca de Souza[1]; Dasiel Obregon Alvarez[1]; Fabio Vitorino Gomes[1]; Naissa Maria Silvestre Dias[1]; Paulo Sergio Pavinato[2]; Siu Mui Tsai[1]
CENA/USP[1]; ESALQ/USP[2]

The amazon rainforest soils are relevant global sinks to methane, but the forest-to-pasture conversions turn these soils in methane sources. The process that leads to this change are few understand, regarding the microorganisms and soil pH modulation. Addressing this, the structure of microbial communities and methane flux through different land uses and pH amendment were determined in mesocosm experiment. Soils from Ariquemes/RO (09°54'58"S 63°02'27"W - Apr/2017), of Primary Forest (FP), Degraded Pasture – established in 2004 (P04) and Conserved Pasture – established in 1972 (P72) were collected, sieved to 5mm and moisture standardized to 70% of pot water retention capacity. The pots were filled to a 10cm layer and the initial pH_{CaCl2} (FP – 4,0; P04 – 4,7; P72 - 4,6) of all soils were changed to $5,8_{CaCl2}$ (85 - V%). The gas fluxes were measured by 120 days in static chambers for 10 minutes using infrared gas analyzer (UPGGA, Los Gatos Research) and linear regression to determine fluxes. After 40 days of amendments, DNA was extracted (PowerSoil, QIAGEN) and molecular analysis performed: qPCR of genes to methane consumption (*pmoA*) and production (*mcrA*) and high throughput sequencing of 16S gene DNA of Bacteria and Archaea (Illumina Miseq). The gas fluxes and qPCR data were analysed with *t*-test ($\alpha < 0,05$), the analysis of differential composition in community with ANCOM (q-values < 0,05). All soils exhibited methane consumption at atmospheric conditions. The consume scale was FP> P72> P04 for both control and modified pH soils. The pH amendments reduced the methane oxidation in all soils, intensely in FP, but with small impact in pastures well managed than in the degraded pasture area. The pmoA/mcrA ratio reduced with pH amendments for all soils, intensely in FP. The methanotrophic bacteria identified in Forest soils belong to the *Beijerinckiaceae* family; methanogenic were not detected. In Pastures the *Methylocystaceae* family predominate (fewer in degraded pasture area), as well the methanogenic (decreasing order): *Methanocellales, Methanosarcinales and Methanobacteriales*. The composition of methane associated communities was not affected in terms of relative abundance with pH modulation, but the relative increase of *mcrA* copies indicate increase of producers. We conclude that the microbial methane consumers in the Amazonian soils are diverse, occupying contrasting environments (soil usage and pHs), but the efficiency of soils in consume methane is distinct.

(8738 - 1852) Plant diversity affects GHG fluxes in an ecological engineering experiment in a disturbed *Sphagnum* peatland (La Guette, France)

Sébastien Gogo[1]; Christophe Guimbaud[1]; Fabien Leroy[1]; Benoit D'Angelo[1]; Léonard Bernard-Jannin[2]; Fatima Laggoun-Défarge[3]
Université d'Orléans[1]; Univesité D'Orléans[2]; CNRS[3]

Many *Sphagnum* peatlands are experiencing vegetation change caused mainly by hydrological disturbances. In this, greenhouse gases (GHG) fluxes are affected by peat oxygenation, changes in litter composition (and thus decomposition) and rhizospheric processes. This could lead a C sink system to switch to a source. To restore peatland functioning, ecological engineering works can be undertaken. Our study site, La Guette peatland (central France) is invaded by *Molinia caerulea* because a drain at the output decreased the water table depth. It was shown that it functioned as a source of C. In 2014, hydrological works were undertaken: 8 dams were installed, ditches were dug perpendicular to the water flow and back-filled with a mixture of shales and bentonite. In addition, a biodiversity experiment with 2 identical experimental stations was implemented: “downstream”, close to the hydraulic works (relatively wet), “upstream”, (relatively dry), with types of 3 vegetation plot (2m x 2m, n=4): 1) “control”: intact vegetation (Molinia caerulea, Erica tetralix), 2) “bare” peat: vegetation and 5cm of peat were removed, 3) “Sphagnum”: bare peat+*Sphagnum*. Our study aims to assess the effect of the vegetation treatment on the GHG fluxes. CO_2 (ecosystem respiration or ER, Gross Primary Production or GPP, and Net Ecosystem Exchange) and CH_4 fluxes (manual accumulation chamber), air and soil temperature, water table level, soil moisture were measured. After 18 months, half of the surface of “bare” and “Sphagnum” plots were covered by vegetation (*Eriophorum angustifolium*, *Rynchospora alba*, *Trichophorum cespitosum*). With time, as succession unfolds in these 2 types of station, ER and GPP increased. The sensitivity of ER to temperature increased sharply in “bare” and “Sphagnum” plots with years and became higher than the sensitivity in “control” plots. GPP increased with the total vegetation percentage cover, especially in “bare” peat plots. NEE were still lower in the “bare” and “sphagnum” peat plots than in “control”. However, the difference tends to decrease. In November 2015, the “sphagnum” peat plots were still functioning as a sink of C, whereas the other plots functioned as a source. As a conclusion, the “bare” and “sphagnum” treatments, after 3 years, were not able to store C as much as the control during the daytime measurements undertaken. C budget for each treatment still have to be calculated to determine the sink or source functioning of the different treatment.

(6687 - 1728) Shoot:root ratio and belowground carbon inputs of oats (*Avena sativa* L.) in a southern Brazil Inceptisol under grazing intensities.

Ricardo Henrique Ribeiro[1]; Bruna Ramalho[1]; Priscila Luzia Simon[1]; Caroline Amadori[1]; Guilherme Romani de Mello[2]; Felipe Bratti[2]; Jorge Luiz Locatelli[2]; Elisandra Cristina Ribeiro[2]; Jeferson Dieckow[1]; Jonatas Thiago Piva[2]

The carbon dioxide (CO_2) fixed into the plants by photosynthesis is the primary carbon (C) source the soil receives carbon (C). In the case of pastures, as the shoot biomass is removed by animal grazing, roots are the main component of C input. The grazing intensity is one of the major management practices influencing rooting patterns and thus C inputs to soil. The objective of this work was to evaluate black oats shoot and root biomass production and belowground C inputs to soil under grazing intensities in a tree-year experiment in a subtropical Inceptisol, Curitibanos, Santa Catarina, Brazil. The experimental design was randomized block with three treatments and four replicates. The treatments were high and moderate grazing intensities that corresponded to the residual plant height after grazing cycles (0.7 and 0.15 m respectively) at a black oat (*Avena sativa* L.) pasture, besides the treatment without grazing. The treatments were fertilized with 150 kg N ha^{-1} before beginning the grazing. Shoot biomass was determinated at each grazing cycle. Soil samples were taken at 0.0-0.3 m depth, at oats flowering, after two grazing cycles. The samples were washed, roots manually removed from the soil and dried at 45 ^{o}C to determine dry biomass and C content by dry combustion method. Belowground C input was calculated with the total C in root plus rhizodeposits (considering 0.65 of total C-root). No grazing resulted in the greatest shoot:root ratio (3.9), shoot biomass (5.6 Mg ha^{-1}), and C-root content (31.9 %), while the other treatments did not differ among them, with average values of 2.6, 3.7 and 31.3, respectively. This can be related to the constant renewal in shoot, caused by grazing, stimulating root carbohydrates translocation to shoot meristems and leading to lower C-root content. Also, grazing could increase root growth rate, resulting in less aromatized C compounds, thus lower C content in root tissues. There were no significant differences among other variables. The average belowground C input was 1.2 Mg C ha^{-1} and root dry mass was 1.5 Mg C ha^{-1}. No grazing resulted in the greatest shoot production, but did not affect belowground C input. Regardless of grazing intensity, shoot and root production and belowground C input were similar, resulting in the best pasture management of the soil, with the benefit of beef production and additional income.

Keywords: Root biomass; soil organic carbon; annual pasture.

(1589 - 1000) Short-term effects of deep ploughing on soil C stocks following renewal of a dairy pasture in New Zealand

Roberto Calvelo Pereira[1]; Michael J. Hedley[1]; James Hanly[1]; Mike Bretherton[1]; Dave Horne[1]; Peter Bishop[1]; Jorn Dijkstra[2]; Mike Beare[3]; Sam McNally[3]

Massey University[1]; Massey Univeristy[2]; Plant & Food Research[3]

In New Zealand's high producing permanent pastures the topsoil constitutes a large reservoir of soil organic carbon (SOC), which shows a marked stratification with depth. As consequence, sub-surface layers can contain 10 times less carbon than the surface soil. In permanent pastures with high carbon inputs, the formation and decomposition of these surface SOC stocks are often at equilibrium and C storage shows little change over time. Pastoral based dairy systems utilising ryegrass plus clover cultivars require renewal every 7-10 years to avoid reversion to less productive grasses. This may involve spring cultivation (either no-till, shallow till or full cultivation), summer forage cropping and autumn re-grassing. It has been hypothesised that SOC stocks can be increased by inverting the soil profile at pasture renewal through infrequent (once in 25-30 years) deep mouldboard ploughing (up to 30 cm depth). Increased C sequestration occurs when the new grass quickly rebuilds SOC stocks in the new topsoil (exposed low C sub-soil) at a rate faster than the decomposition of SOC in the rich former topsoil transferred to depth (now below 15 cm). However, benefits form accelerated C storage may be offset if crop and pasture production is adversely affected by the ploughing event (e.g., as result of compaction or excessive drainage). Hence, the aim of this work was to assess the short-term effects of infrequent inversion tillage of long-term New Zealand pastoral-based dairy soils under summer crop management and autumn re-grassing. An imperfectly drained Typic Fragiaqualf under dairy grazing was deep ploughed (approx. 25 cm) and re-sown with turnip in October 2016; other treatments included were shallow (< 10 cm) cultivation and no-till. The site was core sampled (0-40 cm) before cultivation and after 5 months of turnip growth to assess changes in SOC. Plant growth, herbage quality, and nutrient leaching were monitored during the 5-month period; root growth was assessed at the end of the crop rotation. Full cultivation transferred SOC below 10 cm depth, as expected. Soil bulk density decreased whereas root mass increased (10-20 cm depth; $P < 0.05$) under deep cultivation only. Besides, losses of mineral N were attenuated under deep tillage, resulting in a relative increase in crop yield. The potential for infrequent inversion tillage increasing soil C sequestration as a greenhouse gas (GHG) mitigation tool is currently being tested at other sites in New Zealand.

(3362 - 667) Soil Carbon and Nitrogen content in areas of agricultural expansion in southern Brazil

Felipe Bonini da Luz[1]; Lucas Aquino Alves[2]; Cícero Ortigara[2]; Carlos Augusto Bonini Pires[3]; Julio Cezar Franchini[4]; Henrique Debiasi[4]; Vanderlei Rodrigues da Silva[1]

Federal University of Santa Maria, 98400-000 Frederico Westphalen, RS, Brazil[1]; Federal University of Rio Grande do Sul, 91540-000 Porto Alegre, RS, Brazil[2]; Federal University of Santa Maria, 97105-900 Santa Maria, RS, Brazil[3]; Embrapa Soybean, P.O. Box 231, 86001-970 Londrina, PR, Brazil[4]

In Brazil, in recent years, areas of light soils (sandy) have been incorporated into the productive process of grains, cultivated pastures and bioenergy. However, there is a lack of information about the expansion of agriculture to sandy soils, as well as the implementation of production systems that aim at improving soil quality. The objective of this work was to evaluate the content of soil carbon (C) and nitrogen (N) in sandy soils of the southern region of Brazil due to different land uses. Soil samples were collected in a Entisols (Quartzipsamments) with 10% of clay in Santo Inácio-PR, in three layers to the depth of 0.30 m in the land uses under native vegetation, pasture managed at 17 years, sugarcane with 12 years and integrated crop-livestock system (ICLS) managed at 13 years. The results show that in the 0.0-0.10 m layer, the land uses with pasture managed and ICLS presented contents of C (6.72 g kg^{-1} and 5.67 g kg^{-1} respectively) and N (0.91 g Kg^{-1} and 0.72 g Kg^{-1} respectively) similar to native vegetation (5.72 g Kg^{-1} of C and 0.89 g Kg^{-1} of N) and higher contents of C and N that the soil cultivated with sugarcane (2.42 g Kg^{-1} of C and

0.30 g Kg^{-1} of N). The uses of land with pasture managed and ICLS correspond to some of the actions described in the Brazilian plan for low carbon agriculture (ABC Plan) and based on the results of this work, these uses have total conditions to maintain and/or raise the quality of the tropical soils, even sandy ones, through the accumulation of C and N in the soil. In addition, the results of this study suggest that the expansion of sugarcane areas in the center-south region of Brazil should be avoided in sandy soils, because due to their fragility, and a subsoiling at each planting/renewal of sugarcane plantations, it demonstrates potential to reduce C and N content, compromising soil quality.

(7328 - 208) Soil carbon dynamics from a degraded pastureland to an agrisilviculture system in the Cerrado

Thais Rodrigues Coser[1]; Cícero Célio de Figueiredo[1]; Boban Jovanovic[1]; Túlio Nascimento Moreira[1]; Thamires Dutra Pinheiro[1]; Sara Kananda da Silva Rocha[1]; Letícia Pereira da Silva[1]; Mateus Oliveira Gomes[1]
Universidade de Brasília[1]

To decrease deforestation and land degradation in agricultural-environmental-hotspots, ecological intensification of agriculture has been proposed and stimulated by various countries. Among Brazil`s measures to reduce deforestation, improve ecosystems services and stimulate a low-carbon (C) economy, there is an incentive to restore 15 million hectares of degraded pastures and to increase five million hectares of agroforestry and/or integrated cropland-livestock-forestry systems by 2030. Agrisilviculture systems may potentially increase soil organic matter (SOM) and its quality due to its diversified and large C inputs. However, few studies have investigated SOM labile and stable carbon fractions within cropping seasons in agriculture and pastoral systems. Therefore, this study aimed to evaluate the transition of a degraded pasture to an agrisilviculture system of corn + *Gliricidia sepium* + *Panicum maximum* cv. Massai along a four-year field experiment under a clayey Oxisol in the Brazilian Cerrado on SOM fractions. Soil samples were collected in four cropping seasons: T0 - under degraded pasture, T1, T2, T3 – 2^{nd}, 3^{rd} and 4^{th} years after implementing the integrated production system, respectively. C from the particulate SOM increased by 476%, 305% and 368% at 0.00 – 0.10, 0.10 – 0.20 and 0.20 – 0.40 m layers, respectively, and was found to be the most sensitive indicator for changes in soil management systems. The microbial biomass C ranged from 265 mg kg^{-1} at the 0.00 – 0.10 m layer to 113 mg kg^{-1} at the 0.20 – 0.40 m layer and showed no difference between the evaluated seasons, except at the 0.10 – 0.20 layer where T0 was found to be 45%, 46% and 59% lower than T1, T2 and T3, respectively. Both mineral associated and total soil organic C increased from T0 to T3. Surprisingly, inert C increased up to 0.20 m layer from T0 to all the other seasons and represented 21 to 42% of total soil organic C. The agrisilviculture system with the use of corn, *Panicum maximum* cv. Massai and *Gliricidia sepium* increased soil organic C and SOM quality in a short-term period, thus showing its potential to be used as an ecological intensified agricultural practice.

(8168 - 212) Soil carbon stock predictive models on archaeological black lands - natural and transformed

Renato López Noronha[1]; Marcelo Dayron Rodrigues Soares[1]; Ingrid Nehmi de Oliveira[1]; Camila Viana Vieira Farhate[2]; Zigomar Menezes de Souza[1]; Stanley Robson de Medeiros Oliveira[3]
State University of Campinas (UNICAMP)[1]; State University of State University of Campinas (UNICAMP)[2]; Brazilian Agricultural Research Corporation (EMBRAPA)[3]

In the Amazon region, types of soil known as Archaeological Black Lands (ABL) present anthropic horizon A and are associated with prolonged human occupation by indigenous societies from the pre-Columbian period, where chemical and physical attributes have better quality than other types of soil in the Amazon, setting a large organic carbon reservoir. However, the conversion of these natural ecosystems into cultivated environments make emerge changes in soil carbon dynamics, often leading to a decline in soil organic carbon content. Therefore, our aim was to use data mining techniques to generate predictive models for the effect of soil use on carbon stock in natural and transformed areas of Archaeological Black Lands. We carried out our experiment in Manicoré and Apuí, Amazonas State, Brazil. After field data collection and laboratory analysis, we obtained a set of data consisting of 21 attributes, 20 predictive attributes consisting of 13 soil physical attributes, 6 soil chemical attributes, 1 soil use related attribute, and 1 response variable, referring to soil carbon stock (SCS), which is the classification target. Due to the large number of attributes, we performed a selection procedure to eliminate attributes of low correlation to the response variable. For data classification, we used the binary induction technique of the decision tree through software Weka 3.8. The results obtained showed that for the depth of 0.00-0.05 and 0.05-0.10 m, the best selected subset was determined using the Wrapper method for attribute selection. In the depth of 0.00-0.05 m, we generated a model of 79% accuracy containing only six rules, including, as the most important classification attribute was soil use. For the depth of 0.05-0.10 m, we generated an eight-rule decision tree of 74% accuracy including sand as the most important attribute. In this context, we highlight the Wrapper method efficiency to select subsets of predictive attributes, capable to generate more understandable decision trees, using a smaller number of attributes in the classification process, making it faster and with a lower computational cost. In addition, data mining techniques were efficient at providing predictive models capable to assist the decision-making process on possible management practices with the potential to conserve or increase soil carbon stock in archeological black lands.

(9594 - 1157) Soil carbon, nitrogen and phosphorus stocks of forest islands of west Africa

Caleb Melenya[1]; Vincent Logah[1]; C. A. Queseda[2]; J. O. Azeez[3]; H. Compaore[4]; E. N. Tetteh[5]; K. Ouattara[6]; S. A. Mesele[3]; A. B. Bougma[7]; J. Lloyd[8]
Department of Crop & Soil Sciences, Kwame Nkrumah University of Science and Technology, Ghana[1]; Istituto Nacional de Pesquisas da Amazonia, Manaus, Brazil[2]; Department of Soil Science and Land Management, Federal University of Agriculture, Nigeria[3]; Institut de l`Environnement et de Recherches Agricoles, Kaboinse, Burkina Faso[4]; Crops Research Institute, Council for Scientific and Industrial Research, Fumesua, Ghana[5]; K. OUATTARA[6]; Université Polytechnique de Bobo-Dioulasso, Burkina Faso[7]; Department of Life Sciences, Imperial College, London[8]

The biogeochemical mechanisms underlying the 'forest island' phenomenon in open savanna landscapes of West Africa remain under investigated despite the potential of utilising such information in community carbon offset programs in the era of climate change. In

this study, we report soil carbon, nitrogen and phosphorus stocks of eleven forest islands across a range of landscapes in three West African countries comparing them with adjacent farmlands. Soils were sampled in each forest island using stratified random sampling technique at half canopy radius from tree trunks (T) and at half the maximum distance between two adjacent trees (G). Soil carbon stock of the forest islands ranged from 9.9 to 45.5 Mg ha^{-1} at 0-5 cm depth and from 17.6 to 273.6 Mg ha^{-1} at 0-30 cm depth across all sites in all three countries. The corresponding soil N stock of the forest islands were in the ranges of 0.8 to 3.3 Mg ha^{-1} and 1.3 to 19.8 Mg ha^{-1}. The soil C and N stocks of adjacent farmlands were markedly lower ranging from 2.5 to 8.6 Mg C ha^{-1} and 0.2 to 0.8 Mg N ha^{-1} across all sites at the 0-5 cm depth. Values ranging from 11.9 to 56.6 Mg C ha^{-1} and 1.0 to 5.0 Mg N ha^{-1} were observed at the 0-30 cm depth. Results showed higher distributions of C and N at T than at G positions. Soil total phosphorus stocks of the forest islands were also greater than that of the adjacent farmlands. With our observed forest island C and N concentrations being much higher than what is considered typical characteristic of West African soils, this study suggests that there is a considerable potential for forest islands to serve as significant carbon sinks aiding climate change mitigation in Africa.

(1057 - 3232) Soil CH_4 and N_2O fluxes in an improved-fallow slash-and-mulch agroforestry system for one year in secondary forest and one year of crop cultivation in eastern Amazonia of Brazil

Aaron Joslin[1]; Daniel Markewitz[1]; Lawrence Morris[1]; Francisco de Assis Oliveira[2]; Steel Vasconcelos[3]; Oswaldo Kato[3]

University of Georgia[1]; Universidade Federal Rural da Amazônia[2]; Embrapa Amazônia Oriental[3]

Agricultural practices and associated activities account for approximately 25% of global GHG emissions. Slash-and-burn preparation methods are common among tropical, smallholding farmers, contributing to CO_2, CH_4, and NO_x gases to the global emissions budget via burning. Slash-and-mulch technology has been developed to replace burning during site preparation, reducing total GHG emissions compared to slash-and-burn practices. Improved-fallow practices incorporate N-fixing plants into the crop-fallow cycle in an effort to increase N stocks and biomass in the agricultural system without the use of mineral fertilizers. Increased system C and N content may also cause increased CH_4 and N_2O fluxes from the soil, negating GHG sequestration via soil and biomass C storage. We investigated the CH_4 and N_2O fluxes of an improved-fallow, slash and mulch agroforestry system in eastern Amazonia of Brazil for one year prior to, and one year following, conversion of secondary forest to cropped field. Fertilization with P+K fertilizer was the main-plot treatment and the inclusion of an N-fixing tree (*I.* edulis) in the improved-fallow planting mix was the sub-plot treatment in the split-plot design. Samples were taken along a transect, at distances of 0.25, 0.5, 1.0 and 2.0 m from the base of each of 2 trees in each plot. No significant increases in CH_4 or N_2O fluxes during the year pre-conversion in either the main or sub-plot treatments were found, yet there was a significant increase in the flux of N_2O in the N-fixer sub-plot treatment during the year post-conversion. Rates of N_2O flux were significantly different, and greatest, only at 1.0 m from the base of the tree. There was a trend of increasing N_2O and CH_4 fluxes with P+K fertilizer.

(8302 - 2443) Soil CO_2 emission and correlations with soil properties in under no-tillage with different crops rotations

Gustavo André de Araújo Santos[1]; Mara Regina Moitinho[1]; Bruna Oliveira Silva[1]; Luiz Fernando Favacho Morais[1]; Katharine Viana Batista[1]; Daniel De Botoli Teixeira[2]; José Eduardo Corá[1]; Newton La Scala Júnior[1]

Universidade Estadual Paulista[1]; Universidade de Marília - UNIMAR[2]

Agriculture is one of the human activities that contribute most to the emission of greenhouse gases, among them CO_2. Understanding the dynamics of this gas in the soil still very complex, since several factors influence this process. The objective of this study was to relate the soil CO_2 emission (FCO_2) with the soil physical attributes in under no-tillage with different crops rotations in tropical soil. The study was conducted in an area under no-tillage system in the municipality of Jaboticabal-SP, Brazil. The treatments were combinations of three sequences of summer crops and two winter crops, assuming as summer crops: maize monoculture (MM), soybean monoculture (SS) and soybean with corn rotation. The winter crops were: sunhemp and corn. The experimental design was in blocks with three repetitions. Between July and August 2016 FCO_2, soil temperature and moisture were conducted with 16 evaluations. FCO_2 evaluated with a portable system from the company LI-COR (LI-8100). Soil temperature was evaluated using an automatic thermometer and soil moisture using a TDR-Campbel® (0-20cm). The soil undisturbed samples was collected in depth 0.2m for soil porosity analysis. No interaction ($p>0.05$) was observed on the summer crops with the winter crops on the attributes of the soil, for this reason the winter crops were compared isolated from the summer crops. FCO_2 showed no difference between the summer sequences ($p>0.05$). However, for winter crops, soil under sunhemp residues showed higher FCO_2 (1.03µmol $m^{-2}s^{-1}$) when compared to corn crop (0.94µmol $m^{-2}s^{-1}$). Soil temperature explained the FCO_2 in all treatments, (MM) ($R^2_{aj.}$=0.40; $p<0.0001$), (SM) ($R^2_{aj.}$=0.28; $p=0.003$) e SS ($R^2_{aj.}$=0.38; $p<0.0001$) corn ($R^2_{aj.}$=0.39; $p<0.0001$) and sunhemp ($R^2_{aj.}$ =0.31; $p<0.0001$). In the soil under residue (MM) the FCO_2 was explained only for soil microporosity ($R^2_{aj.}$=0.26; $p=0.004$). In (SM) FCO_2 correlated with macroporosity ($R^2_{aj.}$ = 0.33; $p = 0.001$) and soil microporosity ($R^2_{aj.}$=0.21; $p=0.03$). For (SS) was with microporosity ($R^2_{aj.}$=0.51; $p=0.0001$) and soil total porosity ($R^2_{aj.}$=0.25; $p=0.004$). For winter crops, for sunhemp that FCO_2 was explained with macroporosity ($R^2_{aj.}$=0.27; $p=0.001$) while corn with microporosity ($R^2_{aj.}$=0.20;$p=0.02$). Therefore, in tropical soils under no-tillage, FCO_2 can be explained by soil temperature, macroporosity, microporosity and total soil porosity.

Understand how soil CO_2 emissions (FCO2) varies in space is an important task since few works have studied the spatial variability of carbon loss in Brazilian Cerrado soils. The objective of this work was to evaluate the spatial dependence of FCO2 and its relation with soil carbon stock (EstC) and humification index of soil organic matter (H_{LIF}), in areas of Cerrado with 30 years of conversion from conventional tillage (annual crops, maize and soybean) to silvopastoral system (aroeira and *brachiaria* - SI) and Eucalyptus plantation (EU). The experiment was conducted in the Fazenda de Ensino e Pesquisa area of the Faculty of Engineering of Ilha Solteira (UNESP), located in the municipality of Selvíria (Mato Grosso do Sul State). FCO2 measurement using the LI-COR system (LI-8100). The experiment was conducted during two periods: rainy period from February to March and dry period in June of 2017. Soil samples were collected in the 0.0-0.10 m depth layer to calculate the carbon stock (EstC) and to determine the H_{LIFS} by the laser-induced LIFS technique fluorescence. The spatial dependence of the variables were analyzed by geostatistical techniques from the fit of theoretical mathematical models to the experimental variograms and the interpolation of spatial patterns by the ordinary kriging. During rainy period, we observed a significant difference ($P<0.05$) in FCO2 when SI (4.47 µmol m^{-2} s^{-1}) was compared to EU (5.84 µmol m^{-2} s^{-1}). In dry period the same results were observed, SI showed the emission of 2.96 µmol m^{-2} s^{-1}, significantly inferior ($P<0.05$) when compared to EU, 3.86 µmol m^{-2} s^{-1}. EU presented the higher value of EstC (21.75 Mg ha^{-1}) when compared to SI (20.26 Mg ha^{-1}), however, EU presents higher H_{LIF} value, indicating more recalcitrant material on soil organic matter. The variographic analysis indicated that the range of spatial dependence of FCO2 for SI ranged from 9.7 m to 86.9 m (dry period) while in the EU the range values ranged from 15.3 m (dry) to 100.8 m (rainy). The FCO2 and EstC presents positively and significantly ($P<0.05$) spatial correlation in both areas only in the dry season, 0.23 and 0.33 to SI and EU, respectively. On the other hand FCO2 presented a negative and significant spatial correlation ($P<0.05$) with H_{LIF} for the rainy season in SI (-0.22) and for the dry period with EU (-0.31).

Keywords: geostatistics, soil respiration, humification index, ordinary kriging.

(3467 - 1467) Soil fluxes of nitrous oxide and methane in Pampa grassland afforested with *Eucalyptus* spp.

Frederico Costa Beber Vieira[1]; Josiléia Acordi Zanatta[2]; Cimélio Bayer[3]; Daniel Alexandre Iochims[1]; Cristiano Carvalho da Silva[1]
Federal University of Pampa[1]; EMBRAPA Forestry[2]; Federal University of Rio Grande do Sul State[3]

Plantation of eucalyptus trees can contribute to mitigate global warming potential (GWP) through carbon sequestration in plant biomass, but few is known regarding the effect of the conversion on soil nitrous oxide (N_2O) and methane (CH_4) fluxes. This study aimed to investigate the effect of the conversion of a representative grassland in the Brazilian Pampa biome to *Eucalyptus* spp. forest on soil N_2O and CH_4 fluxes. Field experiment was located at São Gabriel, Brazil, on an Acrisol soil, in a completely randomized design, three replicates and four adjacent treatments: eucalyptus forest with one (E1) and six (E6) years of plantation in the beginning of the study, native grassland with cattle breeding (NG+C) and native grassland isolated from breeding since one year before the beginning of the study (NG-C). Gas sampling (by static chamber method), analysis (by chromatography) and soil and climate monitoring was performed biweekly for 39 months. Emission of N_2O from the E6 soil was similar to those from the grassland soils (NG+C and NG-C), usually below 40 µg N_20 m^{-2} h^{-1}. However, top dressing fertilizations with urea in E1 increased significantly N_2O emission, peaking at 286 µg N_20 m^{-2} h^{-1}. Effluxes from E1 soil remained larger during all the first year of evaluation, with average of 103 µg N_20 m^{-2} h^{-1}, coinciding with bigger contents of NO_3 and NH_4 in the soil. After that, flux rates were similar to those from the other treatments. The accumulated emission of N_2O in 39 months from the E1 soil was 8045 g N_2O-N ha^{-1}, while E6, NG+C and NG-C had 753, 423 and 2633 g N_2O-N ha^{-1}, respectively. For CH_4, in turn, the presence of eucalyptus tended to promote influx of this gas, while native grassland tended to promote efflux. Such result is probably due to the smaller humidity in the soil with eucalyptus. Average values of water-filled porous space were 80 and 83% for NG+C and NG-C, respectively, while it decreased to 54 and 35% for E1 and E6, respectively. Accumulated CH_4 fluxes in 39 months were -3470, -3540, +1846 and +5178 g CH_4-C ha^{-1} for E6, E1, NG-C and NG+C, respectively. When N_2O and CH_4 are transformed to equivalent-carbon, it can be inferred that their contribution to the GWP is much smaller than that from the C sequestration in the biomass of the trees. Afforestation of grassland soil in the Pampa can contribute to mitigate GWP, but special care is required in the first two years of plantation in order to diminish N_2O emission from N fertilization.

Keywords: Greenhouse gases; forest; accumulated emission.

(1165 - 798) Soil organic carbon dynamics in traditional rubber tree agroforestry systems in southern colombian Amazon

Adriana Silva Olaya[1]; Fausto Andres Ortiz Morea[1]; Juan Pablo Chavarro[1]; María Paula Llanos Cabrera[1]; Vanessa Tique Mendoza[1]
University of the Amazon[1]

Agroforestry systems have been pointed out as a potential strategy for global warming mitigation due to its contribution on reducing soil degradation and improving SOM stocks. Here, we assessed soil C dynamic in three typical agroforestry systems (AFS) in southern Colombian Amazon region established in 1999, using a native vegetation (NV) area as reference. Our results indicated not significant differences at soil C stocks between NV and AFS, however when considering the time span since establishment AFS, annual C losses in the average of 0.75 Mg ha^{-1} where detected when conversion from NV to this typical AFS is performed. Soil C microbial biomass and basal respiration were also affected by that land use transition, with lower microbial C at AFS than NV and similar respiration rates between the study areas. Carbon content at particulate organic matter fraction also diminished significatively from NV to AFS. Converting tropical forests into rubber tree agroforestry system could cause important C losses in those soils. Alterations at the quality of litter, soil C inputs rates and

in the activity of the soil microbial component could be some of the causes of this response, since our results showed a low efficiency of microorganisms to utilize the available substrates.

(8660 - 1558) Soil potential to methane uptake in native and planted forests

Josiléia Acordi Zanatta[1]; Marcos Fernando Glück Rachwal[1]; Rosana Clara Victoria Higa[1]
Embrapa Florestas, Estrada da Ribeira, km 111, Colombo – PR, 83411-000, Brasil[1]

Naturally, soils have capacity to uptake methane (CH_4) from atmosphere and so contribute to reduce greenhouse gas emission and mitigate global warning potential. However, the conversion of native forest to agriculture or plantation forest can effect this sink due promotion of changes in nitrogen dynamics, stocks of carbons pools and others soil properties that resonate in the activity of methanogenic and methanotrophic microorganisms, responsible for the production and consumption of CH_4 in the soil, respectively. The objective this study was assessed the potential of soil methane oxidation on mixed ombrophilous forest and loblolly pine plantation (*Pinus taeda*). The survey was realized in Rio Negrinho – SC (South of Brazil), where pine has a favorable climatic condition to expressed high productivity. For two year (2014 and 2015) the soil methane uptake was performed in several conditions using static chamber procedures and analyses by chromatography. Native forest was monitored in four environments that represent medium and initial preservation stage of forest. Pine plantation was investigated in the conversion from forest with 3, 9 and 13 years in second rotation and from pasture with 1, 3 and 9 years in first rotation. The environments were located on a Cambisol with 50% clay in three replicates. In both native and pine forests CH_4 fluxes were negative, indicating that CH_4 sink was kept. However, in native environments the fluxes was three times more elevated (-60 to -120 µg C m^{-2} h^{-1}) than in pine plantation (-20 a -60 µg C m^{-2} h^{-1}). Among native environments the highest uptake of CH_4 were observed in more preserved forest (-9.9 kg C ha^{-1} $year^{-1}$) indicating that the partial withdrawal of native vegetation has a suppressive effect (30%) on soil sink capacity as much as pasture use (-0.17 kg C ha^{-1} $year^{-1}$). With regard to previous use of the soil there was minor oxidation of CH_4 in environment with pine that was converted from pasture (pine 1 year: -0.58 kg C ha^{-1} $year^{-1}$), coinciding with bigger contents of NO_3 and NH_4 in the soil. The increase in the age of reforestation, independent of previus use, indicated a tendency to increase in the rates uptake of CH_4 by soils (3 years: -2.02 kg C ha^{-1} $year^{-1}$; 9 years: -3.04 kg C ha^{-1} $year^{-1}$; 13 years: -3.35 kg C ha^{-1} $year^{-1}$). Native forests and pine reforestation soils have potential to mitigate CH_4 emission although this potential can be improved.

(2104 - 2476) Soil-aggregate groups at various depths under silvopasture in comparison with planted and native forests and managed pasture in a Brazilian Oxisol

Felipe M. Pinheiro[1]; P.K. Ramachandran Nair[2]; Vimala D. Nair[3]; Maria C. M. Viana[4]; Ramon C. Alvarenga[5]
University of Florida, School of Natural Resources & Environment[1]; University of Florida, School of Forest Resources & Conservation[2]; University of Florida, Soil and Water Sciences Department[3]; EPAMIG Centro Oeste[4]; EMBRAPA Milho e Sorgo[5]

Soil management practices and land-use systems (LUS) have considerable influence on the soil's aggregate hierarchy. We evaluated the relative distribution of three soil aggregate-size classes: macroaggregates (MA: 250–2000 µm), microaggregates (MI: 53–250 µm), and silt + clay size-fraction (<53 µm), in four soil-depth classes (0–10, 10–30, 30–60, and 60–100 cm) under different LUS in a replicated field experiment on an Oxisol at EPAMIG research station, Prudente de Morais, MG, Brazil. The objective was to compare silvopasture (SPS) with three other LUS: planted forest, native (Cerrado) forest, and managed pasture. The SPS had three tree-planting configurations: i) trees 3 m apart in double rows, 20 m between rows; ii) trees 2 m apart in double rows, 9 m spacing, and; iii) trees 2 m apart in single rows, 9 m spacing. Eucalyptus hybrid was the tree in SPS and planted forest treatments, and *Urochloa decumbens* was the grass in SPS and Pasture treatments. The trees were 8 years old at the time of sampling and cattle had been introduced three years after planting trees. The native forest was semi-deciduous, with > 10 tree species, ~ 10 m height. From each treatment, composite soil samples were collected from the depth-classes, three replications, and from two sites each in SPS: NT (near trees, 1.5 m from trees) and MR (middle of two rows). In the laboratory, 100 g of each sample was manually fractionated by wet sieving into the three aggregate-size classes. The data were analyzed using ANOVA and Tukey's test at 95% confidence interval. The results showed that MA were significantly higher under pasture and SPS 20 m between rows, NT than under other treatments. The MI were higher under SPS 9 m single rows, MR than under other treatments, and the silt + clay fraction was higher under tree plantation and 9 m double rows SPS (NT and MR). Comparing the depths, the amount of MA decreased and that of MI increased, up to 1 m depth. Given that soil organic carbon (SOC) in MA is relatively easily decomposable, the managed pasture, the SPS of 20 m between double rows, and the native forest can be considered as LUS with higher capacity to retain easy-to-decompose SOC. These LUS were observed to have more soil cover (either by tree litter or grass), while the two SPS of 9 m between rows and the Eucalyptus plantation had lower grass productivity and more bare soil, which might have affected the MA formation/stability.

(3337 - 1202) Stock and carbon aculmulation in latosolo (oxisoil) under eucalyptus cultivation in Cerrado

Adilson Alves Costa[1]; Bruno de Oliveira Dias[1]; Erlane Souza de Jesus[2]; Auriléia Pereira da Silva[1]; Vânia da Silva Fraga[1]
Federal University of Paraíba, Post-Graduation in Soil Science, Center of Agrarian Sciences, Areia, PB, Brazil,[1]; Graduated in Agronomic Engineering from the State University of Bahia, Barreiras, BA, Brazil[2]

The current concern about climate change and the use of land and forests as a means to minimize the impact on CO_2 emissions from deforestation and burning activities has attracted the attention of researchers to understand the dynamics of soil organic matter. Thus, with the opening of agricultural frontiers in the Cerrado, demands for forest products gain representativeness. The objective of this work was to evaluate the carbon stocks and accumulation in areas cultivated with eucalyptus with different planting ages in the Cerrado. The geographic coordinates of the study site are 12 ° 20'33 "S and 45 ° 56'27" W and an altitude of 810 m, located at Palmeiras I farm, Luís Eduardo Magalhães municipality, Bahia, Brazil. The soil was classified as Latossolo Amarelo distrófico típico (Oxisoil) with medium texture.

Soil samples were collected in the 0-10 cm, 10-20 cm and 20-30 cm layers in four different eucalyptus plantation areas under different ages, being an area under native vegetation of stricto sensu Cerrado (ACN), two-year-old eucalyptus (EU2), five-year-old eucalyptus (EU5) and eight-year-old eucalyptus (EU8). The total organic carbon content and, consequently, the carbon stocks were calculated, whose correction of the mass was made by the equivalent mass of the soil. The rate of carbon accumulation was made relative to the area under native vegetation. Among the total organic carbon contents there was a significant difference in the area of EU2 in the depth of 10-20 cm when compared to the other areas. However, when comparing the depths, the largest carbon stocks were as follows: 0-10 cm > 10-20 cm > 20-30 cm, regardless of the age of the eucalyptus. In relation to the carbon accumulation, all areas presented lower values when compared to the soil under Cerrado, except for AEU8 that presented increase of up to 2 $Mg.ha^{-1}$. Eucalyptus cultivation for 8 years in the Cerrado has increased carbon stocks in depth, favoring a greater accumulation of carbon over the years.

(8445 - 2529) The Changes of Soil Carbon Content According to Organic Material Types in Upland Soil

Hyeoun-Suk Cho[1]; , Myung-Chul Seo[1]; Tea-Seon Park[1]; Jun-Hwan Kim[1]; Wan-gyu Sang[1]; Pyeong Shin[1]; Geon-Hwi Lee[1]
National Institute of Crop Science[1]

Organic matter is a substance that contains carbon. When applied to soil, it can improve the physical and chemical properties of soil and supply nutrients to plants. Also, it is decomposed in soil due to microbe activity, and utilized by crops. The remaining differential to materials is accumulated in the soil and increases organic matter content in soil. Therefore, we analyzed the types of carbon content according to time while cultivating beans in soil with 4 different kinds of organic matter applied. Total carbon content was higher in organic matter application than in control (non-organic matter). Among the other organic matters, it was especially high in livestock manure(LM) application with 11.38 g kg^{-1}, Hairy vetch(HV, 8.88gkg^{-1}), Oil cake(OC, 8.92gkg^{-1}), and Rice strow(RS, 8.24gkg^{-1}) did similar. According to soil carbon form, Humin carbon(HnC) had the highest total carbon content of 62.6 ~ 64.4 %, Humic acid carbon(HC) had 35.6 ~ 37.7 %, and Fulvic acid carbon(FC) had 17.0 ~ 19.3 %. This pattern was the same in both control and organic matter application. Every type of carbon was the highest in LM application. Therefore, it was concluded that LM, which had a high level of humin carbon that is difficult to decompose, was the best for accumulating carbon in soil.

(2131 - 3147) The effect of bamboo powder application on the yield of Japanese white radish (*Rhaphanus sativus* L.) and soil properties

Atsunobu Kadono[1]; Yasutaka Inoue[2]; Tamaki Nanjo[2]; Ayumi Fukumoto[2]; Kaoru Kominami[2]; Kota Migishita[2]
Tottori University of Environmental Studies[1]; Tottori University of Environmental[2]

The application of organic matter on soils have been studied widely because of its positive effects on carbon sequestration and the diversity of soil ecosystems. We tested different dose (30, 3 and 0 Mg/10a) of bamboo powder to enhance the amount of soil organic carbon (SOC) and microbial biomass and diversity in a soil under the growth of Japanese white radish (*Rhaphanus sativus* L.). SOC was measured by a dichromate oxidation method, microbial biomass by substrate induced respiration method and microbial diversity by BIOLOG method. We found significant increase of SOC, microbial biomass and microbial diversity in the high dose site, while the yield was significantly lower than the none dose site. After the observation in the field and some additional experiments *in vitro* to confirm that the high amount of organic amendment caused inhibiting effect on the yield of the radish, we might conclude the lower oxygen concentration (probably with the higher hydrogen sulfide concentration) in the soils in the high dose site attributed the lower yield.

C3.3.6 - Sustainable phosphorus fertilizer use in tropical soil

(5015 - 1783) Agronomic characteristics of *Brachiaria ruzizienses* grass in response of different doses of phosphorus

Renan Marré Biazatti[1]; Lucas Vinícius Albuquerque de Oliveira[1]; Rogério Gonçalves Teixeira[1]; Pablo Rogério Ciechorski[1]; Ramaiany Lohanny Sousa Cremer[1]
Fundação Universidade Federal de Rondônia[1]

Choose of forage and a chemical equilibrate fertilization, in formation of pasture are the base for a cattle breeding highly productive. In this context a forage specie very used is Brachiaria ruzizienses that have a good develop in wet conditions but no flood. However, like all agricultural production, this grass has limitations according to the fertilization of the soil, principally with the phosphorus availability. So that being, the study search consider the best dose of triple superphosphate fertilization that express the best increase o dry mass, that is the agronomic characteristic more searched in the extensive cattle. There was five treatments in different doses (0, 100, 200, 400 e 800 Kg.ha-1) with four repetitions each, conducted in polyethylene vessels. The dry mass was evaluated in 30 and 60 days, the dose of 400 Kg.ha-1 was indicated the most expressive of dry mass production. In 60 days, the dose with more significant results was 800 $kg.ha^{-1}$. The justification of these results is due to the essentiality of the mineral phosphorus, which participates in the production of vegetal energy, negatively affecting the accumulation of photo-assimilated. When it compared to the control treatment (with no fertilizer) there was an increase almost 2-fold in dry mass production. Therefore, was observed that the phosphorus affect directly the initial growth and subsequently the forage development. Thus this higher productivity reflect in the management activity of the extensive cattle, is that can reduce increasingly the nutritional increments of cattle feed with mineral rations.

(9148 - 2658) Agronomic response to different doses and forms of application of organomineral phosphate fertilizer produced with chicken manure

Jerusa Maia e Sá[1]; Adelson Paulo de Araújo[1]; José Carlos Polidoro[2]; Paulo César Teixeira[2]; Bianca Braz Mattos[2]; Vinícius de Melo benites[2]
Federal Rural University of Rio de Janeiro[1]; Embrapa Soils[2]

The efficiency of phosphate fertilization is very low because of the chemical, physical, and mineralogical characteristics of the soil and of the solubility, composition, and physical structure of the fertilizer. Organomineral fertilizers can supply part of the nutrient demand to crops and ensure better management of agricultural waste. Peak application of P represents a practical way to expedite the implantation step in grain crops. The objective of this work was to evaluate the agronomic performance of an organomineral fertilizer (FOM) produced from chicken manure, in relation to the use of soluble

phosphate fertilizers, in different fertilizer application forms. Maize and soybean were cultivated in succession in a sandy loamy Yellow Latosol with corrected fertility in Luis Eduardo Magalhães, BA. The experimental design was a randomized complete block design in a 3x3x2 + 1 factorial arrangement with 4 replicates, combining FOM, monoammonium phosphate (MAP) and single superphosphate (SSP) fertilizers, applied in three doses (40, 80 and 160 kg ha^{-1} of P_2O_5), with fertilization in total area cover or buried in the sowing furrow, in addition to a control without P. The accumulation of phytomass in maize (at 21, 63, 84 and 148 days after emergence - DAE) and soybean (at 36, 44, 82 and 104 DAE), the productivity and accumulation of P in the grains were evaluated. There was no response to increased doses on productivity. Localized fertilization promoted greater accumulation of phytomass, productivity and P accumulation in maize. There was no residual effect of the fertilization form on the agronomic variables evaluated in soybean in succession. Therefore, the phosphate application in total area presents a promising possibility to practice the stage of implantation of grain crops. FOM and MAP provided greater accumulation of P in the grains in relation to SSP. The results indicate good potential of using chicken manure as a component of organomineral formulations.

(9096 - 922) Chemical attributes of the soil in pasture area arising from application form of phosphorus doses after seven years in western Amazon

Andressa Gregolin Moreira[1]; Edinelia Roos[1]; Bianca Souza Selhorst[1]; Adriele Laurindo Sobreira[2]; Vanessa Rodrigues de Brito[1]; Jairo André Schlindwein[2]; Fábio Régis de Souza[1]; Elaine Cosme Fiorelli-Pereira[1]
Federal University of Rondonia, Av. Norte Sul, 7300, Nova Morada, Rolim de Moura - RO, CEP 76940-000, Brazil[1]; Federal University of Rondonia, Av. Presidente Dutra, 2965, Centro, Porto Velho- RO, CEP 76801-974, Brazil[2]

This work had as objective evaluate the alterations of chemical attributes of soil arising from application forms of phosphorus doses in cultivated soil with Brachiaria brizantha after seven years (2010-2017), The experiment was develop in a property in the municipally of Rolim de Moura, Rondônia, Brasil in an Oxisol, representative of the major pasture areas on Rondônia, on October 2010 to July 2017. The pasture was found established more than 10 years with no management of correct fertilization. The experimental design was in randomized blocks, in a factorial scheme 5x2, five doses of phosphorus (0, 100, 200, 400 and 800 kg ha^{-1} o P), and two applications form of phosphorus on soil (surface and incorporated with subsoiling). Was realized the collect in two depth 0,0-0,10 and 0,10-0,20 m. The chemical analyses were incurred using standards methods. The attributes evaluated were pH in water, levels of changeable Al, P, Al+H and organic matter of soil. There was no interaction with phosphorus dose and the form application of P in any of the studied factors, in two depth 0,0-0,10 and 0,10-0,20 m. The variations of P doses promoted alterations in pH in the two depths studied linearly. The soil phosphorus in the layer 0,0-0,10 m had a quadratic behavior with rising doses of P, and at the highest dose 800 kg ha^{-1} of P obtained 3 mg dm^3 of P, (Al+H) the results were similar of phosphorus in the same layer. The level of changeable Al in the 0,10-0,20 m layer linearly reduced with rising doses of P. After seven years the phosphorus application, any studied factors interacted with the applications form. However the variations in the doses of P promoted alterations in the residual form of concentrations of P and Al+H in the depth soil at 0,0-0,10m and in the changeable Al in the 0,10-0,20 layer.

(7696 - 1564) Diffusion flow of phosphate sources in different contact time

Miguel Martins Neto[1]; Maila Adriely Silva[2]; Gustavo Ferreira de Sousa[2]; Paulo Henrique Soares[1]; Murilo Mendes Machado[1]; Carlos Henrique Eiterer de Souza[1]
Centro Universitário de Patos de Minas[1]; Universidade Federal de Lavras[2]

Due to the high levels of weathering in the tropical region, there is a greater index of phosphorus adsorption, therefore, technologies has been seek to increase the phosphates sources efficiency. Thereby, the objective of this study is evaluate the diffusion flow of the polymer-coated and conventional phosphates fertilizers, in different contact time. The experiment was conducted at the laboratory Central de Análises e Fertilidade de Solo – CEFERT, located at Centro Universitário de Patos de Minas – UNIPAM in Patos de Minas, Minas Gerais State, Brazil. A randomized complete block design was used, in factorial scheme (4 x 6), with 4 phosphate sources (Conventional monoammonium phosphate [MAP], polymer-coated MAP, conventional triple superphosphate, polymer-coated triple superphosphate) and 6 times (3, 6, 14, 21, 40 and 60 days after the application). To the experiment conduction, were used samples of dystrophic red latosol with clayey texture, they were dry, sifted to 2 mm to get the air-dry soil. Incubation chambers with 0,25 dm^3 of volume were used as experimental unit. To the determination of the diffusion flow, the resin anion was used. The used resin was the AMI-7001S treated with sodium bicarbonate with 2,5 x 5 cm of dimensions. To the incubation chambers assembly 1/3 of the soil was put it and inserted the resin on the horizontal position, after that, it was added more 1/3 of the soil, put the fertilizer parallel to the resin and finally covered with the rest of the soil. After the assembly, the soil was irrigated with 80% of the field capacity and the chambers were closed. The data were submitted to the variance analyses, and the sources were compared with Tukey test 5% and adjusted to the regression model. There was interaction between the source and time, at the conventional and polymer-coated MAP had the decreasing regression linear adjustment. On the day 3, the conventional MAP showed higher values of diffusion flow than the polymer-coated, on the following times, the polymer-coat source was superior, this happened because of the slow-release provided by polymer, also reduce the phosphorus direct contact with the soil colloids, minimizing the loss of that nutrient by the adsorption process on the clay mineral. Concluded that the diffusion flow from conventional MAP in a short time is better, and the polymer-coated is more efficient in a prolonged time.

(2994 - 2383) Diffusion of phosphorus from granular monoammonium phosphate with different proportions of phyllosilicate in Oxisols of Brazil

Marco Antonio Pereira de Ávila[1]; Paula Castanho Borges[2]; Thiago Cardoso de Oliveira[3]; Takashi Muraoka[3]
University of São Paulo, Center of Nuclear Energy in Agriculture (CENA/USP), 303 Centenário Ave, Piracicaba, Zip Code 13416-000, São Paulo State, Brazil. (marcopereiraavila@yahoo.com.br)[1]; São Paulo State University (UNESP)[2]; University of São Paulo, Center of Nuclear Energy in Agriculture (CENA/USP)[3]

Phosphorus (P) is an essential element for agriculture worldwide and is considered one of the most limiting nutrients of crop yield. Soils in Brazil have low P content available to plants and soluble phosphate fertilizers have low performance due to complex reactions, from the

interface soil/granule to its diffusive path in the soil. The objective of this study was to evaluate the behavior of granular monoammonium phosphate (MAP) with different proportions of Silicon (Si) (source: phyllosilicate) on the pH, as well as diffusion and availability of P in the soil around the granule. For that purpose, two Oxisols (Latosols) with contrasting textures and maximum phosphorus adsorption capacity (Pmax) were used. The soils were classified as dystrophic Red-Yellow Latosol medium-textured with Pmax 660 mg kg^{-1} and dystrophic Red Latosol clayey with texture showing Pmax 1495 mg kg^{-1}. The incubation experiments were carried out in Petri dishes and assembled in a completely randomized design with 11 treatments (10 phosphate fertilizers produced from MAP and phyllosilicate in P-Si proportions in the granule from 1 to 9 and 10 to 0 and the control treatment) and five repetitions. In the center of each Petri dish, 10 mg of P was added and the dish was incubated for five weeks. After this period, soil samples were collected in the form of concentric rings from the center and subjected to the analyses of the pH, P-total and P-available. The results showed that all fertilizers tested promoted changes in the soil pH around the granules, especially in the first and second sections from the point of application. The dystrophic Red-Yellow Latosol of P applied spread to the third section of soil, and in the dystrophic Red Latosol, significant amounts of P were found only up to the second section of soil from the point of application of the granule. In both soil fertilizers with higher Si proportions in relation to P in the granule provided higher levels of P-total and P-available in the first soil section. Only fertilizers with proportion P-Si 1-9 and 2-8 increased the total P-available in Petri dishes filled with dystrophic Red-Yellow Latosol, and this result was not observed for dystrophic Red Latosol. The results suggest that the presence of phyllosilicate in the granular structure of MAP changed the diffusive dynamics improving P availability in the microregion of influence of the granule of the fertilizer applied.

(7222 - 1810) Do Content, Concentration and Co-Applicants Spatially Impact Liquid Phosphorus Fertilizer Fixation in a Brazilian Oxisol?

Joseph J Weeks[1]; Ganga M Hettiarachchi[1]
Kansas State University[1]

Fixation reactions with iron and aluminum can significantly reduce the use efficiency of phosphorus (P) fertilizers in tropical acid soils. Finding economical and simple methods grower's can implement to keep the nutrient in a plant available form will mitigate deficiency increase yield, lower production costs and reduce non-point source pollution of nearby surface waters. Understanding how P fertilizer type and the concentration in which the nutrient is applied contributes to or prevents fixation is one step to making progress on the use efficiency front. An additional proposed solution that often receives attention, albeit controversially, is to coapply humic substances with fertilizers to complex solution cations that immobilize P and compete with P for sorption sites on soil colloids. Commercial humic substances can vary considerably in composition as their categorization is operationally defined by their extraction procedure thus requiring deeper scientific inquiry to illuminate the mechanisms through which their efficacy is observed. This study investigated the effects of fertilizer type, concentration, and commercially distributed co-applicants on phosphorus applied as liquid fertilizers in a Brazilian oxisol. Monoammonium phosphate (MAP), diammonium phosphate (DAP), ammonium polyphosphate (APP), and an 80/20 MAP/APP mixture were applied at two rates using a concentrated or 5x diluted formulation and with/without commercial fertilizer enhancement products. Soils were incubated for four weeks in Petri dishes and sectioned in concentric rings from the point of application. Anion exchange resin extractability as a percent of total P assessed potential plant availability, while a suite of other wet chemical assessments were employed to investigate how P fate and transport were impacted. Orthophosphates remained more labile than polyphosphates and concentrated P applications outperformed more dilute solutions applied at the same total P rate. These results agree with the site saturation model that assumes a given volume of acid soil possesses the ability to sorb a finite amount P leaving the rest available for plant uptake. Co-applicant results varied and did not consistently alter lability. Further study will be necessary to determine how and if humic substances can best be utilized in future agricultural systems and whether the results of the fertilizer trials are reproducible across acid soils possessing a range of inherent characteristics.

(2546 - 1408) Economic analysis of different sources of phosphorus applied to oxisoils under no-tillage at different levels of fertility in the Central-South region of Paraná

Magno Batista Amorim[1]; Sandra Mara Vieira Fontoura[2]; Renato Moraes[2]; Joana Schroeder de Souza[3]; Tales Tiecher[3]; Cimélio Bayer[3]
Federal institute of Rondonia[1]; Agraria Foundation[2]; Federal University of Rio Grande do Sul[3]

The center-south region of Paraná is one of the major grain producers in Brazil. With the increase in production and, consequently, the demand for fertilizers and the emergence of new sources of phosphorus (P), producers need more information, since large-scale productions require more investment, and the profit is conditioned to the efficiency of the applied fertilizer. Thus, to evaluate how different sources of P influence productivity in soils with different levels of P under no tillage (NT), we have conducted experiments with seven P sources (Super Simple-SS, Super Triple-ST, Yoorin, Yookarin, FN Bayóvar, Shell TSPS and Mosaic MES9) in three Oxisoils, with three phosphorus levels (low, medium and high), in the center-south region. The treatments consisted in the annual application of the recommended dose (115, 190 and 350 kg ha^{-1} of P_2O_5 for soils with high, medium and low level respectively) for each source in two special fertilization programs (System and Culture) with three block repetitions by chance. After three years of cultivation, the total crop production and the economic efficiency of each source were evaluated. For the phosphorus-high soil, the total grain yield of six crops (Wheat / Soybean - Barley / Soybean - Oats / soybeans) exceeded 30 tons without application of P. All sources increased the total production of the system with the application of phosphorus, surpassing 32 tons. For the phosphorus-low soil, the most soluble sources (ST, SS and Yookarin) were higher than the others, reaching a total grain yield in four crops (Soybean / wheat - Soybean / Barley) of more than 12 tons. The rock phosphates Yoorin and Bayovar had the lowest total production among the analyzed sources (<10.3 t). Similar results were found in soil with average P content, where the highest total grain yields in five crops (Barley / Soybean - Wheat / Soybean) were from soluble sources (> 25 t) in relation to rock phosphates. The economic return on P deficient soils (medium and low) is higher when soluble sources are used, especially ST. However, for soils with high P content there was no economic difference for the sources used, and the producer could opt for lower cost sources. Therefore, when the P content in the soil is low, the supply of P to the crops and the replacement of P in the soil should be made using soluble sources. In corrected soils, all sources tested can maintain high yields.

Keywords: Rock phosphate; fertilization; economic return.

FCA UNESP-Botucatu[1]; FCA UNESP- Botucatu[2]; North Carolina State University[3]

The major limitation to establishing and maintaining productive pastures in Brazilian Oxisols is the extremely low levels of plant-available phosphorus (P). P is important in root development and tillering of grasses. When sulfuric and phosphoric acids are applied to phosphate rocks in high-grade fertilizer production, it generates some by-products that are also produced in wastewater treatment with phosphoric acid.These are relatively rich in P, but are considered an environmental liability. These waste byproducts are relatively rich in P, but are considered an environmental liability.With regard to interactions of P in the soil-plant system and its availability to crops, there is a need for greater fertilization efficiency.The objective of this study was to determine the effect of soil pH on the solubility of P in waste by-products from fertilizer production, and its availability to Marandu grass.We hypothesizes that P solubility and availability in the byproducts are greater than that of soluble phosphates due to the increase of the H protonation during growth of Marandu grass.A field experiment was carried out in randomized blocks in 3x5 factorial scheme and four replicates, totalizing 60 plots of 30 square m^2 each.The experiment continued across 4 growth/harvest sequences.Treatments included 4 sources of phosphate fertilizers:decanted phosphate (DP) and precipitated phosphate (PP) from the waste stream, reactive phosphate, and triple superphosphate, in addition to a control treatment without phosphorus application. All P amendments were applied at 100 kg ha^{-1} P_2O_5 .Two lime treatments for soil acidity included an unamended control, amendment with calcite at an intermediate rate to achieve 45% base saturation (V%), and a a corrected treatment to achieve 60% V%. Results were statistially analyzed for differences in crop biomass (dry matter - DM) and crop P contents using a Tukey test at 5% probability. The PD treatment showed better yields under the corrected acidity conditions. PP treatment gave better yields of DM, tillers, and accumulation of P, especially under conditions of intermediate acidity, and was generally superior to all analyzed P sources. FNR provided the highest dry matter production and the highest agronomic efficiency of P only in the treatment where there was no application of limestone in the fourth and last cut. Superior performance of PP indicates that the byproducts can provide high P efficiency and high biomass production.

(5159 - 550) Effect of phosphate solubilizing microorganisms on maize yield and yield attributes in the Sete Lagoas region

Rafael Augusto Lima Rodrigues[1]; Vitória Palhares Ribeiro[1]; André Thomazini[1]; Ivanildo Evódio Marriel[2]; Christiane Abreu de Oliveira Paiva[2]

UFSJ[1]; Embrapa Milho e Sorgo[2]

Brazilian agribusiness is still highly dependent on the foreign market for fertilizer supply. In order to develop a safe and low-cost technology that could reduce and / or supplement phosphate fertilization in corn plantation areas, the use of phosphate solubilizing microorganisms (MSP) associated to fertilization with low solubility phosphate sources has been proposed. To address this, the use of bacteria as inoculants in the corn crop has been evaluated so that the efficiency of the crop's nutrient acquisition could be enhanced. The purpose of this study was to evaluate the effect of the MSP inoculation over the maize productivity as well as to analyse how the soil attributes change after maize cycle. The experiment was conducted by analysing the 2016/17 harvest in the experimental field of Embrapa Milho e Sorgo in Sete Lagoas-MG. The crop was planted in a split-plot design with four 5 - meter lines and three replicates, spacing 0.70 meters from each other. Three bacterial strains of the genus Bacillus were used. Phosphate fertilization was based on the total dose of 100 kg P_2O_5 / ha by using two different sources of phosphate: the triple superphosphate and the Araxá rock phosphate. The mixture of this two phosphate sources was conducted in the same proportion and the control treatment was carried without phosphate fertilization. It was examined: the grain productivity and the dry mass, the N, P and K contents in the grain as well as N and P in the aerial portion. They were quantified, submitted to analysis of variance and the medium values were compared by using the SCOTT-KNOTT test. The use of a fertilization mixture composed by Araxá rock phosphate and A strain has resulted in a 29% rise in the productivity in relation to the non-inoculated treatment . Another studied combination was Araxá phosphate with B strain that has showed an 52% increase in the Mg content on soil when compared to the uninoculated treatment with the same fertilization. The best solubilization performance was noticed by A and B strains : it has resulted in productivity increases, higher N, P and K contents in the grains as well as higher P and N contents in aerial portion. Among the microorganisms evaluated in this work, the A and B strains have presented a high potential to be used as inoculants in order to enhance the biosolubilization of nutrients.

Keywords: Key words: Inoculant, fertilization, phosphate biosolubilization.

(6080 - 2074) Effects of phosphate fertilization on the growth of *Vochysia haenkeana* Mart. seedlings

Matheus da Silva Araújo[1]; Gustavo Matos Coelho[2]; Stephany Diolino Cunha[2]; Camila dos Santos Silva[2]; Adilson Pelá[2]; Barbara Elias Reis Hodecker[3]; Vitor Correa de Mattos Barretto[4]

University of Brasília[1]; University State of Goiás[2]; Union Pioneer of Integration Social[3]; University State of Paulista[4]

Due to the scarcity of information about fertilization in *Vochysia haenkeana* Mart, the objective of this study was to evaluate the initial growth of seedlings of *Vochysia haenkeana* Mart. in response to different doses of phosphorus. The experiment was conducted in a greenhouse, in plastic containers with a capacity of 5 dm^3 and used as substrate, soil samples identified as Oxisol (USDA soil taxonomy). The experimental design was completely randomized, with five treatments and five replications, totalizing 25 experimental units. The treatments had consisted of five doses of P: 0; 50; 100; 150 and 200 mg dm^{-3}, being the triple superphosphate the source of P fertilizer. After 120 days of growth were measured the plant height, collect diameter, number of leaves and shoot, root and total dry matter. Increasing doses of phosphorus did not promote the increment of plant growth. The species *Vochysia haenkeana* Mart. showed low phosphorus nutrition requirement in the early stages of growth, not demanding the application of phosphorus via fertilizers. The soil used as substrate contained 0.8 mg dm^{-3} of P, which was enough to satisfy the nutritional demands of the plants in the first four months of its development. Keywords: Macronutrients; forest nutrition; forestry. Financial Support: University State of Goiás.

(1157 - 1147) Efficiency of phosphorus absorption in corn hybrids

Mussa Mamudo Salé[1]; Juliana Brito da Silva Teixeira[1]; Miguel David Fuentes Guevara[1]; Yasmin Dos Santos Lourenço[1]; Sibele Maria Porto Grill[1]; Thais Antolini Vecozzi[1]; Marlon Rodrigues[2]; Ledemar Carlos

Vahl[1]
UFPel[1]; UEM[2]

Among the nutrients that most limit plant growth and development, phosphorus (P) stands out mainly in acidic soils of the tropical and subtropical regions, although it is the macronutrient less absorbed by crops, this is one that provides more expressive answers in terms increase in production. The increase in the phosphorus absorption efficiency favors the reduction of the doses of phosphate fertilizers used in the fertilization, as well as the immediate use of the P before being fixed in the soil matrix, with favorable impacts on the agricultural sustainability, net income of the rural producer, utilization of marginal areas in terms of soil fertility, and in the fertilizer economy worldwide. There is a significant genetic variation of plants to tolerate stress due to P deficiency, a character called efficiency in use, which may be based on the ability of plants to acquire P from soil through changes in root morphology or architecture, exudation of components P mobilizers, or alterations in the transporters of organic P from the plasma membrane, in addition to that the efficiency can contribute with smaller quantities of P required at the cellular level, or more efficient remobilization of P within the plant. However, a phosphorus absorption kinetics test was carried out in two hybrids of the maize crop, in the greenhouse of the Federal University of Pelotas, Department of Soils, Faculty of Agronomy Eliseu Maciel. The assay was mounted in pots containing 2.4 liters of nutrient solution with pH ranging from 5.5 to 6.0 units and electrical conductivity at around 1.8 mS. Twenty days after the assay was set the morphological parameters (length, surface area, radius radius) and absorption kinetics (maximum inflow, Michaelis-Menten constant, minimum concentration and absorptive power) were measured, concluding that the hybrid GSS 40000 Thunder is more efficient in absorbing phosphorus than the Bandeirante hybrid.

(4004 - 983) Efficiency of the calcined bone meal used as phosphate fertilizer in rice culture

Francisca Terezinha Feitosa Bezerra[1]; Claudia Roberta Braga de Azevedo[1]; Daniel Rodrigues Mafra[1]; Daniel Miranda dos Santos[1]; Veriton Viana da Costa[1]; Eliane de Oliveira[1]
Universidade Federal do Acre -UFAC[1]

Phosphorus is crucial in the initial growth of plants and in the process of energy storage and transfer. In the soil, phosphate fertilizers become progressively non-labile due to the specific adsorption phenomenon common in tropical soils. Animal waste is rich in nutrients and calcined bovine bones can act as a source of phosphorus and calcium for plants. The objective of this work was to evaluate the calcined bone meal (CBM), as a source of phosphorus, in relation to the Triple Superphosphate (TS) fertilizer in rice cultivation (*Oryza sativa*), Agulhinha variety. The experimental design was a randomized block with 9 treatments and 4 replicates in the first and second harvests and 8 replicates in the third harvest, totaling 144 plots constituted by 2 kg of fine earth air dry (FEAD). The fertilizers with CBM and TS were: 50, 100, 150 and 200 kg ha-1 of P2O5, and for the control 0 kg ha-1. All treatments were fertilized with urea (equivalent to 80 kg ha-1 of N) and potassium chloride (equivalent to 80 kg ha-1 of K). Six rice seeds were sown per pot, after germination, only two seedlings were left in each container, allocated in open air, with daily irrigation. The collect were carried out on 28/8/2017, 10/10/2017 and 09/11/2017. Afterwards, the aerial part was dried in an oven at 60ºC until reaching constant weight. In the first collection, the treatment with 200 kg ha-1 of P2O5 of TS obtained a higher average (1.40 g plant-1), contrasting with the control treatment (0.27 g plant-1) and treatment fertilized with 50 kg ha-1 of P2O5, with CBM (0.65 g plant-1). In the second harvest, the treatment with TS, 50 kg ha-1 of P2O5, presented a higher average (4.6 g plant-1), differing from the control (1.06 g plant-1) and fertilized treatment with CBM dose 50 kg ha-1 of P2O5 (2.74 g plant-1). In the third harvest, the treatments with TS or CBM, 200 kg ha-1 of P2O5, presented a mean dry weight of 4.3 and 3.4 g plant-1, respectively, differing statistically from the control treatment (1 , 01 g plant-1) and average grain yield of 1.91 and 1.57 g plant-1 respectively, whereas the control presented a mean of 0.33 g plant-1. It is concluded that the CBM used as phosphate fertilizer showed efficiency close to the TS fertilizer.

(6508 - 2699) Estimation of reference values of foliar concentration of N, P, K and Ca, adjusted to Andean blackberry crops (*Rubus glaucus* Benth.), in Colombia

Cardona, William Andrés[1]; Bolaños - Benavides, Martha Marina[1]
Corpoica[1]

Soils cultivated with *R. glaucus* in Colombia are fertilized without to bear in mind their nutritional status. The objective of this research was to estimate foliar concentration of N, P, K, and Ca reference values for Andean blackberry crops in Colombia. Proposed five levels for each factor, as well as the combination of these factors, by means of an orthogonal central compound treatment design in randomized complete block arrangement. Each fertilization was carried out according to the growth of the plant. After each fertilization, destructive sampling was carried out: 72, 112, 138, 166, 195 and 225 days after transplant (dat) (vegetative stage), 293, 355 and 435 dat (reproductive), 481, 548, 625, 681 and 758 dat (production year 1), 793, 863, 919 and 972 dat (production year 2). In each sampling separated the different organs of each plant (leaf, stem, root, flower and fruit). The plant tissue complete analysis (macro- and micronutrients) was performed in each organ. Vegetative index (VI) was calculated with the concentration values (Valenzuela *et al*., 1993). Normal values between 1 and 2 were proposed to define appropriate ranges of VI. Taking as reference the ranges of concentration leaf for *Rubus* sp., reported by SBCS (2004). In the vegetative stage, plants had high leaf N concentration. Foliar P concentration was below the normal range in any of the five samplings. At 72 and 138 dat, plants presented deficit of K. Ca concentration was adequate in different sampling. At 435 dat, the concentration of N in leaf below the normal value. The concentration of N, P and K was highest during the stage of reproductive bud that in fruit set. The P concentration was low throughout the reproductive period. The concentrations of K and Ca showed normal values. VI values in reproductive bud, are much lower than in fruit set, demonstrating the importance of Ca and Mg in the emitting its floral buttons. During the production, excessive concentrations of N, K, and Ca were not found. The concentration of P in all sampling showed low values. The IV of fruits was greater than 2, in all sampling. It was necessary to adjust the ranges foliar P sufficiency; finding that, during the vegetative stage the normal sufficiency range must be 0.22 – 0.27%, at reproductive stage (0.12 – 0.22%) and finally during production (0.12 – 0.19 %.). For N, K, and Ca, it is proposed to work with the values of SBCS (2004). The foliar analysis must be carried out at two years of established crop.

(7826 - 877) Fused phosphates agronomic efficiency in soils with different P levels

Juliana de Lima Moretto[1]; Leonardo Theodoro Büll[1]
UNESP[1]

Experimental results point to high agronomic efficiency for fused phosphates (TFs) applied to the tropical soils, even when compared to water soluble phosphate sources. However, it is common between Brazilian agricultural producers the belief that such fertilizers are less efficient than water soluble sources, under low fertility soils (low P levels). The objective of this study was evaluate TFs efficiency under two soil conditions: Adequate and low P level for annual crops. The experiment was carried out in a greenhouse using 20L pots with a Nitosol collected at an agricultural production area and has medium concentration of P (35mg dm^{-3} – soil MP); adjacent to this area the same soil was collected, but in natural forest, with low P level (7mg dm^{-3} – soil BP). The sources used were three fused phosphates: magnesium (TM), potassium (TK) and "thick" (TG); and triple superphosphate (ST) as reference. A cycle with millet and another with maize were conducted, for approximately 50 days after emergence, as test plants. By the end of the experiments the soil labile P (resin) and the accumulated P in the plants shoot were evaluated. The variables were submitted to analysis of variance by the F test (α = 0.05) and the means compared by Tukey test (α = 0.05). The fused phosphates provided, since the first crop cycle, expressive higher amounts of P in the soils, in comparison to ST. The accumulation of P in plant tissues, in the first cycle, was TM = 44.29; TK = 41.29; ST = 44.16 and TG = 2.52 mg/pot, for soil BP; and for the soil MP: TM = 79.47; TK = 76.80; ST = 71.33 and TG = 56.12 mg/pot, the accumulation was similar between TM, TK and ST, in both soils, verifying that the powdered TFs have high efficiency in the P availability for annual crop, independent of the initial soil fertility. In the second cropping cycle, in soil MP, P accumulation was TM = 59.42; TK = 56.73; TG = 47.31 and ST = 43.56 mg/pot, showing that TM and TK provided the largest accumulations. In soil BP, TK surpassed the others, promoting the greatest accumulation of the nutrient: 44.17 mg/pot; TM = 30.29; TG = 16.57 and ST = 14.89 mg/pot. In these experiments the powdered phosphates exhibited greater capacity to increase P content in the soil. They are as efficient as a soluble source for the P accumulation in plants, and more efficient when considering the residual effect (second crop). Coarse fused phosphate has lower efficiency than the others TFs.

(1031 - 1573) Impact of subterranean clover (*Trifolium subterraneum* L.) root exudates on phosphorus availability for grapevine (*Vitis vinifera* L.) plants in intercropping systems in Andisols

Francisco Contreras[1]; Adamo Domenico Rombolà[2]; María de la Luz Mora[1]

University of La Frontera[1]; University of Bologna[2]

Phosphorus (P) is an essential nutrient required for plant growth and development. In Andisols, P availability is limited to crops because is sorbed in mineral surfaces or constituting part of soil organic matter. Continuous application of P fertilizers increases production costs making necessary to develop agricultural practices improving P use efficiency, in this context, intercropping is a feasible alternative for enhance nutrient management in soil. Intercropping is an agricultural practice where two or more crops grow simultaneously in the same field and time, preserving soil fertility and improving plant nutrition. Therefore, in this study was evaluated the effect of *Trifolium subterraneum* L. (*T. subterraneum* L.) on P uptake by *Vitis vinifera* L. (*V. vinifera* L.). The vegetal material used in this experiment were *V. vinifera* L. var. Chardonnay on rootstock 1103 Paulsen 1 year old and plants of *T. subterraneum* L. var. Seaton Park cultivated preliminarily during 1 month in germination dishes. To test the intercropping interaction under controlled conditions in greenhouse, both species were cultivated in Hoagland hydroponic solution during 2 months. The experimental design was completely random using three treatments: T1 (*T. subterraneum* L.); T2 (*V. vinifera* L.) and T3 (*T. subterraneum* L. + *V. vinifera* L.) with three replicates. To prove the interaction were evaluated the concentration of organic acids, flavonoids and amino acids in root exudates collected from the hydroponic solution. The most important organic acids found in both species were oxalic, malic and citric; where *T. subterraneum* L. exhibited the highest concentrations. The most important amino acids found were glycylglycine, glutathione and L-threonine; L-threonine was detected only in *T. subterraneum* L. exudates while glycylglycine and glutathione were detected in both species. Finally, flavonoids found were isorhamnetin and kaempferol-3-glucuronide in both species while epicatechin was detected only in *T. subterraneum* L. root exudates. For the compounds found above, there are significant differences in root exudates composition and concentration between species suggesting that there is an interaction where combining these species which can improve soil phosphate availability for grapevine plants cultivated under controlled conditions.

Keywords: Root exudates, phosphorus availability, intercropping.
Financial support: This study was supported by CONICYT scholarship (CRM:0001408).

(6834 - 1242) Impacts of lake sediment reuse on plant growth and soil properties in the field

Mina Kiani[1]; Asko Simojoki[1]; Olga Tammeorg[2]; Priit Tammeorg[1]
Department of Agricultural Sciences, University of Helsinki, Helsinki, Finland[1]; Department of Environmental Sciences, University of Helsinki, Helsinki, Finland[2]

Lake sediments are in many cases known to be rich in nutrients, organic carbon, and clay minerals. These compounds originate from eroded agricultural soils acting as primary sediment source. European countries produce about 200 million m^3 y^{-1} of sediment removed from waterbodies which provides the potential of recycling nutrients from sediments in crop production. There are just a handful studies available exploring the potential of recycling the nutrients from sediments and none have been conducted under field conditions. Therefore, there is a need to develop efficient ways to reuse sediments on agricultural lands to preserve phosphorus and other nutrients and respond to crop demands. The aim of this research was to investigate the effects of different ways of sediments applications to soil on grass growth, soil, and environment. The study was conducted in the shore of a 1-ha heavily eutrophicated lake from which sediments were excavated. Four different sediment application methods were tested in a RCBD design with four replicates. The treatments were pure topsoil, a mixture of soil and biochar on top of the sediment, a mixture of biochar with top 20 cm of sediment, and a 75–100 cm layer of sediment directly on topsoil. In June 2017, mixture of red fescue, Kentucky bluegrass, ryegrass, and white clover was sown to all plots with meat bone meal organic fertilizer. The leaf area index, the relative leaf chlorophyll values, aboveground biomass, soil moisture content, total carbon and nitrogen, GHG emissions, and the soil penetration were measured in all plots in August 2017. The analysis of representative samples of sediments revealed that the sediments were not contaminated by heavy metals, PAHs, and PCBs. The moisture content was significantly higher in sediment plots (33±5%) than soil (19±1%). Relative leaf chlorophyll value and leaf area index were significantly 1.3 and 1.7 times greater in sediment plots than in the soil plots, respectively. Moreover, the treatments containing biochar had the highest C:N ratio. Sediment phosphorus (P) content was high, providing sufficient available P to agricultural lands. The final presentation will include data on yields of 2018, GHG emissions, and the mechanical soil resistance in different treatments. Our results emphasizes the importance of preventing the transport of nutrients to water bodies and considering the assessment of sediment nutrient contents and pollutants in the disposal of removed sediments.

(3682 - 2943) Improving bone-based phosphate fertilizer by pyrolysis

Cristiano Dela Piccolla[1]; Dean Hesterberg[2]; Etelvino Henrique Novotny[3]; Takashi Muraoka[4]; Thalita Cardoso Anastacio[1]; Josimar Vieira dos Reis[1]

Soil Science Department, Luiz de Queiroz College of Agriculture, University of Sao Paulo[1]; Crop and Soil Science Department - North Carolina State University[2]; Embrapa Soils[3]; Center of Nuclear Energy in Agriculture - University of Sao Paulo[4]

Phosphorus is a macronutrient for all organisms, and its projected future scarcity generates a need for more efficient P recycling technologies. Because animal bones are rich in P, they could be employed to recycle part of P fertilizer inputs in agriculture, while diminishing environmental issues and health risks associated with cadmium in phosphate rock-based fertilizers. Moreover, pyrolysis is an alternative treatment to calcination that could both eliminate disease sources from bones and generate an efficient fertilizer ("bone char"). Our aim was to evaluate the physical and chemical characteristics of P in pyrolized pig bones as affected by temperature (400, 550 and 800 °C) and atmospheric conditions (sealed chamber, purging with N_2, or steam activation). In addition to characterization of specific surface areas, porosities, and mineralogy, pyrolysis products were evaluated for their potential to provide P to plants using chemical extractions with water, neutral ammonium citrate, and 2% citric acid. All bone chars met the minimum total-P requirements and maximum cadmium restrictions for commercialization in Europe, a reference market. Bone chars also showed higher solubility than bone subjected to calcination. Synchrotron-based X-ray diffraction showed that bones are composed of hydroxyapatite (HAP), and pyrolysis in a sealed chamber or with flux of N_2 diminished HAP crystallinity compared with pyrolysis performed under steam flux and calcination (800 °C). Linear combination fitting of calcium K-edge XANES spectra revealed that the 20% of poorly crystalline HAP was entirely converted to highly ordered HAP as pyrolysis temperature rose from 400 °C in a sealed chamber to 800 °C under steam activation. Triggered by organic matter losses, HAP crystallization decreased bone char surface area and solubility. Pyrolysis carried out in a sealed chamber at 550 and 800 °C showed higher total and citric-acid-soluble P contents, thus being recommended for a bone based-fertilizer production, whereas the 400 °C treatment diminished bone char pore volume, surface area, and 2% citric-acid-soluble P/total P. Pyrolysis is a promising waste-treatment technology in which the final product can be potentially used to fertilize P-deficient soils in the tropics. Moreover, the acidity of most tropical soils would promote HAP dissolution and P release.

(2357 - 3111) Maize cob productivity fertilized with different phosphorus sources and dosage

Ianna Bizerra Barros[1]; Iolanda Maria Soares Reis[2]; Carlos Alberto Costa Veloso[3]; Arystides Resende Silva[4]; Eduardo Jorge Maklouf de Carvalho[4]

Universidade Federal de Viçosa[1]; Universidade Federal do Oeste do Pará[2]; Embrapa Amazonia Orienatl[3]; Embrapa Amazônia Oriental[4]

The organic and inorganic phosphorus forms of the soil are influenced by the soil use and management. In cultivated soils, where there are periodic phosphates additions, the management system determines changes in the distribution of forms and phosphorus concentrations in the profile and, more specifically, in the surface layer. The objective of this work was to evaluate the maize cob yield fertilized with different phosphorus sources and dosages. The experiment was carried out in the experimental field of Embrapa Amazônia Oriental, in Belterra City - PA, under a dystrophic Yellow Latosol, with a clay texture. The experimental design was randomized blocks, arranged in a 3x5 factorial scheme, with three replications. Three sources (Simple Superphosphate (SS), Triple Superphosphate (ST) and Natural Reactive Phosphate (Arad) were used and five dosages (0; 60; 120; 180 and 240 kg ha-1) of P2O5 were used. The experimental plots, except control treatment, received mineral fertilization of 120 kg ha-1 of N (urea) and 90 kg ha-1 of K2O (Potassium Chloride), divided in sowing and cover. The maize cultivar used in seeding was AG 7088 PROX, with three seeds per linear meter, whose plots presented dimensions of 5x8 m. The harvest occurred at 141 days after seeding, to determine the maize cobs yield. The data were submitted to variance analysis and the means adjusted to the quadratic polynomial regression and compared by the Tukey test at 5% of probability. The interaction between phosphorus sources and dosages was significant for cob yield. The Arad proved to be inefficient in terms of phosphorus supply to the plants, in view of the non-occurrence of cob yields at any of the applied doses. This fact can be attributed to the low solubility of this type of fertilizer, which promotes longer phosphorus availability. The most efficient interaction in terms of cob yield (6.111 t ha-1) occurred between ST and the dose of 120 kg ha-1 of P2O5, decreasing thereafter. In general, the highest increase in cob yield for both SS and TS occurred until the dosage of 120 kg ha-1 of P2O5, making it unnecessary to apply higher dosages, noting that dosages greater than 120 kg ha-1 of P2O5 cost of production and reduce production. The maize cobs productivity presents a significant response to phosphorus application. The dosage of 120 kg ha-1 of P2O5, with ST as the source, provides higher cob productivity. There was no response in productivity when fertilized with Arad.

(8339 - 940) Natural phosphate efficiency use in corn applied with different nitrogen sources

Moniki Campos Janegitz[1]; Gustavo Faria Seródio[1]; Rafael de Paiva Andrade[1]

Colleges Gammon of Paraguaçu Paulista[1]

Phosphate (P) fertilizers as nitrogen are essential for high crop production. Ammonium application can improve phosphorus efficiency use and phosphorus available in soil to the crops. The aim of this study is evaluate the effect of ammoniacal fertilization impacts in the natural P efficiency use to the development initial of maize plants. The experiment was carried on greenhouse at Colleges Gammon in Paraguaçu Paulista –SP from June to September, 2017. The experimental design was randomized blocks in factorial: two nitrogen fertilization (ammonium sulfate and urea) x five doses of natural phosphate (0, 40, 80, 120, 180 mg P dm-1 of soil) with four replications. The experimental condition was in pots with 15 dm-3 of soil. After 30 days of emergency plants height, shoot dry matter, root dry matter, root/ shoot rate and natural phosphate efficient use were determined. Doses of P resulted in higher dry matter yield, plants height and efficient use of P in initial development corn plants. Ammonium sulfate plus doses of P, decreased the root / shoot rate. Natural phosphate efficient use was in 80 mg dm-3, independent of the source of nitrogen applied.

(9832 - 2595) Partial acidification of Arraias Rock Phosphate improves P use efficiency in tropical soils

Vinicius de Melo Benites[1]; Sulian Junkes Dal Molin[2]; José Augusto Cabral Santos[3]

Embrapa Solos[1]; UDESC[2]; UniRV[3]

Natural rock phosphates are characterized by low P water solubility. Acidification is the normal method to improve P solubility on these materials but it represents costs and operational issues. The aim of this study was to evaluate the agronomic efficiency of partially acidulated Arraias rock phosphate. The experiment was conducted in a greenhouse at the University of Rio Verde, Rio Verde, GO. A Red Yellow Oxisol from Cerrado was used as testing soil (pH_{CaCl2} = 5.17, clay = 540 g kg^{-1} and P = 0.3 mg dm^{-3}). Plastic pots (2 L) were filled with 2 kg of this soil (dry basis). The treatments consisted in Arraias Rock Phosphate (ARP) (Arraias, Tocantins, Brazil); Triple super phosphate (TSP) and three partially acidulated rock phosphate (PARP) with 5, 10 and 15 % H_2SO_4 relative to RP mass. Fertilizers were applied in the rate of 100 mg P per pot, mixed in the whole soil mass before seeding. Maize was seeded with 5 seeds per pot and one week after emergence were thinned to 2 plants per pot. Soil moisture was maintained between 60% and 50% of the field capacity. After 45 days, plant shoot was cut close to the soil surface. Shoot dry mass and its P concentration, after plant digestion, were measured, and P uptake was calculated. TSP treatment results in the highest shoot dry mass. Among PARPs, the highest dry mass yield was observed in the 15 % PARP which was higher than 5 %, the Arraias rock phosphate and the control. The higher dry mass yield in the 15 % PARP was due to higher water solubility of the phosphate. Unlike the dry mass yield, the ARP has shown the highest P content in shoot tissue, contrasting with the control and other fertilizers. Lower tissue P concentration in higher yield biomass treatments is due to a dilution effect on the P content in shoot tissue in the fertilizers of greater solubility. The amount of P uptake was correlated to shoot dry mass yield, with highest P uptake on TSP followed by the 15 % PARP which differed from control, ARP and 5 % PARP. The relative efficiency in shoot dry mass increase with rate of H_2SO_4 until 35.84 % in the 15 % PARP treatment. The partial acidification of the Arraias rock phosphate increased shoot dry mass and P uptake as well as its efficiency relative to TSP. We concluded that acidification with 10 % H_2SO_4 was the best alternative, since it was similar to 15 % and represents a lower industrial cost.

(9014 - 1169) Partially acidulated rock phosphates containing zeolites for regulating the solubility in soils.

Ana Paula Bettoni Teles[1]; Paulo Sérgio Pavinato[1]; Gabriel Novoletti[1]

Escola Superior de Agricultura Luiz de Queiroz[1]

The consumption of phosphate fertilizers in Brazil has almost triplicated in the last decades and the most common ones used in agriculture are the solubles or with high reactivity, mostly with low efficiency in tropical soils. Thus, knowing that the sources of phosphate are finite, a study was developed aiming to: evaluate the solubility of partially acidulated phosphates with the incorporation of zeolites (Zeo), produced from distinct rock phosphates; Araxá (RFA), Bayóvar (RFB) and Morocco (RFM); and to evaluate P availability from these sources in the soil. To obtain the fertilizers the Zeo was mixed with rock phosphates in powder and then partially acidified (25 and 50% of the total chemical reaction) by the addition of sulfuric acid. Eleven treatments were evaluated: 1) RFA + Zeo + 50%; 2) RFA + Zeo + 25%; 3) RFB + Zeo + 50%; 4) RFB + Zeo + 25%; 5) RFM + Zeo + 50%; and 6) RFM + Zeo + 25%; 7) Triple superphosphate (TSP); 8) RFA; 9) RFB; 10) RFM and 11) Control (Without P). The solubility was evaluated in soil leaching columns (thermoplastic acrylic tubes with 2.1 cm internal diameter and 25 cm height). To each column was added 50 g of soil with low available P content and then it was saturated with distilled water. Fertilizer treatments were added in a dose of 100 mg P per column, superficially. For 60 consecutive days it was added 20 ml of deionized water to the columns and the leachates were collected for P content evaluation (Murphy and Riley, 1962). After, the soil was sampled in layers of 0-1; 1-2; 2-3; 3-6 and 6-10 cm from the top, and the available P by ion exchange resin was evaluated (first step of P fractionation proposed by Hedley et al., 1982). It was observed a partial solubilization of all fertilizers after 60 days, evidenced by the presence of P in the leachates. RFB and RFM both with 50% acidulation had 25 and 23% of the P leached, respectively, otherwise TSP presented highest leaching, with 63.7% of the total applied. No P leaching was observed under the control and under RFA, RFB and RFM without acidification. Phosphate fertilizers addition has provided increase in available P in all the layers of the soil, being this most significant increase in the toplayer (0-1 cm). The sources RFB + Zeo + 50% and RFM + Zeo + 50% provided available P values like those observed for TSP, and could become good options for slow-release fertilizer for crops.

(8088 - 1508) Phosphate Fertilization via monoammonium phosphate in Corn Crop in Oxysol from Brazilian cerrado region

Gustavo Ferreira Sousa[1]; Maila Adriely Silva[1]; Paulo Henrique Soares[2]; Miguel Martins Neto[2]; Larrissa Pereira da Cunha[2]; Carlos Henrique Eiterer de Souza[2]

Universidade Federal de Lavras[1]; Centro Universitário de Patos de Minas[2]

The phosphorus (P) is the element that exercises great influence on the crop development, however, it exhibits differentiated behaviour on the most soils cultivated, which makes to became unavailable for some plants. Thus, the objective of this study was evaluate that the aim of fertilizer to increase the efficiency of the nutrient utilization and with the use of the P stabilization technology. The experiment was carried out with the corn crop during the growing seasons 16/17, at the Fazenda Lanhosos, in Patos de Minas (Minas Gerais State – Brazil) under the Red Eutrophic Latosol. The soil has the following chemical attributes analyzed in depths of 0-20 cm; pH (H_2O) 5,84; H+Al (AcCa) 2,6 cmol dm^{-3}; Al (KCl) 0,08 cmolc dm^{-3}; Ca (KCl) 1,4 cmolc dm^{-3}; Mg (KCl) 1,4 cmolc dm^{-3}; K (Meh-1) 66,7 mg dm^{-3}; P (Meh-1) 0,22 mg dm^{-3}; P-rem ($CaCl_2$) + KH_2PO_4) 8,48 mg L^{-1}; V% 53. The area that the experiment installed was occupied for understory vegetation typical from Brazilian Cerrado region, therefore the current growing season was the first performed. It was used the randomized complete block design in factorial scheme (3 x 4) + 1, with 3 sources of monoammonium phosphate (MAP + humic substances, conventional MAP and polymer-coated MAP), 4 doses (30, 60, 90 and 120 Kg^{-1} of P_2O_5) + the additional treatment, without P application. To 92 days after sowing, evaluations of plant height, culm diameter, stem and leaves dry matter were performed. To 140 days after sowing evaluations of ears size, one thousand grain mass, predicting production. The data were submitted to the analyses of variances and when the significance mean among the sources were analysed by the Tukey test at 0,05 and the P_2O_5 doses were adjusted to the regression model. Significant difference was observed for the sources on the parameters of plant height, stem and leaves dry matter, therefor the conventional MAP source indicated higher values in relation to the others sources. When the doses application were evaluated, the increase linear adjustment was observed to the plant height, stem and

leaves dry matter and ears size were observed. Also were observed, interaction between the sources factors and doses in the stem diameter and productivity evaluation, therefor the conventional MAP source indicated superior. It is concluded that the corn crop is responsive in a linear way to the phosphate fertilization and the conventional MAP provided higher productivity.

(8205 - 3127) Phosphorus and sulfur content in calcareous Vertisol under influence of elemental sulfur

Ewerton Gonçalves de Abrantes[1]; Alexandre Paiva da Silva[1]; Raphael Moreira Beirigo[1]; Josinaldo Lopes Araujo[2]
Universidade Federal da Paraíba[1]; Universidade Federal de Campina Grande[2]

Calcareous soils present low availability of phosphorus (P), as a function of the presence and sorption in calcium carbonates, and in different forms of calcium phosphates. Thus, the increase of P availability in these soils is due to the reduction of pH and increase in the solubility of the precipitated phosphates, which can be achieved with the use of elemental sulfur (S^0). The objective of this work was to evaluate the effect of the application of elemental sulfur rates on the pH and phosphate and sulfate contents in a calcareous Vertisol of Apodi Plateau, RN. The work consisted of an incubation test, using soil (4 mm ø), collected in the 0-0.20 m layer, presenting the following chemical attributes before installation: pH (H_2O) = 8.5; organic matter = 3.73 g kg^{-1}; P = 142 mg dm^{-3}; SO_4^{2-} = 44 mg dm^{-3}; Ca^{2+} = 29.0 $cmol_c$ dm^{-3}; Mg^{2+} = 10.7 $cmol_c$ dm^{-3}; $EqCaCO_3$ = 95.8 g kg^{-1}, remaining phosphorus = 16.7 mg L^{-1}; clay = 300 g kg^{-1}. The work was conducted in completely random experimental design with treatments arranged in a 5 × 5 factorial scheme, with four replications. The factors studied were five S^0 rates (0, 15, 30, 45 and 60 g kg^{-1}) and five incubation times (T) (14, 28, 42, 56 and 70 days). The experimental unit consisted of a pot containing 0.3 kg of soil, with humidity maintained at 75 % of the field capacity. In the respective incubation times, the soil samples were collected and dried in an oven (35 °C), and destined to the pH determinations in water (1: 2.5), P-Olsen and sulfate extracted with 0.01 mol $CaCl_2$ L^{-1}. There was a significant effect ($p \leq 0.01$) of the factors of S^0 rates and T, and the interaction between the factors in the variables evaluated. Elevation of S^0 rates reduced pH values (from 8.4 to 6.4) and increased sulfate contents (from 68.0 to 3800 mg dm^{-3}). However, the increase of S^0 rates reduced the phosphate contents (from 150.0 to 140.0 mg dm^{-3}). Regarding the effect of the incubation time, a decrease in pH (from 8.0 to 6.2) and increases in phosphate content (from 140.0 to 141.0 mg dm^{-3}) and sulfate (from 698 to 4,496 mg dm^{-3}). P values did not correlate with pH values (0.34^{ns}) and sulfate contents (-0.39^{ns}), but there was a significant negative correlation between pH values and sulfate content (r = -0.98*). It was concluded that the application of S^0 reduced the pH and increased the sulfate content, but little influenced the phosphate contents.

(8139 - 3007) Phosphorus availability in cultivated and non-cultivated soils by the Mehlich-1 and Mehlich-3 extractants

Josimar Vieira dos Reis[1]; Takashi Muraoka[1]; Cristiano D. Piccolla[1]; Aijânio G. B. Silva[1]; Mariana G.M. Gonçalves[2]; Thalita C. Anastacio[1]
"Luiz de Queiroz" College of Agriculture[1]; University of Lavras[2]

Due to the high doses of P applied in cultivated soils for decades, there is an increase of different soil P forms. In these soils, it may occur the loss of the predictive capacity of available soil P content by the Mehlich-1 extractant, the most used in Brazil. Our objectives were: to correlate the available P content by Mehlich-1 (P-M1) and Mehlich-3 (P-M3) extractants, in cultivated and non-cultivated soils with yield indices of maize plants, and to correlate the extractants' P recovery rates with soil characteristics related to the P buffering capacity, remaining-P (rem-P), P Maximum Adsorption Capacity (P-MAC), and clay content. The maize plants were grown under greenhouse conditions, in plastic pots with 2.0 dm^3 of soil. The treatments consisted of a factorial 10 × 6, with 10 soils samples, with contrasting characteristics related to the availability of soil P, and 6 doses of P (mixture of 70 % of Single Superphosphate and 30 % of Bayóvar). There were two successive cultivations, with 42 days each. The determinations of the available soil P content by the extractants were performed on soil samples collected after incubation with limestone, before the first cultivation, and in the samples collected before the second seeding. After the cultivations, the production of the shoot dry matter, the P content and the accumulated P in the plants were determined, and the P recovery rates by the extractants in the first cultivation were calculated. In both cultivations, the highest correlation coefficients were obtained with the P content in the plants (0.975*** and 0.901** for P-M1, and 0.980*** and 0.918*** for P-M3). As the P content in the plants suffer dilution effect, the conclusions should be based on the accumulated P in the plants. In the first cultivation, the correlation between P-M1 and the accumulated P was 0.874*** and decreased to 0.710*** in the second cultivation. For P-M3, the correlation was 0.870** in the first cultivation and 0.865*** in the second cultivation. There was a significant correlation between the P recovery rates by the two extractants with rem-P (M1 = 0.887**, M3 = 0.875**), P-MAC (M1 = -0.828**, M3 = - 0.769*) and clay content (M1 = - 0.717 * and M3 = -0.756*). Therefore, the two extractants are indicated for determination of the available soil P content in soils with low and high availability of P, although M3 showed slightly better correlations. As with M1, M3 is also influenced by the soil P buffering capacity.

(4131 - 1527) Phosphorus extracted by Mehlich 1 and anion exchange resin in in dystrophic Clayey Red Latosol subjected to the anticipation phosphates fertilizer

Maila Adriely Silva[1]; Gustavo Ferreira de Sousa[1]; Pedro Rocha Santos[2]; Miguel Martins Neto[2]; Ariane Emilia Celita Barbosa[2]; Carlos Henrique Eiterer de Souza[2]
Universidade Federal de Lavras[1]; Centro Universitário de Patos de Minas[2]

The phosphorus (P) can be find it in labile fractions on the soil, non-labile and readily available on solution. The availability is directly connected to the development and productivity, as we know the P is the third most extracted nutrient for the most of the plants. Thereby, the objective of this study was evaluate the phosphorus extraction by Mehlich 1 and anion exchange resin methods in dystrophic clayey red latosol after the anticipated application of phosphate fertilizers. The experiment was conducted at Fazenda Santos Reis, Lagoa Formosa, Minas Gerais State, Brazil. The area soil is characterized as dystrophic clayey red latosol and has 1.09 mg dm^{-3} of P Mehlich 1. A completely randomized block design was used, with the factorial scheme 5 x 4, therefore the fertilizing was anticipated in five times (0, 7 , 14, 28 and 42 days) and four sources of phosphate fertilizer (Conventional MAP, polymer-coated MAP 1, polymer-coated MAP 2 and MAP with humic

substance) with four repetitions. It was used 120 Kg ha^{-1} of P_2O_5 and after the last application time, was sowing the maize crop. At the late crop season, soil samples were collected on the plot centrelines for the phosphorus extraction by Mehlich 1 and anion exchange resin methods. The results were submitted to the variance analyse, and the regression models were adjusted for the incubation time. Moreover, the Tukey test was used for the sources comparation, considering 5% of probability. The variables analyzed were influenced by the anticipation phosphate fertilizing time ($p < 0,05$), however did not adjusted to the regression model. The phosphorus extraction by the Mehlich 1 extraction the application of the fertilizer on the sowing day provided increasing P levels to the sources of conventional MAP, MAP with humic substance, polymer-coated MAP 2 and polymer-coated MAP 1, with 1,82 mg dm^{-3}, 1,74 mg dm^{-3}, 1,28 mg dm^{-3} and 1,02 mg dm^{-3}, respectively. The phosphate fertilizer application over time did not provide changes on the phosphorus availability classes, even after the application the rating is still very low. For the results found with the anion exchange resin methods, the availability for all fertilizers in every time remained as average (10,1 to 20,0 mg dm^{-3}). Therefore, concludes that the times of anticipation phosphate fertilizing and the sources used did not influence on the phosphorus extraction y Mehlich 1 and anion exchange resin methods.

(4434 - 477) Potential for the use of calcined bone meal as a source of phosphate fertilizer for corn

Daniel Rodrigues Mafra[1]; Daniel Miranda dos Santos[1]; Claudia Roberta Braga de Azevedo[1]; Francisca Terezinha Feitosa Bezerra[1]; Veriton Viana da Costa[1]; Eliane de Oliveira[1]
Universidade Federal do Acre-Campus Floresta[1]

Phosphorus is an essential element for plants, stimulating the plant and root growth. However, it constitutes a severe limitation for agricultural production in tropical regions, due to its low availability caused by the specific adsorption to the soil colloids and to the low purport in the soil source material. The use of alternative sources of fertilizers is a strategy to reduce production costs, when it is using phosphate fertilizers to correct soil fertility. With the objective to evaluate the performance of calcined bone meal (CBM) as a source of phosphorus, in relation Triple Superphosphate (TS) fertilizer, an experiment was carried out at the Universidade Federal do Acre - Campus Floresta, on city of Cruzeiro do Sul, state of Acre, Brazil, from 25/08/2017 to 11/12/2017, using maize (Zea mays) - early variety BM-810, Biomatrix. The experimental design was a randomized complete block design with nine kind of fertilizations and three collection seasons (or subplots), with four replications. The plots was constituted by pots with 5 kg of soil. The adubations tested were 0, 50, 100, 150 and 200 kg ha-1 of P2O5, adoting CBM or TS fertilizers as phosphorus source . The harvests were carried out on 10/10/2017, 11/14/2017 and 11/12/2017. The dependent variable was dry matter of the aerial part, dried in an oven at 60 ° C until constant weight. In the first harvest, the treatment corresponding CBM fertilized at level 100 kg ha-1 of P2O5 obtained a better average with 6.3 g plant-1, contrasting significantly by theTukey Teste ($P<0,05$), with the control treatments and treatments fertilized with 50 kg ha-1 of P2O5, regardless of the source of phosphorus used. The other treatments did not differ from each other. In the second harvest, ST at a dosage of 200 kg ha-1 of P2O5, presented a mean of 19.2 g plant-1 differing significantly, by the Tukey Test ($P<0,05$), from the control and the CBM dosage treatmen of 50 kg ha-1 of P2O5. In the third harvest, treatments with 200 kg ha-1 of P2O5, from both TS and CBM, presented averages of 22.1 and 17.6 g plant-1, respectively, differing statistically by Tukey Test ($P<0,05$) from the control treatment and from 50 kg ha-1 fertilization of P2O5 treatments with TS and with CBM. The results showed that the calcined bone meal, used as phosphate fertilizer, presented efficiency close to the triple superphosphate fertilizer.

(5286 - 3035) Production system of *Lupinus mutabilis* Sweet "chocho" on terraces and hillsides with phosphate fertilization in Cajamarca

Silvia Aguero-Aguilar[1]; Luis Tomassini Vidal[1]; Mario Tapia Nuñez[1]
Universidad Nacional Agraria La Molina[1]

The grains of *Lupinus mutabilis* Sweet "chocho" are high in phosphorus and concentrate up to 50% protein, it is very important for food security. The production system of *L. mutabilis* and its response to phosphate fertilization are analyzed. In the district of La Encañada (2500 -3700 ma.s.l), Cajamarca (Peru), a RCBD was established on sloping plots and embankments, fertilized with triple calcium phosphate super (46% P_2O_5) at 0, 40 and 80 kg.ha-^{1}. We evaluated biological parameters, size and number of nodules, yield, whose results were processed in INFOSTAT v.2017 (LSD Fisher α=0.05). When the phosphorus dose was increased, significant differences were recorded for hillsides in grain yield, pod number/plant, pod length, number of grains/pod, weight of grains/plant, weight of 250 grains, size and number of nodules. In terraces, it responded significantly only in number of grains/pod, size and number of nodules. The 36.4% farmers planted chocho on fallow/fallow land. The profitability of the Benefit/Cost crop was 1 to 4. Phosphate fertilization to soils can be included in the slope fertilization plans under the principles of how much, how and when, to improve grain quality, farmer's economy and food security.

(7352 - 1312) Soil chemical attributes as a function of the superficial and localized phosphate fertilization for the soybean in the Cerrado

Mayara Martins e Martins[1]; Vitor Vargas[2]; Mathaus Mandro[1]; Paulo Sergio Pavinato[1]
ESALQ/USP[1]; SLC Agrícola SA[2]

The soybean crop is highly demanding in soil available phosphorus (P), and the supplement of this nutrient via phosphate fertilizers promotes significant increases in production, even in the first years of cultivation in cerrado opening areas. The P is almost immobile in the soil and can reach the plant root by diffusion. Phosphate fertilizers in Brazilian farms are usually applied localized at the planting furrow or broadcasted all over the soil surface with or without incorporation. Based on this, the objective was to evaluate soil chemical attributes in response to different levels and management of phosphate fertilizer application. The experiment, conducted at the Pioneira farm - SLC Agrícola SA, located in Querência (MT), a region of the current agricultural expansion of the Brazilian Cerrado, is in a recently cultivated area, which is under a soybean-millet (cover crop) succession system since 2014/15. The soil of the area is classified as Hapludox (Latossolo Vermelho-Amarelo distrófico) with 30% clay content. The experimental design in randomized blocks arranged in the factorial scheme 2x5+1, consisting in two phosphate management applications; in the sowing furrow (Xingu seeder) and broadcasted (Brutus distributor), with five doses of P_2O_5: 60, 120, 180, 240, 300 kg ha^{-1}, in addition to a control treatment without P application. Based on the soil chemical analysis performed after three consecutive years of cultivation, significant changes were observed in the resin-extracted P in the 0-5 and 10-20 cm layers, while the organic matter was only modified in the first layer. The superficial (broadcasted)

application was effective in increasing resin P in the layer 0-5 cm, being the localized application in the furrow more efficient to alter this attribute in the deepest layer, of 10-20 cm. For the other nutrients and chemical attributes (Ca, Mg, S, K, Al, H + Al, m% and V%) no trend was observed between the application management and the doses used. In general, localized fertilization (furrow) is more efficient when opening new areas of Cerrado since the P applied via fertilizer is better exploited in the soil profile, reaching layers of 10-20 cm.

(1179 - 1454) Sugarcane yield and technological quality under phosphate sources and filter cake applied at plant establishment.

Thais de Marchi Soares[1]; Valdevan Rosendo dos Santos[2]; Amin Soltangheisi[1]; Gabriel Cato[1]; Henrique Coutinho Junqueira Franco[3]; Oriel Kolln[3]; André Cesar Vitti[4]; Paulo Sergio Pavinato[1]

Luiz de Queiroz College of Agriculture- ESALQ/USP[1]; Federal University of Alagoas - UFAL[2]; National Center for Research in Energy and Materials - CNPEM[3]; São Paulo Agribusiness Technology Agency - APTA[4]

The guarantee of high sugarcane productivity in restrictive environments, especially in soils previously occupied by pastures, with low natural fertility and low available phosphorus (P), is one of the main challenges of the Brazilian sugar and ethanol industry. Several strategies may be integrated in order to provide satisfactory P levels for good sugarcane productivity, like the use of soluble phosphate sources (single or triple superphosphate), natural rock phosphates and organic sources such as filter cake. The use of filter is profitable since it is a by-product of the sugar-ethanol plant and presents high P content, which is gradually made available through the mineralization processes, which can turn the use of this waste an environmentally feasible and inexpensive source of nutrients. However, there is still a gap regarding the action of this source in association with mineral fertilizers in soil P dynamics in restrictive areas. This work aimed to evaluate the effect of soluble and reactive phosphate sources associated with filter cake on the yield and quality of sugarcane in an expansion area (sandy soil) and in established area for long time (clayey soil). The sources used were triple superphosphate and reactive rock phosphate at the rates of 90 and 180 kg P_2O_5 ha^{-1}, associated with 10 Mg ha^{-1} DM of filter cake. The parameters evaluated were: sugarcane yield, biometry, nutrient extraction in the tissue and technological analysis (Pol%, total recoverable sugar (TRS), tonne of sugar per hectare (TSH) and total sugar). The association of filter cake with mineral fertilizers increased yield, TRS, TSH and extraction of P by sugarcane in the first year in both soils evaluated. In the second year, there was an increase in TRS, Pol% and in the yield just in the sand soil area with the addition of filter cake. The association of the filter cake with rock phosphate can be considered a good management option due to the higher release of P in the first year and by the important residual effect of the rock phosphate throughout the cycles of the culture.

(2058 - 1911) The anticipation of phosphate fertilization on the maize crop

Murilo Mendes Machado[1]; Pedro Rocha Santos[1]; Miguel Martins Neto[1]; Victor Gustavo Soares Ribeiro[1]; Bruna Resende Martins[1]; Carlos Henrique Eiterer De Souza[1]

Centro Universitário de Patos de Minas[1]

The phosphorus (P) is one of the main nutrients responsible for the limitation of the grains development in maize crop, having an important role on the breathing and photosynthesis. However, despite the great importance of phosphorus to the plants, the most of Brazilian soil the phosphorus present the lack of adequate concentrations of nutrient and the strong soil interaction, resulting in fixation as well as do not supply the demand of the plant. Although, the objective of this study was evaluate the earlier application of phosphate fertilizer on the maize crop. The experiment was conducted in a greenhouse located at Campus do Centro Universitário de Patos de Minas (UNIPAM), Patos de Minas, Minas Gerais State, Brasil, in plastic pots of 5 dm^{-3}. The used soil is classified as Dystrophic Clayey Red Latosol. It was used the randomized complete block design in double factorial scheme, corresponding to 4 phosphate fertilizer sources x 6 time of earlier fertilization with four repetitions. The phosphate fertilizers sources were conventional triple superphosphate, polymer-coated triple superphosphate, polymer-coated MAP and conventional MAP, the anticipation time are 0, 15, 60, 90, 120, 150 days before the sowing. The used dose was 200 mg dm^{-3} of P_2O_5, it was corrected to the respective used fertilizers concentration according to their concentration. The evaluation used were stem diameter, plant height, performed 60 days after the sowing. The data, were submitted to the variance analysis, the compared averages by Tukey test with significance of 0,05 and the time adjusted to the regression model. For the stem diameter analysis, there was significant difference between the sources, wherein, the conventional and polymer-coated MAP sources presented better results than the others. For this evaluation there is no regression adjustments for the time tested. For the height plant did not have interference from anyone factors. Thus, the conventional and polymer-coated MAP application enable greater gain in corn plant stem diameter, and the treatments did not influence on the corn plant height. On the studied conditions, the anticipation of phosphate fertilization up to 150 days before the sowing does not reflect in loss of stem diameter and corn plants height in a greenhouse.

(8697 - 2503) Transitions to sustainable management of phosphorus in Brazilian agriculture

Paulo S Pavinato[1]; Paul J A Withers[2]; Marcos Rodrigues[1]; Amin Soltangheisi[1]; Teotonio S. de Carvalho[3]; Luiz R G Guilherme[3]; Vinicius de M Benites[4]; Luciano C Gatiboni[5]; Djalma M G de Sousa[6]; Rafael de S Nunes[6]; Ciro A Rosolem[7]; Fernando D Andreote[1]; Adilson de Oliveira Jr[8]; Edson L M Coutinho[9]

ESALQ/USP[1]; Bangor University, UK[2]; UFLA[3]; Embrapa Soils[4]; UDESC[5]; Embrapa Cerrados[6]; FCA/UNESP[7]; Embrapa Soybean[8]; FCAV/UNESP[9]

Brazil's large land base is important for global food security but its high dependency on inorganic phosphorus (P) fertilizer for crop production is not a sustainable use of a critical and price-volatile resource. A new strategic analysis of current and future P demand/supply concluded that the nation's secondary P resources which are produced annually (e.g. livestock manures, sugarcane processing residues) could potentially provide up to 20% of crop P demand by 2050 with further investment in P recovery technologies. However, the much larger legacy stores of secondary P in the soil could provide a more important buffer against future P scarcity or sudden P price fluctuations, and enable a transition to more sustainable P input strategies that could reduce current annual P surpluses by 65%. Here we examine the current and future P demand of Brazilian crop production, and investigate transitional strategies for meeting this demand more

sustainably by reducing reliance on costly and finite PR resources. In summary, there is large scope to expand cropland output in Brazil without impeding the nation's extensive grazed beef production systems or contravening deforestation rules. Brazil's high P fertilizer demand leads to large inefficiency because it does not account for legacy soil P reserves. Crop production to meet demand will continue to represent a drain on global P resources unless more sustainable P input strategies are adopted. These strategies should include (a) national and regional investment in P mining and P recovery technologies to provide cost-effective domestic PR sources, or secondary P resources that can substitute for imported P, and (b) transition to maintenance, or below maintenance, P input strategies where legacy soil P stocks provide all, or a portion, of crop P requirements and reduce reliance on diminishing PR reserves. With a bank of soil P fertility for long-term P security, farming systems could be redesigned to perform profitably and efficiently under lower levels of soil P fertility.

(3317 - 1581) Triple superphosphate granulation with biochar: kinetics of P release

Denison Pogorzelski[1]

Universidade Federal de Viçosa[1]

Phosphate fertilization presents low efficiency, mainly in tropical soils. In general, highly weathered soils had oxidic mineralogy, clayey texture and low organic matter content. These characteristics favor the adsorption of phosphorus (P) by soil, reducing the availability of P to plants. Slow release fertilizer (SRF) has been considered a promising strategy to improve the nutrient supply. Currently, SRF are composed of synthetic polymers that increase the cost of production. Biochar (BC) is a potential alternative to replace polymers, due to its low cost and sustainable technology. BC has physicochemical characteristics that can influence release kinetics, such as porosity and surface charges. In this sense, point of this study was to synthesize an SFR composed by BC. To investigate the P release kinetics of the triple superphosphate (TS) and organomineral, granules (3.35 – 4.00 mm) were synthesized from the feedstocks: BC (wood chips *Eucalyptus sp*. pyrolyzed at 350 °C for 1 h) and TS, both powders. The BC was added to the TS in two forms: blending or coating. In addition, BC was added to TS in three doses (5, 15 and 25 % of BC w/w). In granulator rotative, six organominerals and one control (TS) fertilizers were produced. P release assay was performed on a continuous stirred-flow system using deionized water (20 °C) with duration 6 h for each fertilizer. Briefly, the system consists of a high performance liquid chromatography (HPLC) piston pump and a Teflon reaction chamber (17 mL) and a fraction collector collects the solution passing through the chamber at each 2 min. Moreover, specific surface area (SSA), pore volume (PV), pore size (PS) of the fertilizers were measured by adsorption of N_2 and P adsorption isotherm was performed on BC. In summary, BC showed inert behavior for P. This result suggests that kinetics of P release on granule can be governed by physical interactions between TS and BC. Furthermore, TS released 94 % of the P content in 1.5 h, blending granule (25 % BC) releases 78 % and coating granule (25 % BC) released 30 % of the P for the same test time. In addition, increasing doses of BC to TS enhanced SSA and PV in the granules. However, the coating treatment provides lower PS, which increase the residence time of the water in the pore, reducing the release kinetics of P. The coating of the TS granules with 25 % of BC allows obtaining a slow release organomineral fertilizer.

C3.3.7 - Contribution of zero tillage (no-till) to sustainable use and management of soils

(3832 - 780) biological soil decompaction using forage radish and crotalaria

Daniel Dias Valadão Júnior[1]; Franciele Caroline de Assis Valadão[1]; Natalia de Oliveira Fiorillio[1]; Paulo Rogério Guimarães[1]

Instituto Federal de Mato Grosso, Campus Campo Novo do Parecis.[1]

In tropical no-till system, it is common the appearance of compacted layers due to the machinery traffic and the absence of coverage. Routinely, the elimination of this layer is done with the use of mechanical equipment, being the system undone. It is worth remembering that the reduction of the compaction observed in the first year after soil mobilization is temporary, besides favoring the subsurface compaction. In this context, the adoption of cover plants with a deep and well-distributed root system capable of breaking compacted layers may be an alternative to mechanical methods of soil preparation, which may improve the stability of aggregates, porosity and resistance to soil penetration with additional benefits by recycling nutrients in the profile and increasing organic matter. Thus, this study aimed to propose an alternative to the use of machines for the recovery of compacted soils with the use of cover plants. The experiment was carried out in a Latossolo Vermelho Distrófico tipico in a 5x2 factorial randomized block design with three replicates. The first factor was five tractor traffic-induced compaction levels (with no additional traffic, one pass, three passes, six passes and eleven passes of the tractor), and the second factor consisted of two cover plants (Raphanus sativus and Crotalaria ochroleuca). After the traffic, the physical properties of the soil were characterized. These same properties were determined at full flowering of the crops, where root growth, dry mass productivity and green cover rate were determined. Tractor traffic changed the physical properties of the soil, affecting the analyzed variables. Comparing the physical properties of the soil before and after the cover crops, there was a reduction in soil penetration resistance (RSP) in areas with crotalaria. Values higher than 1.82 MPa RSP prevented the forage radish root growth. Mean values of RSP showed a decrease of approximately 1 MPa after the cultivation of cover crops, and Crotalaria ochroleuca had a greater influence on the decrease of RSP when compared to forage radish.

(9580 - 2175) Bulk density and total porosity of a Dystric Planosol cultivated with pepper in conventional and no-tillage management systems

Isabela Beatriz Pereira da Cruz[1]; Pedro Araújo Garcia[1]; Raíza Ritielle Carvalho Scalzer[1]; Gustavo Candido da Silva Rodrigues[1]; Nivaldo Schultz[1]

Universidade federal Rural do Rio de Janeiro[1]

Compaction is a process that alters the physical soil characteristics, resulting in increased bulk density, reduction of pore volume and consequent water infiltration into the soil, as well as its aeration. The objective of this study was to evaluate the bulk density and total porosity of a Dystric Planosol of medium texture cultivated with pepper (*Capsicum annuum*), comparing the values of the rows and between the rows at conventional and no-tillage systems. The accumulation of straw of the cover plants was 17.2 Mg ha^{-1}. The straw was incorporated into the conventional system. The experiment was developed in the Horticulture sector of the Federal Rural University of Rio de Janeiro (Universidade Federal Rural do Rio de Janeiro - UFRRJ). The experimental design was divided into subdivided plots, where the plots are the management systems, and the subplots are the rows and between the rows, with 4 replications. The experiment

was implemented in November 2016 with the sowing of the cover plants, and the evaluation was carried out in November 2017, collecting in the rows and between the rows of each management system, 0.0-10, 0.10-0.20 and 0.20 -0.40 m depth. Sampling was performed with Uhland collector and a PVC ring of 88.67 cm^3.The macro and micro soil porosity were determined by the tension table method. Soil bulk density was determined from the relationship between the dry soil mass at 105 ^oC for 24 h and the volume of the PVC ring. The data were submitted to statistical analysis using the Sisvar 5.3 program, comparing the means by the Tukey test at 5% of probability. There was no difference in the total porosity in the rows and between the rows, independently of the management system (conventional and no-tillage), as well as in the mean between the systems, at depths of 0.0-0.10 and 0.20-0.40 m, however, at the depth of 0.10- 0.20 m, the conventional system presented higher total porosity than no-tillage (39.4% and 32.6%, respectively). The increase in porosity in the 0.10-0.20 m soil layer of the conventional system is the result of soil revolving and the absence of human traffic. About the soil density, the systems did not differ, with the values of 1.56, 1.64 and 1.69 g cm^{-3} on the rows, and between the rows values of 1.53, 1.54 , 1.60 g cm^{-3}, both for the layers of 0.0-0.10, 0.10-0.20 and 0.20-0.40 m, respectively. Based on these results it is concluded that management systems do not affect total porosity and soil density over a crop cycle.

(4648 - 1378) Carbon and nutrient stocks in cronossequency of crops under no-tillage system in the eastern Amazon

Rúbia Carla Ribeiro Dantas[1]; Alessandra Danieli Miranda de Araújo[1]; Letícia Cunha da Hungria[1]; Sidney Daniel Araújo da Costa[1]; Edilson Carvalho Brasil[2]; Mario Lopes da Silva Júnior[1]
Amazon Federal Rural University[1]; Embrapa Eastern Amazon[2]

Different cropping systems and agricultural management can influence changes in organic carbon and nutrient stocks, interfering with soil quality. The objective of this study was to evaluate the influence of no-tillage (NT) system on carbon and nutrient stocks (P, K, Ca and Mg) on a Yellow Latosol (Oxisol) of the Eastern Amazon. The study was conducted in the municipality of Paragominas, southeast Pará, in an area under chronosequence of NT crops, using a completely randomized experimental design, with four replications, in subdivided plots. The plots were composed of management systems and depths (0-10, 10-20, 20-30 and 30-40 cm) were considered in the subplots. The management systems were: NT with nine (NT9), eleven (NT11), thirteen (NT13), fourteen (NT14) and fifteen (NT15) years of adoption, plus a reference treatment (native forest-NF). The stocks of organic carbon and nutrients (P, K, Ca and Mg) were adjusted to the same soil mass. Regardless of the depth, organic carbon stocks in NT9 (28.1 kg ha^{-1}) and NT11 (24.4 kg ha^{-1}) were highest than the other NT15 (18.5 kg ha^{-1}), NT14 (18.3 kg ha^{-1}), NT13 (20.5 kg ha^{-1}) and NF (19.7 kg ha^{-1}). These results may be due to management practices, such as subsoiling, carried out in areas under NT with longer adoption times, which may have caused oxidation of organic matter and as a consequence of carbon stocks. In the soil surface layers, the P stock increased in function of the time of adoption of the NT, observing that in the depth of 0-10 cm the quantities were equivalent to 18, 24, 26, 28 and 40 kg ha^{-1}, respectively, for the areas under NT9, NT11, NT13, NT14 and NT15. At depths of 10-20 cm, P stocks were equivalent to 12, 15, 18, 20 and 20 kg ha^{-1}, respectively, for the same management systems. In the 0-10 cm layer, NT15 (464 kg ha^{-1}), NT14 (484 kg ha^{-1}) and NT13 (453 kg ha^{-1}) presented highest K stocks than NT9 (360 kg ha^{-1}) and NT11 (238 kg ha^{-1}). However, in the other layers, we observed an inverse behavior, in which the NT9 and NT11 presented the highest stocks of K, in relation to the other systems. In the 0-10 cm layer, with the time of NT adoption, there was an increase in Ca and Mg stocks. However, in the subsurface layers the stocks were reduced over time of NT adoption, especially in NT13, NT14 and NT15.

(8191 - 3022) Carbon content and aggregate stability in Oxisol after ten years of cultivation under no-tillage and fertilization with swine manure

Paulo Cezar Cassol[1]; Maria Sueli Heberle Mafra[2]; Marco André Grohskopf[3]; Paulo Roberto Ernani[1]
Universidade do Estado de Santa Catarina[1]; Universidade do Planalto Catarinense[2]; Universidade Estadual Paulista[3]

Soil fertilization with organic fertilizer, such as swine manure (SM), allows high crop productivity and may favour the soil aggregation. In addition, some studies have shown that manure isolated or combined with mineral fertilizer is more efficient than only mineral fertilizer for the increase in the soil organic carbon (SOC) content. Thus, the objective of this work was to evaluate the influence of continuous annual applications of SM, mineral and combined fertilization on the soil aggregates stability and to the SOC content, within the aggregates, of a Southern Brazilian Oxisol under no-tillage corn-oat succession. The evaluation was carried out after 10 years of conducting a field experiment with the annual application of the following treatments: soluble fertilizer (SF); 25 m^3 ha^{-1} of SM plus SF; SM at the doses: 25, 50, 100, and 200 m^3 ha^{-1}; and a control without fertilization. The experimental design was randomized blocks with 4 replicates. Undeformed samples of the layers 0-2.5, 2.5-5, 5-10 and 10-20 cm of soil depth were collected in order to preserve its structure. The stability of the aggregates was determined by the weighted average diameter (WAD) and by the geometric mean diameter (GMD). The SOC contained within the aggregates was determined by de Walkley-Black method after assessing the stability of the soil aggregates retained in sieves, separating the following three diameter classes: between 8.0 and 4.75 mm (class 1), between 4.75 and 2.0 mm (class 2) and less than 2.0 mm (class 3). The treatments and the SOC content did not affect the soil aggregate stability. The SOC content in the aggregates larger than 2.0 mm increased with the increase of the SM dose up to 50 m^3 ha^{-1} $year^{-1}$ and stabilizes with the doses greater than this. The stability of the soil aggregates did not vary with the increase in the dose of SM annually applied, however the SOC content within the aggregates greater than 2.0 mm increases with the SM dose up to 50 m^3 ha^{-1} $year^{-1}$.

(5980 - 1057) Changes in spatial variability of soil properties due land use change

Valle, S.R[1]; Cárdenas, C.[2]; Zumelzu, M.[2]; Dörner, J.[1]
1Universidad Austral de Chile/Facultad de Ciencias Agrarias/Instituto de Ingeniería Agraria y Suelos. 2Centro de Investigación en Suelos Volcánicos (CISVo)[1]; 1Universidad Austral de Chile/Facultad de Ciencias Agrarias/Instituto de Ingeniería Agraria y Suelos[2]

Changes of land use, to provide land for agricultural use, livestock and forestry, is the main cause of the disturbances to the soil, not only affecting their quality and its functions, but also in the spatial variation of their properties. The objective of this study was to evaluate the spatial variability of soil properties as result of different land uses (LU) in two different soils of southern of Chile. The Hueicoya soil (HEY,

Ultisol, derived from schist) was sampled to register the total soil depth as well as samples were collected at 20 cm of soil depth under four forest land uses to measure soil organic carbon (SOC). In the second soil, Los Ulmos (ULM, Ultisol derived from volcanic ashes) two tillage systems were evaluated, conventional (CT) and No-tillage (NT), at two soil depths (0-10 and 10-20 cm). All samples were georeferenced. Different soil properties were evaluated in both studies as SOC, pH, extractable Al, Olsen-P, bulk density and air conductivity. The LU change in HEY induced differences ($p< 0.05$) for total soil depth (5-100 cm) and the SOC (1.1-10.5%), where higher differences show the consequence of soil horizon losses due to soil erosion. And, for ULM soil, there were differences ($p< 0.05$) between the tillage systems of for all the properties evaluated, where there was a decrease of some properties in NT as bulk density, kl and pH but an increase Olsen-P and SOC. These soil properties varied both spatially and considering their use, e.g., soil pH range was 5.5-6.8; bulk density, 0.56-0.81 g cm^{-3}; air conductivity, -3.28 to -5.7 (log m s^{-1}); exchangeable Al, 519-1487 mg kg^{-1}; SOC, 2.3-12.4% and Olsen-P, 2-46 mg kg^{-1}. Only for Kl can be determined the spatial dependence, for both tillage systems the model of semivariogram adjusted was exponential, but NT showed a range higher than under CT. On the other hand, soil pH and bulk density in both tillage systems cannot be possible to adjust a semivariogram model. In both soils, LU change provoked a change in soil variability pattern; for this would be advisable to shorten the separation distances in future studies.

(6789 - 1440) Chemical attributes of soil and corn production under direct sequence as a function of calcary and plaster application in the eastern Amazon

Sidney Daniel Araújo da Costa[1]; Edilson Carvalho Brasil[2]; Mário Lopes da Silva Júnior[1]; Letícia Cunha da Hungria[1]; Rúbia Carla Ribeiro Dantas[1]
Universidade Federal Rural da Amazônia[1]; Embrapa Amazônia Oriental[2]

The correction of the soil acidity in the area under no-till from the application of limestone becomes limited, due to the low movement of bases without profile. The use of lime with agricultural plaster is a viable alternative, as it favors the vertical movement of bases in the profile. The objective of this study was to evaluate the effect of the combined application of lime and gypsum on soil chemical attributes and corn grain yield under no - till during three crop cycles. The experiment was conducted in Terra Alta, Pará, in the Brazilian Amazon, in the cycles from 2010 to 2012, in a dystrophic Yellow Latosol. A randomized complete block design with three replicates. The treatments were lime (0, 1, 2, 3, 4 t ha^{-1}) and gypsum (0, 500, 1000 kg ha^{-1}). The corn was sown with spacing of 70 cm between the rows, with five plants per linear meter. In the first and third agricultural years, in the 0-20 cm layer, an application of increasing doses of lime promoted a linear increase in soil pH (y_{2010} = 4.522+0.293x R^2 = 0.98; and y_{2012}=5.0148+0.236x R^2=0.94 while in the second year there was interaction between the doses of limestone and gypsum, however the pH remained, even on the influence of the gypsum. In all years, an application of reduced lime or Al^{3+} content, with more effective action in the superficial layers. Not the first year, the Al^{3+} had the behavior y_{2010}=0.5369e-0.449x R^2=0.980. In the second year, there was a greater reduction in Al^{3+} contents in the 0-10 cm layers (y_{2011}=0.392+0.141x-0.0171x2 R^2=0.89) and 10-20 cm (y_{2011}=0.584e-0.364x R^2=0.91). In the third year, there was a greater influence of the lime on the Al^{3+} levels in the layers of 0-10 (y_{2012} = 0.669 + 0.3004x-0.0492x2 R^2=0.97) and 10-20 cm (y2012=0.684+0,3359x -0.0538x2 R^2 = 0.98). In the first year, an interaction between limestone and gypsum increased Ca+Mg content in the 0-10 cm layer (y=1.493+0.4x R^2 = 0.98) and 10-20 (y=0.901+0.467x-0.0978x^2+0.4667x R^2=0.66). What is the measure of increases, especially in the layer up to 20 cm (y_{2011}=1.556+0.29x R^2=0.97, and y_{2012}= 0.828+1.0062x-0.1024x^2 R^2 = 0.98). There was an increase in the grain yield with an application of limestone and gypsum in the years (y_{2010}=2574+208.71x R^2=0.76, y_{2011}=3939+500.97x-59.869x2 R^2 = 0.70, and y_{2012} = 4653+256,54x-20.886x2 R^2 = 0.54). The application of limestone, associated or not with gypsum, promoted improvements in chemical attributes, with positive effects on the production of corn grain

(7332 - 1309) Chiseling efficiency in the reduction of soil mechanical resistance to penetration o under maize no-tillage system

Lizete Stumpf[1]; Paulo César Conceição[1]; Márcia Kochem[1]; Vitor Cauduro Girardello[2]; Maiara Karini Haskel[1]; Weslei Sbalcheiro[1]
Universidade Teconológica Federal do Paraná[1]; Universidade Regional Integrada do Alto Uruguai e Missões[2]

The objective of the study was to evaluate the chiseling efficiency in the reduction of soil mechanical resistance to penetration of an Oxisol under maize no-tillage. Before the implantation of the experiment, the soil presented a mechanical resistance to penetration greater than 3 MPa in the 0.05-0.20 m layer. In May 2015, the four chiseling systems were implanted under a randomized block design with three replications: a) No-tillage chiseling only in the start of experiment (2015) with Jumbo equipment; b) No-tillage chiseling only in the start of experiment (2015) with Terrus equipment; c) No-tillage chiseling annually (2015 and 2016) with Jumbo equipment; d) No-tillage chiseling annually (2015 and 2016) with Terrus equipment. No-tillage with no disturbance was used as a control. In July 2015 and May 2016, sowing of winter cover crops: Oats (60 kg ha^{-1}) + Vetch (30 kg ha^{-1}) + Radish (10 kg ha^{-1}), called the consortium. The soil mechanical resistance to penetration determination were made in March 2016 (after maize harvest and before chiseling), in April 2017 (after maize harvest and before chiseling) and November 2017 (after maize planting and 7 months after chiseling). The data presentation of 0.00-0.05 m, 0.05-0.10 m, 0.10-0.20 m and 0.20-0.40 m layers. Values of less than 0.5 MPa in the 0.00-0.05 m layer were observed in all evaluations, independent of the chiseling system. In the 0.05-0.10 m layer, the soil mechanical resistance to penetration values decreased substantially in relation to the initial characterization, remaining below 1.50 MPa after 12, 24 and 30 months, independent of the chiseling system. After 12 months, the initial soil mechanical resistance to penetration of the layer of 0.10-0.20 m (3.39 MPa) passed to 2.80 MPa in the soil under No-tillage, while the soil under chiseling had values between 1.5-2.0 MPa. However, after 24 months, the soil mechanical resistance to penetration under No-tillage was lower than 2.50 MPa, while the soil under chiseling, consecutive or not, continued to present values between 1.5-2.0 MPa. The initial soil mechanical resistance to penetration values of the experimental area indicated a restriction to the maize root development in the 0.10-0.20 m layer (values close to 3.5 MPa). However, during the evaluation period these were reduced in both chiseling systems, as well as in that in which only the root activity of the maize/consortium (No-tillage) succession was predicted.

(5691 - 1653) CO_2 emission and rearrangement process of soil in short term after soil management submitted to different intensities

Bruna de Oliveira Silva[1]; Mara Regina Moitinho[1]; Gustavo André de Araújo Santos[1]; Ludhanna Marinho Veras[1]; Luiz Fernando Favacho Morais Filho[1]; Daniel de Bortoli Teixeira[1]; Carolina Fernandes[1]; Newton La Scala Júnior[1]
FCAV/UNESP – College of Agricultural and Veterinarian Sciences, Sao Paulo State University[1]

This study aimed to investigate the CO_2 emission (FCO_2) associated to physical properties in the rearrangement process of soil the in short term after soil management was submitted to different intensities. The study was conducted in an agricultural area located at FCAV / UNESP in the municipality of Jaboticabal, São Paulo, Brazil (21º15 'S 48º18' O). The soil was classified as a typical Oxisol Red eutrophic, a clayey texture. The study was conducted in three adjacent areas, measuring 10 x 3 m each, in which two soil tillage systems were performed: (i) rotary hoe + conventional harrow representing a much more intense soil tillage; (ii) disc plowing + disc harrowing, characterizing a reduced soil tillage, and in the third area was no-tillage, without disturbance. After the was management conducted 17 days of evaluations. The daily averages of FCO_2, soil density (g^3 cm^{-3}) and resistance to penetration (MPa) were compared for the different management systems, and they were done by the Scott-Knott test, at a significance of 5% probability. On the first day after management, FCO_2 was 87% higher in intense soil tillage (3,86 µmol m^{-2} s^{-1}) when compared to soil tillage (2,06 µmol m^{-2} s^{-1}) and it was 147% higher when compared to the area without disturbance (1,56 µmol m^{-2} s^{-1}). To soil bulk density ($F = 4.01$, $p < 0.0001$) and soil pentration resistance ($F = 2.26$, $p < 0.0001$), significance was observed in the interaction between managements and time. Soil under no-tillage management had higher average values of soil bulk density and soil pentration resistance, this fact is expected due to the characteristics of this soil, in which a small compaction occurs until the layer of 0-0.20 m depth, when compared to the areas with soil managent. The three treatments evaluated presented a similar pattern of temporal variation for soil bulk density and soil pentration resistance. This fact may be indicative of the process of soil consolidation in intense soil tillage and soil tillage, through the mechanisms of particle rearrangement. The physical soil attributes: soil bulk density, soil pentration resistance showed lower variation from day 12 after soil management, this effect was considered in this study as a natural process of soil consolidation, and this process may also have influenced the temporal variation of soil CO_2 emission.

(5920 - 2614) Content of Deep Organic Carbon and Total Nitrogen in Oxisol: Long-Term Effect of Tillage and Crop Rotation

Enza Rigon[1]; Telmo Jorge Carneiro Amado[1]; Carlos Bonini Pires[1]; Geovane Reimche[1]; Cristiano Keller[1]; Charles W. Rice[2]
Universidade Federal De Santa Maria[1]; Kansas State University[2]

The expansion of agriculture with the intensive use of tillage systems (plowing, disking, among others) promoted the decrease of up to 75% of the original levels of organic matter of the soils under forest or natural pastures. In 12,000 years of agriculture and most notably in the last 200 years, about 133 trillion tons were lost due to the increase in the rate of mineralization of organic matter or erosion of agricultural soils under intensive tillage. In contrast, the development of new agricultural production systems, such as the no-tillage system, promoted the partial recovery of soil carbon content, contributing to greater sustainability in agriculture. In this way, the objective of this study was to evaluate the impact of 32 years of soil management systems and crop rotation about the carbon and nitrogen content up to 0.90 m deep of an Oxisol. The experiment was established in 1985 on a Typic Hapludox in Cruz Alta-RS (Brazil) under a no-tillage (NT) and conventional tillage (CT). Three different cropping systems were studied: wheat (Triticum aestivum L.)/soybean (Glycine max (L) Merr.) (R1); oat (Avena strigosa (L.) Schreber)/soybean/oat+vetch (Vicia sativa (L.) Walp.)/corn (Zea mays L.)/radish (Raphanus sativus L.)/wheat/soybean (R2) and oat/soybean/wheat/soybean (R3). The NT was performed by sowing the crops with a minimal soil disturbance while CT consisted of disk plow (20cm) followed by harrow disk (10cm) prior summer crops sowing and disk harrow before the winter crops. Further soil and crop management practices followed regional best management practices. Total C and N were determined by dry combustion using a CN Soil Flash Elemental Analyzer EA 1112 Series (Thermo Finnigan Italy, S.p.A., MI, Italy) using 50 mg soil sample. Results were tested throughout ANOVA using the R software. The main results show a tillage x depth interaction and means reveal that the use of NT enhance C and N levels when compared to CT, mainly at the 0-5cm top layer. The C contend was 2.77 and 1.72 g kg-1, under NT and CT respectively. The N contend was 2.20 and 1.30 g kg-1 under NT and CT respectively. The results demonstrate that NT system under tropical conditions is effective in maintaining and sustaining organic soil carbon and nitrogen.

(4078 - 1950) Controlled traffic farming in no-tillage system in southern Brazil

Tiago De Gregori Teixeira[1]; Telmo Jorge Carneiro Amado[1]; Geovane Boschmann Reimche[1]; Emanuel Roggia[1]; Darlan Preuss[1]; Marcieli Piccin[1]; Arthur Kich Buhse[1]; Enza Rigon[1]; Gustavo Henrique dos Santos[1]
UFSM[1]

The increasing food demands are requiring the adoption of enhancing crop productivity techniques that are more economically profitable, and especially environmental friendly. Aiming the land usage efficiency and soil and water conservation, the no-till system is well adapted with tropical soils, climate and crops and is adopted in the most part of annual crop producers in Brazil. One of the common problem that areas managed under no-till face are the surface and subsurface soil compaction, harming annual crop root development. Soil compaction reduces micropores so affecting water infiltration capacity thereby stimulating the surface runoff water and consequently favoring the occurrence of rill and interrill erosion favored by steep relief. The increase in density in soil under no-till can be caused by a number of factors, such as cattle, or disorderly displacement of implements and soil managed under excessive soil moisture. Also, the increase of weight of new agricultural equipment by keeping similar area of soil contact, can contributed to compaction. The aim of this work is to study the controlled traffic technique to reduce random compaction in an area managed under no-tillage. For this purpose, traffic lines were established taking into account relief surveys and area format, adjusting the gauges and work widths of the equipment in order to reduce unnecessary strides. The implements have been adapted to work with a width of 3.05m, since the working widths of the seeder and harvester are 9.00meters (m), while the sprayer works in the width of 27.00m. The experimental area is located in the municipality of Carazinho - RS, southern Brazil, presenting a soil classified as a dystrophic Red Oxisol and the Cfa type

climate. The first results indicate that areas managed by traffic control when compared to tradition traffic present higher soil density (0.72%), macroporosity (26.41%) and total porosity (1.01%), while lower microporosity (-4.44%) Results show that soybean cultivated during 2016/17 summer season yield 10.9% higher grain yield and the cover crop (oat) during the 2017 winter season, cultivated after summer crop, presented 33.63% higher dry mass, under traffic control treatments compared to traditional ones.

(7261 - 787) Corn-crotalaria intercropping systems

Franciele Caroline de Assis Valadão[1]; Daniel Dias Valadão Júnior[1]; Vinicius Rossi Ribeiro de Paula[1]; Rafael Torres de Souza[1]; Paulo Rogério Guimarães[1]
Instituto Federal de Mato Grosso, Campus Campo Novo do Parecis.[1]

In Brazil, corn is the crop that consumes most of nitrogen fertilizer; this is due to the requirement of the crop and the large loss of fertilizer applied. Thus, alternative methods that improve the efficiency in the use of N in the system are important for the sustainability of the productive process. In this sense, crotalaria can play a key role in reducing the use of synthetic nitrogen sources in the corn production system by being able to fix high amounts of N per hectare and make it available for the following crop. Another possibility is the intercropping where the main crop would take advantage from N fixed by the legume, either by the direct excretion of nitrogen compounds or by the decomposition of nodules and roots, which will decompose and release nutrients during the development of the main crop. Thus, the goal of this study is to find an intercropping system between corn and crotalaria aiming at the production of straw while maintaining corn yield. To do so, a randomized complete block experiment was carried out in 2015 and 2016, with 7x2 + 1 subplots and three replications on a Latossolo Vermelho Distrófico tipico, with seven intercropping types assigned to the plots, and the species of crotalaria (*Crotalaria spectabilis* and *Crotalaria ocrholeuca*), to the subplots with an additional treatment of single corn. The productive attributes of crotalaria, chlorophyll and total nitrogen, shoot height, shoot dry mass, and thousand grain mass were evaluated. *C. spectabilis* was more sensitive to water fluctuation during the development cycle. Crotalaria sown before corn cultivation with the incorporated seeds present higher phytomass production, but reduce corn productivity. The management in which the crotalaria is sown in the corn interrow using a furrower at the time of corn sowing, as well as the one in which the crotalaria is sown in the corn sowing furrow, are feasible because they provide straw production, do not reduce corn productivity, and not interfere with corn harvesting operations.

Keywords: Zea Mays, *Crotalaria spectabilis, Crotalaria ocrholeuca*)

(3970 - 205) Data mining techniques for classification of soil CO_2 emission

Camila Viana Vieira Farhate[1]; Zigomar Menezes de Souza[1]; Stanley Robson de Medeiros Oliveira[2]; Lenon Herique Lovera[1]; Ingrid Nehmi de Oliveira[1]; Euriana Maria Guimarães[1]
State University of Campinas (Unicamp), Agricultural Engineering (Feagri)[1]; Brazilian Agricultural Research Corporation (Embrapa), Agricultural Informatics, Computational Intelligence Laboratory (LABIC)[2]

A high priority objective currently in the scope of carbon cycle science is to understand the spatial and temporal controls involved in CO_2 dynamics in terrestrial ecosystems. However, estimates of CO_2 emissions from soil to the atmosphere through production systems are difficult and complex due to the diversity of agricultural practices in large areas and significant variations in both soil and climate. In contrast, data mining is a promising alternative to predict soil CO_2 emission from correlated variables. Thus, our objective was to construct a model using data mining techniques, such as selection of attributes and induction of decision trees to predict different levels of CO_2 emissions in the soil. The original data set was composed of 23 attributes (22 predictive attributes and one response variable). The response variable refers to the emission of CO_2 from the soil as the target of the classification. Due to the large number of attributes, a procedure for selecting attributes was conducted to remove those of low correlation to the response variable. For this purpose, we assessed four approaches to attribute selection: no attribute selection, correlation-based attribute selection (CFS), Chi-square method (χ^2), and Wrapper method. For data classification, we used the binary decision tree induction technique on Weka 3.6 software. Our results demonstrated that the data mining techniques allowed the development of an efficient model to classify soil CO_2 emission using the Wrapper method of attribute selection as well as algorithm C4.5 for induction of the decision tree. Wrapper method selected an efficient subset for soil respiration prediction with only five attributes, with the following influence order on the determination of soil CO_2 emission: soil temperature> rainfall> macroporosity> soil moisture> potential acidity. The attributes selected through the Wrapper method have high coherence with literature data regarding both the selected attributes and the decision tree rules.

Keywords: Decision tree, soil attributes, selection of attributes.

(8342 - 3121) Degree of clay flocculation and soil organic carbon stocks under no-tillage as affected by chiseling and gypsum application in southern Brazil

Esmael Lopes dos Santos[1]; Caroline Honorato Rocha[2]; Victor José Agassi[3]; Douglas Henrique Tonsic[3]; Henrique Debiase[1]; Julio Cezar Franchini[1]; Gislaine Silva Pereira[4]
Embrapa Soja, Londrina - PR[1]; Universidade do Oeste Paulista, Presidente Prudente - SP[2]; Universidade Filadélfia de Londrina, Londrina - PR[3]; Universidade Estadual de Londrina, Londrina - PR[4]

Soil compaction under no-tillage (NT) has been a major concern among soybean producers in Southern Brazil. High machinery traffic intensities in wet soils, and low adoption of diversified crop rotations have been pointed out as the main factors leading to critical levels of soil physical degradation to crop production. In some cases, soil chiseling has been indicated to mitigate compacted soil layers in NT, increasing soil macroporosity, water infiltration and reducing soil resistance to root growth. Additionally, gypsum has been widely used in Southern as soil amendment to increase Ca^{2+} and SO_4^- contents and neutralize Al^{+3} mainly at deep layers, enabling soybean deep-rooting. However, the effects of chiseling and gypsum application on water-dispersible clay and soil organic carbon (SOC) stocks are poorly understood considering clayey soils from tropical regions managed under long-term NT. This work aimed at evaluating the degree of clay flocculation and SOC stock in response to soil chiseling and gypsum application in a clayey Oxisol from Southern Brazil, managed under long-term NT. The experiment was carried out in Londrina, Parana State, Brazil, following a 2x2 factorial arrangement in a complete randomized block design, with three replications. Treatments consisted of two management systems [continuous NT, and chiseled NT (NTC)], with or without gypsum application (broadcast application of 3.5 Mg ha^{-1}). Chiseling and gypsum application were perfomed in

May, 2014. All treatments were cultivated with wheat from May to September, 2014, and with soybean from October to March, 2015. After soybean harvest, soil samples were taken from 0,0-0,1; 0,1-0,2; and 0,2-0,4 m soil layers, to determine SOC, water- and NaOH-dispersible clay contents. Degree of clay flocculation (DCF) was estimated as the ratio between water- and NaOH-dispersible clay. Soil cores were sampled at the same depths to determine soil bulk density, enabling SOC stocks quantification. Gypsum application significantly increased DCF under NT, improving soil aggregation and structure. Conversely, gypsum application did not influence DCF in NTC. SOC stocks at 0,0-0,4 m depth were higher in NT (48,4 Mg m^{-3}) than in NTC (45,2 Mg m^{-3}). Gypsum application did not affect SOC stocks. In conclusion, NT in association with gypsum application are important strategies to enhance soil aggregation and structure.

Keywords: Soil structure, aggregation, soil compaction.

(6699 - 2684) Glomalin-related soil protein after two decades of different tropical soil management

Aristides O Ngolo[1]; Sandro LS Moreira[1]; Maurílio Fernandes de Oliveira[2]; Genelício Crusoé Rocha[1]; Igor Rodrigues de Assis[1]; Raphael BA Fernandes[1]
Universidade Federal de Viçosa[1]; EMBRAPA MILHO E SORGO[2]

Glomalin is a glycoprotein released to the soil by arbuscular mycorrhizal fungi. This protein plays a fundamental role in the formation and stability of soil aggregates and is related to reducing soil losses by erosion. This study was carried out in an experimental area of EMBRAPA Milho e Sorgo (Sete Lagoas, MG, Brazil), where three types of soil management for long period (> 20 years) were selected [disc plough (DP), no-tillage (NT), Grid with subsoiler (GS)] besides a natural cerrado (NC) area, used as reference. Soil samples were collected in the surface layer (0.00 to 0.10 m) and were submitted to extraction of two fractions: easily extractable glomalin (EEG) and total glomalin (TG), which are quantified according to colorimetric method using serum albumin bovine as the standard protein. Data of contents of EEG and TG were submitted to ANOVA and mean values of the treatments were first compared using Dunnet test ($p < 0.10$) to verify differences between soil management practices and natural cerrado. After that, Tukey test ($p < 0.10$) was performed aiming comparison between soil management treatments. Results obtained for easily extractable glomalin (NC: 12.8 mg g^{-1}, DP: 14.0 mg g^{-1}, NT: 12.6 mg g^{-1}, GS: 12.2 mg g^{-1}) indicated no means differences between soil management practices and reference (NC). Among soil management treatments, difference were identified just between DP and GS, and values obtained for NT were similar to these both treatments. For total glomalin (NC: 50.2 mg g^{-1}, DP: 32.61 mg g^{-1}, NT: 27.8 mg g^{-1}, GS: 34.55 mg g^{-1}), just PD treatment differed and presented lower mean value than the reference (NC). No differences among soil management practices was verified. Based on these results, two decades of soil management practices do not result in changes in easily extractable glomalin, but present a tendency to reduce total glomalin. Since glomalin-related soil protein is related to physical soil quality, practices should invest in increasing soil organic matter contents aiming to increase the biological activity and glomalin production.

(1986 - 2847) Gypsum and Limestone application methods: Wheat yield, plant mineral nutrition and chemical soil attributes

Marcos Renan Besen[1]; Eunápio de Oliveira Costa[1]; Antônio Feijó Goes Neto[1]; Michel Esper Neto[1]; Fabricio Linhares Mazzi[1]; Lucas Simas de Oliveira Moreira[1]; Tadeu Takeyoshi Inoue[1]; Marcelo Augusto Batista[1]
Universidade Estadual de Maringá[1]

Brazilian tropical soils are mostly acidic soils, with the presence of toxic aluminum (Al^{3+}) and low calcium content (Ca). In no-till system (NT) liming is applied at the soil surface without incorporation of same. Due to the low limestone solubility, the corrective effects are limited as surface layers. Gypsum (GY) is an option to increase the Ca content and decrease the Al^{3+} activity in the soil subsurface. The objective of this work was to evaluate the effect of GY, surface (SL) and/or incorporated liming (IL) on the magnesium (Mg), Ca and sulfur (SO_4^{2-}) levels in an Oxisol and wheat mineral nutrition. The experiment was carried out in Campo Mourão, Paraná, Brazil. The experimental design was randomized blocks in a factorial arrangement 4 x 2 + 3, four levels of base saturation (BS) (44, 60, 70 and 90%); two methods of limestone application (SL and IL) and three additional treatments, involving the use of limestone associated with GY: BS-60% + 3.71 Mg ha^{-1} of GY; BS-70% + 3.71 Mg ha^{-1} of GY and BS-70% + 7.42 Mg ha^{-1} of GY. It was used dolomitic limestone (PRNT 82%). The cultivar TBIO Toruk was sown on May 12, 2017. It was applied 150 kg ha^{-1} of NPK formulation 16-16-16. Leaf tissue samples were collected during the flowering and soil samples were performed at 0.00-0.05, 0.05-0.10, 0.10-0.20, 0.20-0.30, 0.30 -0.40 and 0.40-0.60 m depths after a wheat harvest. The BS levels were unfolded in each liming application form and additional treatments compared to each factorial ($p < 0.10$). A harvest was performed on September 20, 2017. BS and form of limestone application did not influence S absorption, however, Mg and Ca increased linearly in IL. The higher GY dose increased Ca and S leaf contents and decreased Mg contents. SL increased pH and Ca content to 0.10 m and Mg up to 0.30 m, but IL increased Ca up to 0.40 m, pH and Mg up to 0.60 m. GY decreased Mg in superficial layers and increased Ca content in depth (0.40-0.60 m). BS levels did not influence SO_4^{2-}, but GY increased the SO_4^{2-} levels in all profiles. Yield in IL treatment was adjusted to the quadratic model, with a maximum point in 75% BS. GY treatments increased the yield in relation to the two BS lower levels of the IL. However, the mean SL yield (5,597 kg ha^{-1}) showed that although IL increased pH in depth, the best responses were observed without SL. In NT (SL) there was no increase in yield with the limestone application. The BS that provided the highest productivity was 75% in IL.

(6813 - 1974) Identifying indicators in a structurally fragile tropical soil to recommend management practices and prevent land degradation in the Amazonian periphery

Vinicius Ribamar Alencar Macedo[1]; Virley Gardeny Lima Sena[2]; Clemeson Cardoso Vale[3]; Stéfanny Barros Portela[1]; Carlos César Martins de Souza[1]; Alana das Chagas Ferreira Aguiar[4]
UEMA[1]; UNESP[2]; IFMA[3]; UFMA[4]

In the Amazonian periphery, farmers need to intensify their productivity and be assured of the sustainability of the areas designated for crops, to prevent illegal deforestation of new areas. The aim of this study was to identify the main indicators that affect crop productivity in a structurally fragile Amazonian soil, and to determine the importance of maize yield indicator and their relationships with promising management practices to intensify crop production in agricultural areas in a sustainable way. The experiment

was established with three leguminous species, *Clitoria fairchildiana*, *Acacia mangium* and *Leucaena leucocephala*, and an area without leguminous plants. Maize was sown between the rows of leguminous plants. Chemical and physical soil properties and maize grain yield were determined. Multiple linear regression, hierarchical partitioning analysis and spatial variability were used. Our results suggest the possibility of intensifying crop production in tropical soil prone to hardsetting through soil management practices, because Calcium (Ca) and soil organic matter (SOM) contents were highly correlated and exerted strong influence on maize grain yield (accounted for 30 up to 50 % of maize yield in two years). Other indicators like macroporosity, soil density and resistance to penetration, which also influenced the yield, were correlated with Ca and SOM, both of which can be increased or improved by agronomic practices. It is worth highlighting that due to negative influence of pH on total independent contributions to increased organic matter, higher calcium contents must be achieved by gypsum application rather than using liming material.

(3133 - 2007) Land use and land cover dynamics in western Haiti

Wesly Jeune[1]; Eliana de Souza[2]; Márcio Rocha Francelino[2]; Elpídio Inácio Fernandes Filho[2]; Genelício Crusoé Rocha[2]
Université Quisqueya[1]; Universidade Federal de Viçosa[2]

The guidelines for public policies on environmental planning and recovery can be based on detailed studies on changes in land use. This work aimed at assessing the changes in land use and land cover in western Haiti (~4300 km^2), through imagery classification of three-date (1986, 2000 and 2014) on 28-year period. The satellite imageries of Landsat-5, Landsat-7, and Landsat-8 were processed for atmospheric and topographic corrections. Based on supervised classification technique, eight classes of land use and land cover were mapped through the classifiers: Maximum likelihood (Maxver), Logistic Regression (RLG), Artificial Neural Networks (RNA), Random Forest (RF) and Support Vector Machine (SVM). The performance of each algorithm was evaluated through the error matrix, specifically the Kappa index. The Z test was used for statistical comparison of Kappas; and change detection was achieved by comparing pixel-by-pixel the best thematic maps of each year. The 2014 maps were validated using an independent dataset of 180 ground points. All classifiers showed Kappa equal or greater than 0.90, which can be qualified as excellent. RF and RLG presented higher performances for the three dates, especially the RF classifier that showed Kappa of 0.95, 0.94 and 0.92 for 1986, 2000 and 2014, respectively. The RF outperformed the others by showing a statistically significant difference ($p<5\%$). In the external validation of the 2014 map, a statistically significant difference was confirmed between RF and the classifiers Maxver, RLG and SVM. A change detection analysis through the RF maps showed the period 1986-2000 to be the most affected by the changes in urban area (146.5%), bare soil (90.1%), shrub (-35.8%) and forest (-18.6%). For the period 2000-2014, deep alterations were observed in agriculture areas (79.1%), shrub (63.1%) and forest (-52.5%). Areas of waterbody increased from 5.1% in the first period to 16% in the second. The most rapid changes in the first period corresponded to the urban settlement and bare soil, whose change rates were 10.5% and 6.4% per year, respectively. In the second one, the annual changes with the highest rates were recorded for agriculture areas (5.7%), shrub (4.5%) and forest (-3.8%). The changes detected in the land use and land cover during the 28-year period have been greatly accelerated, driven by political and economic factors, which have been identified as the main determinants in increasing the land degradation in the region.

(8492 - 766) Mechanical soil properties in long-term, no-till, integrated crop-livestock system.

Jordano Vaz Ambus[1]; José Miguel Rechert[1]; Paulo César de Faccio Carvalho[2]
Federal University of Santa Maria[1]; Federal University of Rio Grande do Sul[2]

Integrated systems aim to manage land so that different components are integrated to increase environmental diversity and productivity. Integrated Crop-Livestock Systems (ICLS) combine agricultural production with livestock, and in the Brazilian Subtropics are generally characterized by summer crops producing grains, like soybeans (*Glycine max*), corn (*Zea mays*) and rice (*Oryza sativa*), followed by the establishment of pastures with cold-season grasses, such as black oats (*Avena strigosa*) and ryegrass (*Lolium Multiflorum*) intended for animal grazing. If well managed, ICLS can generate several benefits to soil chemical, physical and microbiological properties, but excessive trampling leads soil structure deformation by the pressure of animal's hooves that increases soil bulk density mainly in surface soil layers, with impediment to roots development. Soil compaction is commonly evaluated by means of compressibility tests; however, to evaluate the effects on soil structure caused by trampling of animals, the dynamism with which this process occurs in the field must be taken into account. In this study we performed uniaxial compressibility test, along with cyclic soil compressibility where the sample is subjected to loading/unloading cycles generating an effect similar to animal trampling. The treatments consisted of different grazing intensities determined by sward height, namely: 0.10 *m*, 0.30 *m*, and an area without grazing, in an experimental design of randomized blocks with three replications. Undisturbed soil samples were collected in core samplers in the 0-0.05, 0.05-0.10, and 0.10-0.20 *m* soil layers at the end of soybeans and pasture cycle. The samples were submitted to uniaxial compression at 12.5, 25, 50, 100, 200, 400 and 800 *kPa* and cyclic loading at 200 *kPa* in automatic consolidometer, for determination precompression stress, compressibility coefficient, decompression coefficient, and cyclic compressibility index. The greatest impact of animal trampling is on the topsoil, and without grazing areas the structural quality of the soil is preserved. The soil maintains its structural resistance even after moderate trampling. Cyclic compressibility showed the greatest damage to soil structure is caused in the first loading/unloading cycles, that is, at the beginning of the grazing cycle.

Keywords: Integrated system; animal trampling; soil structure.

(2731 - 673) Microbial biomass of a subtropical soil as affected by crop residue quality in long-term no-till cropping systems

Cristhian Hernandez Gamboa[1]; Cimélio Bayer[1]
Universidade Federal do Rio Grande do Sul, Departamento de Solos, Programa de Pós-Graduação em Ciência do Solo, Av. Bento Gonçalves, 7712 , 91540-000 Porto Alegre, RS- Brasil[1]

The quality of the residue left as cover in crop rotation systems influences the soil microbial populations. Increases in microbial biomass are more related to residues of nitrogen-rich labile coverages such as legumes (L) than with more lignified residues such as those produced by grasses (G). The objective was to evaluate soil microbial biomass in four crop systems under no-tillage with different qualities of the vegetal residue added to the soil, in a 35-year experiment at the experimental station of UFRGS in Rio Grande do Sul Brazil. The crop

systems were: low quality (oat/maize, G/G), medium quality (oats-vetch/maize, GL/G) and high quality (oats-vetch/maize- cowpea GL/GL). As reference, the soil was collected also in soil with no crop – bare soil under no-till (BS). At the beginning of spring 2017, soil was collected in the 0-5 cm layer and microbial biomass was quantified by substrate-induced respiration (glucose). 30 g of soil with glucose were incubated for 3 hours at 22 °C in closed containers glass, the CO_2 was collected in polypropylene syringes and analyzed by gas chromatography. The microbial biomass was determined by converting the CO_2 flux (mg CO_2.kg^{-1}.h^{-1}) in mg C-mic kg^{-1} according to equation [40.04*(CO_2 flux)+0.37] proposed by the methodology. The microbial biomass of the soil increased following the order of the levels BS <low <medium <high residue quality. There was a 27% increase between the no crop – bare soil BS and the high quality of the residue. In comparison with the crop system low quality (G/G), the culture system with residues that included legumes in the winter (G-L/G) increased microbial biomass by 9%, and 14% in the crop system that had legumes both in winter and summer (G-L/G-L). The impact of no-till with higher-quality residue cropping systems on soil microbial will have influence on important biological and physical processes and improving soil quality.

(5208 - 2680) No tillage and other soil and water conservation practices in Paraná State

Tiago Santos Telles[1]; Bruno Volsi[2]; Gustavo Vaz da Costa[2]; Ana Julia Righetto[1]
Instituto Agronômico do Paraná[1]; Universidade Estadual de Londrina[2]

No-tillage is an important conservationist practice, but to be considered a quality production system it must be associated with crop rotation and other soil and water conservation practices, such as contour farming and the use of agricultural terraces. Therefore, the aim of this study was to verify which Paraná State farms realize no-tillage, in addition to other soil and water conservationist practice. For this work, it was used data of the Agricultural Census 2006, from "Instituto Brasileiro de Geografia e Estatística (IBGE)". The information used refers only to the areas of temporary crops, of the agricultural farms with no-tillage in Paraná - that correspond to 50% of the total. For each city of Paraná State, were recorded the farms that employing no-tillage together with crop rotation, contour farming and agricultural terraces. To determine the more or less conservationist cities, that is, the ones that adopt no-tillage with other conservationist practices, it was performed principal component analysis (PCA). In addition, to identify the similarities between the farms, in relation to the conservation standard, a cluster analysis was made, using Ward's minimum variance method. It was verified that 14.70% of the agricultural farms use no-till associated with three other conservation practices, 25.17% with two practices, 57.07% use with one practice and 3.06% no practice associated. These observations suggest that 39.87% of agricultural farms use no-tillage associated with two or more conservation practices and 60.13% of the farms use no-tillage with only one or no conservationist practice. In addition, it is worth mentioning that of the farms with no-tillage that carry out two practices, 15.81% do crop rotation and contour farming, 7.14% use contour farming and agricultural terraces and 2.21% crop rotation and terraces agricultural activities. Among those who only do one practice, 30.66% only carry out contour farming, 21.72% crop rotation and 4.69% use the agricultural terraces. From the PCA, two components were identified, which explained almost 83% of the variability of the data. Using cluster analysis, 4 groups were identified, which indicated a heterogeneity in relation to the soil and water conservation pattern in Paraná. In order to no-tillage in Paraná be considered as quality, agricultural farms still need to make further use of other soil and water conservationist practice, especially in regions where soils are fragile.

Keywords: Terraces; contour farming; crop rotation.

(8320 - 3170) No-tillage as a conservation system

Kátia Luciene Maltoni[1]; William Dubbin[2]
Unesp/Campus de Ilha Solteira[1]; Natural History Museum - London[2]

The conversion of native vegetation (NV) to agricultural systems reduces soil organic matter (OM). The adoption of conservation management could maintain or improve the OM content, and thus improve fertility, reduce density (BD), increase porosity (TP), etc. The aim of this study was to evaluate the improvements in OM, BD, aggregates > 2000 µm, of two different fields, of 10 and 20 years of no-tillage, compared to natural vegetation soil (Cerrado). Undisturbed soil samples (0.0-0.05; 0.05-0.10; and 0.10-0.20 m depth) were collected from Brazil, Central Region, municipality of Selvíria (MS). The soils, Oxisols from Cerrado, were collected from a Natural Vegetation field (NV), and from fields that had been under conventional tillage since 1970s, and 10 and 20 years ago were changed to no-tillage system (NT10; NT20 respectively). The undisturbed samples were sieved (4mm) and the aggregates retained were further fractionated by wet sieving through five sieves (2000, 1000, 500, 250, and 53 µm) with the aggregates distribution expressed as percentage retained by each sieve. The OM, BD, TP, macro and microporosity were also determined. The OM varied among treatments (32.5 g dm^{-3} $Cer_{(a*)}$, 22 g dm^{-3} $NT20_{(b)}$, and 16.4 g dm^{-3} $NT10_{(c)}$), at the depth of 0-0.05 m. The BD varied in depth, from 0.0 to 0.05 m: $1.03_{(a)}$, $1.28_{(b)}$, and $1.29_{(b)}$ g cm^{-3}; from 0.05 to 0.10 m: $1.13_{(a)}$, $1.21_{(a)}$, and $1.41_{(b)}$ g cm^{-3}; and from 0.10 to 0.20 m: $1.21_{(a)}$, $1.29_{(a)}$, and $1.43_{(b)}$ g cm^{-3}, for Cer, NT 10 and NT 20, respectively, for each depth. This results shows that soil under NT system, after 20 years of implantation, has high BD, with values that can restrict productivity, and NT 10 presents the same tendency, with lower values. The macropores of Cer ($26\%_{(a)}$) presented higher values than those observed for NT10 ($22\%_{(b)}$) and NT20 ($14\%_{(c)}$), behavior maintained in the first 0.20 m of soil, corroborating the data of BD and indicating the occurrence of soil compaction due management system. Total porosity is similar between Cer (51%) and NT20 (52%), but does not represent the NT20 soil behavior. The larger amount of aggregates for Cer (88%); NT20 (68%) and NT10 (67%) was identified at >2000 µm, suggesting that for Cer the least occurrence of ruptures of larger aggregates, associating these with OM. *statistical analysis, the same letters meaning no statistical differences>2000 m

(1551 - 661) Organic phosphorus fractions in an Oxisol cultivated with sugarcane under green-harvested management

Benedito Luiz CORREIA[1]; John KOVAR[2]; Michael THOMPSON[3]; Luís Reynaldo Ferracciú ALLEONI[4]
Universidade Federal Rural de Pernambuco (UFRPE), Colégio Agrícola Dom Agostinho Ikas (CODAI)[1]; National Laboratory for Agriculture and Environment[2]; Iowa State University[3]; Universidade de São Paulo (USP), Escola Superior de Agricultura Luiz de Queiroz (ESALQ)[4]

Conservative tillage systems favor the accumulation of organic phosphorus (P_o) in highly weathered soils. Thus P_o may constitute an important source of P for crops. The dynamics of P_o may be assessed by means of the fractionation or sequential extraction technique. This

study aimed to evaluate changes in the forms of P_O from samples of an Oxisol collected in Pradópolis, state of São Paulo, Brazil, cultivated for 14 years with sugarcane harvested without burning. Soil samples were collected in areas with sugarcane harvested with (CQ) and without burning (SQ), in the planting row and in the interrow, at 0-0.05 m, 0.05-0.1 m, and 0.1-0.2 m-layers, and in an adjacent forest (VN). Soil samples were kept under refrigeration until the analytical procedures. The following P_O fractions were evaluated: labile, biomass P_O (P_O bound to microbial biomass), moderately labile P_O, fulvic P_O (P_O bound to fulvic acid), humic P_O (P_O linked to humic acid) and residual or nonlabile P_O. Soil samples from the 0-0.05 m layer had higher contents of P_O biomass in CQ than those from SQ, probably due to the increased microbial activity favored by available inorganic P contained in the ash of burned sugarcane. Soil samples from the SQ system had higher values of moderately labile P_O in the 0.05-0.1 m-layer than in samples from CQ. At 0.1-0.2 m-layer, values of all P_O fractions were higher in SQ than in CQ harvesting system, except for the non labile P_O fraction, in which CQ was higher than SQ. There was no effect of soil sampling position (row and interrow) in the values of P_O fractions of samples from both SQ and CQ systems. The percentage distribution of the fractions had the following order: non-labile P_O > P_O fulvic > P_O humic > labile P_O > P_O biomass > P_O moderately labile, for VN, SQ and CQ systems. In the layer 0.1-0.2 m, soil samples under the non-burned crop had accumulated higher levels of P_O in the labile, biomass, moderately labile, fulvic and humic acids fractions.

(3604 - 3180) Phosphorus and organic matter contents as a function of rotation crops and cover crops under no-tillage system in the Cerrado

Edson Lazarini[1]; Raul Sobrinho Pivetta[2]; João William Bossolani[2]; Luiz Gustavo Moretti de Souza[2]; Lucas Fenelon Parra[2]; Fabiana Lopes dos Santos[2]; Izabela Rodrigues Sanches[2]
1Faculdade de Engenharia/UNESP – Campus de Ilha Solteira, Av. Brasil 56, Ilha Solteira - SP, 15385-000, Brazil (lazarini@agr.feis.unesp.br)[1]; Faculdade de Engenharia/UNESP[2]

In the Brazilian Cerrado, soybean and maize predominate, therefore, there is a low diversity of cultivated species. Currently, it has been in the no – tillage system is the most used in this region. Thus the present study was to evaluate phosphorus and organic matter contents in the soil as a function of monoculture corn or rotated with soybean in the summer and the use of cover crops in the spring, under no-tillage conditions. The experiment started in October 1999. Rotation involved corn and soybean crops and monoculture, only maize crop. Cover crops sown in the spring were: *Crotalaria spectabilis*, *Pennisetum glaucum*, *Crotalaria juncea* and *Panicum miliaceum*, and in addition to a fallow area. The levels of phosphorus (P) and organic matter (OM) of the soil in the layers of 0.00-0.10 and 0.10-0.20m, 15 years after the introduction of the no – tillage system, were evaluated in October/2015. Crop rotation and cover crops provide benefits to soil fertility. For the 0.00-0.10 m layer, in the rotated system or monoculture, the cover plants provided higher levels of phosphorus in the soil when compared to fallow area. In the 0.10 - 0.20 m layer, the phosphorus content did not change as a function of cover crops, however, in the rotational system, the highest levels were obtained in the plots with *C. spectabilis* (25.1 mg dm^{-3}) and *Pennisetum glaucum* (26.0 mg dm^{-3}). The organic matter contents of the soil in the 0.00-0.10 m layer did not increase as a function of cover crops, regardless of the cropping system. In the fallow area (13.6 g dm^{-3}), *Pennisetum glaucum* (14.4 g dm^{-3}) and *Panicum miliaceum* (14.3 g dm^{-3}), the organic matter content was higher when the cultivation system was rotated. In the 0.10-0.20m soil layer, the cropping system and cover crops did not influence the organic matter content of the soil.

Keywords: No – Tillage System, Crop Rotation, *Zea mays*, *Glycine max*

(3268 - 1374) Phosphorus fractions in chronosequence of crops under no-tillage system in the eastern Amazon

Rubia Carla Ribeiro Dantas[1]; Letícia Cunha da Hungria[1]; Sidney Daniel Araújo da Costa[1]; Edilson Carvalho Brasil[2]; Mario Lopes da Silva Jurnior[1]
Universidade Federal Rural da Amazônia[1]; Embrapa Amazônia Oriental[2]

The no-tillage (NT) system promotes the increase in the availability of P in the the surface layer of the soil, which may result in greater transformation of the inorganic P into organic fractions of P of different availability. The objective of this work was to evaluate the preferential fractions of P accumulation in a chronosequence of NT crops in the Eastern Amazon. The study was conducted in the municipality of Paragominas, southeast of Paraense, in an area under chronosequence of NT crops, using a completely randomized experimental design, in subdivided plots. The plots were constituted by the management systems: NT with 9 (NT), 11 (NTP11), 13 (NT13), 14 (NT) and 15 (NT15) years of adoption, plus one area under conventional tillage (CT) and one with native forest (NF); the subplots corresponded to depths (0-10, 10-20, 20-30 and 30-40 cm). Soil management systems presented differential P accumulation capacity. In areas under NT, the P is accumulated in the surface layer and drastically reduced with depth, while in CT this reduction is less pronounced. Up until to 20 cm depth, there was an increase in the labile P content (fraction available for biomass), in function of the time of adoption of NT, whose average values went equivalent to 51; 65; 75; 71 and 85 mg kg^{-1}, respectively, for NT9, NT11, NT13, NT14 and NT15, which were significantly highest than CT and NF. Moderately labile P also showed significant increases with the time of NT adoption, with values ranging from 31 mg kg^{-1} in NF to 242 mg kg^{-1} in SPD15. Regardless of the management system, the non-labile fraction of P was preferentially accumulated in the soil, not being verified difference between the evaluated systems, which suggests the high adsorption capacity of this soil. In the 0-10 cm layer, the total P (obtained by the sum of the fractions) presented significantly higher levels in NT15 (2882 mg kg^{-1}), compared to CT (848 mg kg^{-1}). The management systems were not able to change the P fractions in deeper layers of the soil, 30-40 cm, emphasizing that the Brazilian soils, especially the Latosol, are strong drains of P and their mobility is almost null.

Keywords: P lability, management systems, phosphorus lability

(3008 - 2437) Productivity of corn and soybean in iLPF or PD systems with organic or mineral fertilization

Luciane Cristina Lazzarin[1]; Paulo Hentz[2]; Juliano Corulli Corrêa[3]
UNESP[1]; Instituto Federal Catarinense[2]; Embrapa Suínos e Aves[3]

The practice of fertilization with organic fertilizers promotes productivity gains equal to or greater than mineral fertilizer when carried out for long years. The objective of this work was to evaluate the response of fertilization with poultry litter, swine manure and mineral fertilizers in relation to maize and soybean yields in the 2015/16 and 2016/2017 crops in the iLPF or PD system. The

experiment was set up in a randomized block design in subdivided plots, with three replications, and the plots were set up two conservationist systems of production (Direct Planting - PD and Integration of Plow - Livestock - Forest) and in the sub - plot three sources of fertilizers organic poultry litter or swine manure, a mineral) and control without fertilization. Summer crops with maize were sown in the 2015/16 and soybean 2016/17 crops for yield assessment. Fertilization with different fertilizer sources in a crop-livestock-forest integration system can bring benefits to the system, because it allows similar or higher yields to mineral fertilizers, in addition to contribute to aspects of soil quality improvement.

Keywords: Index terms: Poultry bed, swine manure, mineral fertilizer.

(6331 - 3123) Quality and quantity of crop residues: effects on nitrous oxide emissions.

Raquel Schmatz[1]; Sylvie Recous[2]; Lineu Trindade Leal[1]; João Henrique Fontana[1]; Emanuel Leonardi[1]; Mathias Roberto Leite Rambo[1]; Sandro José Giacomini[1]
Federal University of Santa Maria[1]; Institut National Recherche Agronomique[2]

Nitrous oxide (N_2O) is a potent greenhouse gas naturally produced in agricultural soils by nitrification and denitrification process. Crop residues may affect N_2O emissions directly (e.g., substrate supply) and indirectly (e.g., influence on moisture and soil temperature), and the magnitude of emissions, depending on the quality and quantity of residues added to soil. The experiment was carried out for 360 days in a Typic Paluedalf, at University Federal of Santa Maria, Rio Grande do Sul, Brazil. The experiment was laid out as a randomized complete block design replicate four times. The treatments were composed of vetch (3.5% N and 53% soluble fraction) and wheat (0.5% N and 16% soluble fraction) crop residues in amounts equivalent to 3, 6 and 9 Mg ha^{-1} of dry matter, and a treatment with no residues (control). N_2O fluxes were periodically measured using closed static chambers and N_2O concentrations in the samples were analyzed by gas chromatography. The N_2O emission factor (EF) were calculed by IPCC (2006). Six a priori contrasts were performed to assess differences among treatments. Crop residues addition to soil increased N_2O fluxes, especially after rainfalls events, independently of the quantities of crop residues added. The highest N_2O fluxes occurred in the first 50 days after the residues addition to soil and in treatments with vetch residues (3 g N m^{-2} h^{-1}). After 50 days, N_2O emissions reduced to levels close to baseline, even after rainfall events. Contrast analysis indicated that cumulative N_2O were two times higher in vetch than wheat (4.05 *vs*. 1.91 g N ha^{-1}). In contrast, the EF was higher for the wheat than vetch residues (4.81% vs 1.81%). For the two residues, the emission factor exceed the value of 1% suggested by the IPCC (2006). The quantity of residues affected cumulative N_2O emissions only for vetch, increasing linearly N_2O emission until the quantity of 6 Mg ha^{-1}. The highest emission with vetch residues is due to high N (low C: N ratio) and soluble fraction content in these residues, which are readily available C and N source to microorganisms. In addition, higher decomposition rates of vetch residues increased soil inorganic N, another key factor for N_2O production. Thus, our results suggest that residues from cover crops such as vetch contribute more to N_2O emission than residues from crops harvested at maturity such as wheat; the effect of quantity of crop residues added to soil on N_2O emissions is related to residues quality.

Keywords: decomposition; C:N ratio; greenhouse emissions.

(8848 - 2782) Resistance to soil compaction of an Acrisol under different soil management systems

Wellingthon da Silva Guimarães Júnnyor[1]; Isabella Clerici De Maria[2]; Cezar Francisco Araujo Junior[3]; Etienne Diserens[4]; Camila Vieira Viana Farhate[5]; Zigomar Menezes de Souza[5]
Instituto Agronômico (IAC), Campinas, São Paulo – Brasil (wellingthon.agro@gmail.com)[1]; Instituto Agronômico (IAC), Campinas, São Paulo – Brasil[2]; Instituto Agronômico do Paraná (IAPAR), Londrina, Paraná– Brasil[3]; Agroscope Reckenholz - Tänikon ART Research Station, Ettenhausen - Switzerland[4]; Faculdade de Engenharia Agrícola, UNICAMP (FEAGRI), Campinas, SP – Brasil[5]

The intense traffic of agricultural machinery in the course of harvest has been responsible for the increase of soil compaction in sugarcane agrosystems. This study evaluated the influence of management systems on soil resistance to compaction caused by the machines used to harvest sugarcane. Three soil management systems were evaluated: no-tillage with peanut (PNT); no-tillage with sorghum (SNT) and conventional tillage without cover crop (CT), in an Acrisol, clay loam texture, in RBD experimental design, with three replicates. Undisturbed samples were collected from the center of the traffic line, in the depth of 0.10-0.13 m. The samples were equilibrated in four water contents and submitted to the uniaxial compression test. The preconsolidation pressure (σp) values were adjusted as a function of the volumetric moisture content, to produce load bearing capacity models (LBCM), which were compared by the homogeneity test. The maximum vertical stresses applied to the soil by each wheel of the machines, a sugarcane harvester John Deere 3520, a trailer ATA 10.500 and a tractor Valtra BH 180, were estimated. In general, the degradation of the soil structure due to the effect of the machinery wheel in the traffic line followed the order: peanut no-tillage < sorghum no-tillage < conventional tillage. The LBCM suggest that, if sugarcane harvesting is executed with soil moisture near to field capacity (0.23 m^3 m^{-3}), additional compaction will occur in all management systems. The σp in soil field capacity was 236, 138 and 52 kPa, respectively, for CT, SNT, PNT. The trailer loaded with sugarcane exerts a vertical stress of 272 kPa on the soil and may cause additional compaction on PNT and SNT, for volumetric moistures content > 0.11 m^3 m^{-3}. This machine can also cause additional compaction on CT, even though this management system has the highest resistance to soil compaction. The maximum vertical stress applied by the harvester (94 kPa) can cause additional compaction only for PNT, under soil volumetric moisture content greater than 0.16 m^3 m^{-3}. In CT, after soil tillage operation with a disc harrow, the soil remains unprotected, as any cover crop was sown and there is direct contact of the wheels with the soil. Then this can promote increases of the LBC in the depth of 0.10 -0.13 m. The cover crops has an influence on the load bearing capacity model. The PNT system presents the lowest LBC, which makes this management system more susceptible to soil compaction.

Keywords: No-tillage, vertical stress, cover crop, preconsolidation pressure.

(9822 - 1387) Soil and sugarcane yield response to tillage management in southern Brazil

Ricardo de Oliveira Bordonal[1]; Leandro Carneiro Barbosa[2]; Henrique

Coutinho Junqueira Franco[1]; João Luís Nunes Carvalho[1]
CTBE/CNPEM – Brazilian Bioethanol Science and Technology Laboratory, National Center for Research in Energy and Materials[1]; FEAGRI/UNICAMP – Faculty of Agricultural Engineering, University of Campinas[2]

Soil organic carbon (SOC) is of primary importance for maintaining soil functions, and agricultural management practices may significantly influence physical properties, SOC and crop yields. Importantly, in a scenario with straw removal for bioenergy production, the adoption of no-tillage during sugarcane crop renovation could be an opportunity to offset possible adverse effects on soil quality and crop yields. A field experiment was carried out in an Oxisol (sandy soil) located in Quatá-SP (22º14'S–50º42'W), southern Brazil, to assess the effects of no-till (NT) on selected physical properties, soil C stocks and sugarcane yields in relation to conventional tillage (CT) on a short-term basis (three crop cycles). Trials were established in a randomized block design with four replications and two management systems: CT and NT. Disturbed and undisturbed soil samples were collected for determination of SOC content, soil bulk density (BD), total porosity (TP) and soil resistance to root penetration (PR), and stalk yields were accounted through an instrumented truck equipped with a loading cell. The short-term effects of adopting NT during sugarcane crop renovation showed evidences of higher SOC content to a depth of up to 40 cm, with significant differences in the upper layer of soil (Tukey's test, p<0.05). Although not statistically significant in deep sub-soil layer (0-100 cm), a transition from CT to NT significantly increased soil C stocks at a rate of 0.5 Mg ha^{-1} yr^{-1} in the 0-40 cm layer (p<0.05). The data also showed significant differences in soil physical attributes for both treatments over three years (p<0.05), with reductions in TP and increases in BD and PR. Differences between treatments on physical attributes occurred only in the first crop cycle (p<0.05), in which NT presented higher PR compared to CT. Regarding the impact of tillage management on stalk yields, there was no difference between CT and NT in terms of biomass production. These results suggest that additional long-term studies should be encouraged to fully understand the potential of conservationist management practices coupled with controlled traffic as a key strategy for improving soil physical quality and increasing cane yields. Our findings support the conclusion that NT increased C stock, while the degradation of soil physical quality occurred for both treatments over the assessed period, especially because of intense machinery traffic during sugarcane crop management.

(8015 - 2288) Soil structural properties under addition of crop residues and limestone

Jorge Lemainski[1]; José Eloir Denardin[2]; Guilherme Kangussú Donagemma[3]
Embrapa Trigo, Rodovia BR 285, km 294, Caixa Postal 3081, CEP 99050-970 Passo Fundo, RS, Brasil. E-mail: jorge.lemainski@embrapa.br[1]; Embrapa Trigo. E-mail: jose.denardin@embrapa.br.[2]; Embrapa Solos, Rua Jardim Botânico, 1024, Jardim Botânico, CEP 22460-000 Rio de Janeiro, RJ, Brazil. E-mail: guilherme.donagemma@embrapa.br[3]

Soil structure depends on physical, chemical, and biological factors. The interaction of these factors is a result of quantity and quality of residues and other inputs added to the soil, as well as their physicochemical conditions. Liming is an essential management practice in acid soils. When in excess, liming alters the electrolytic solution of the soil with impacts on its structure. In this sense, negative charges increase with pH, reducing the attraction between clay particles and resulting in increased clay dispersion and soil aggregate destabilization. In Brazil, Oxisols under no-till management system with biomass production lower than 12 ton/ha/year, the concentration of limestone in the uppermost soil layer aggravates these effects. The readily dispersed soil clay increases the concentration potential in the percolated water through soil profile, resulting in clay deposits into soil pores, and, consequently, changes pore size and continuity. These processes decrease soil permeability to water and air, and increase soil density in subsurface layer, soil penetration resistance, and soil susceptibility to erosion. The results of a study carried out in an Oxisol, located at subtropical region of Brazil confirm these statements. Liming at the soil surface or the incorporation of limestone in the topsoil layer of 0–5 cm depth increased soil pH to values higher than 7.0 and the electronegative potential of the surface of soil colloids, enhancing clay dispersion in topsoil layer. The migration of the clay through soil profile altered soil structure in subsurface layer, obstructing soil pores, reducing pore continuity, and increasing soil density and soil penetration resistance. In another study, in the same soil, associating liming on the soil surface or the incorporation of limestone in the layer 0-15 cm deep, soybean monocropping under no-till (production of crop residues lower than 4 ton/ha/year) or crop diversification with two or more harvests per year under no-till system (production of crop residues higher than 12 ton/ha/year), clay dispersion increased only with soybean monocropping. Conversely, in crop diversification with two or more crops per year, the high stability of soil aggregates avoided clay dispersion. Thus, liming, that is essential to acid soil management under no-till, should always be associated to production models that produce crop residues in amount, quality, and frequency, in order to maintain the stability of their aggregates.

(2300 - 2101) Structural changes of dystrophic yellow latosol in the function of the adoption of the direct plantation system

Jéssica Rodrigues Dalazen[1]; Renan Garcia Malikouski[1]; Andréia Lopes de Morais[1]; Carla da Penha Simon[1]; Kamila Cabral Mielke[1]; Elcio das Graça Lacerda[2]
Universidade federal do Espírito Santo[1]; Instituto Federal de Educação, Ciência e Tecnologia do Espírito Santo[2]

Soil compaction is one of the main problems encountered in conventional agriculture because it affects the physical quality of the soil, hindering the root development of the plants. This effect is enhanced by the intense traffic of agricultural machinery. With the use of no-tillage, soil compaction and density are less intense due to the reduction of machine traffic, without the soil preparation steps required in the conventional method. In this way, the objective of this work was to evaluate the compaction and density history of a clayey eutrophic Yellow Latosol soil, during the implantation of the no-tillage system in the bean crop. This study was developed at IFES Campus Santa Teresa, state of Espírito Santo, in the period of August 2014 and July 2015, in a sample mesh of 3 x 10, measuring 20 x 20m each, totaling 12 data collection points all georeferenced through the demarcation of latitude and longitude with the aid of GPS. Initially, the planting of melga (sorghum spp.) was carried out in order to form the vegetative cover on the soil, after the sowing of the bean (phaseolus vulgaris L.) variety Ouro Vermelho, under the central pivot system. Three soil physical characterization analyzes were carried out, one prior to the planting of the melga, another after the development of the same, and the last one in the development stage of the bean crop. The parameters of density and resistance to penetration (at 12 points) at different depths (0.0 - 0.20 and 0.20 - 0.40 m) were evaluated. It

was observed by the average values of density that the layer of 0.20 – 0.40 m has a higher density, consequently the level of compaction of the same one is higher due to the greater amount of particles of the soil in a certain volume, thus presenting a smaller porosity. This is due, in fact, to sequential years of conventional cultivation, and by not decompressing the deeper layers. For the resistance to penetration there was a decrease in the values of the first to the second evaluation, such phenomenon could have occurred due to the activity of the root system of the melga, which, when growing in search of water and nutrients, promoted a soil particles rotation. In the third sampling, an increase in soil resistance to penetration was observed. This value can be explained by soil moisture, where the larger the amount of water present, the easier it will be to move the soil particles. Soil density and resistance to soil penetration decreased with no-till practice.

Keywords: Physical impediment; density of soil; resistance to penetration.

(7967 - 1505) Sustainable alternative to increase organic matter in soil profile

Miguel Ángel Martínez-Gamiño[1]; Martín Espínosa Ramírez[1]
INIFAP[1]

Traditional soil tillage for sowing agricultural crops in the plateau of San Luis Potosi, Mexico, is performed with a fallow and one or two harrowing steps. These practices destroy soil structure, invert its profile, dilute and accelerate the oxidation of organic matter, increase runoff, and promote compaction. In addition, crop residues are removed almost entirety to use as fodder and the free grazing after harvesting reduces the amount of plant leftovers that reincorporates into the soil. Conservation agriculture is a technique where soil is not removed, crop residues are left on the surface, crops are rotated, and roots are accumulated in the soil profile. The Lima-Paris Action Plan on climate change and global warming, calls for alternatives to increase organic matter by 0.4%, to ensure food production of a world population that by 2050 will reach 9 billion. The objective of this study was to evaluate the effect of conservation agriculture on the accumulation of organic matter, due to crop roots, in the soil profile. This study was conducted in the Experimental Station San Luis, located in Palma de la Cruz, Soledad de Graciano Sánchez, S.L.P., Mexico, in a field experimental plot that began in 1995 with different soil tillage methods and an irrigated corn-oat rotation. In 2017, dry weight of corn and oat roots was evaluated in the tillage treatments of fallow plus harrow (F+H) and conservation agriculture (CA). Three random samples were taken per treatment in two replications. Roots were washed and dried at 40 °C. Data were analyzed by a randomized block analysis with three replications. Statistical analysis of corn root dry weight reported differences ($p < 0.05$) favorable to CA with a value of 10,297 t/ha and 3.39 t/ha in F+H. The same analysis for oat showed also statistical differences ($p < 0.05$) in the dry weight of roots, favorable to the treatment of CA, with 3.4 t/ha against 1.2 t/ha of F+H. The total dry matter per year that is left in the profile of the soil product of the sum of roots of corn and oats indicated that CA recorded 13.697 t/ha while with F+H was 4.59 t/ha. The contribution of organic matter based on the volume of soil at a depth of 0.3 m was 0.109% with F+H and 1.57% with AC. The rotation of corn-oats with CA is a sustainable alternative to increase the organic matter in the soil profile and maintain and improve soil fertility.

Keywords: Roots; corn; oat; conservation agriculture.

(8266 - 1897) Total Carbon Stock of Soil unde Cover Crops and Nitrogen Fertilization

Leandro Alves Freitas[1]; Paulo Cesar Conceição[1]; Márcia Kochem[1]; Weslei Sbalcheiro[1]; Dieyson Fernando Peruzzolo[1]; Felipe Lunardelli Sandrin[1]; Larisa Ianca Vagner Schaedler[1]
Universidade Federal Tecnológica do Paraná[1]

Carbon plays multiple roles in the soil, as well as being used as an indicator of the sustainability of agricultural systems. Thus, the soil organic carbon stocks was quantified on cover crops, with or without nitrogen fertilization, in an experiment conducted since 2010 in the experimental area of the University of Technology Federal Parana (UTFPR), Campus Dois Vizinhos, under a Red Latosol. The experimental design was a randomized complete block design in a factorial scheme (8x2), with three replications, that is, seven summer cover crops and one fallow areas, with or without the application subplots of mineral N (0 and 180 kg ha -1) in corn cover crop . The C content was evaluated by wet combustion and the total soil carbon stocks calculated based on soil density at depth of 0.00-0.40m. There was a significant difference in the interaction between the cover crops and nitrogen fertilization. The contrast in carbon stocks at depth (0.00-0.40 m) were the bitter only for Crotalária spectabilis, Guandu dwarf and Mucuna gray when not used nitrogen fertilization, respectively (117.69 Mg ha $^{-1}$; 143.79 Mg ha $^{-1}$; 138.1 Mg ha $^{-1}$). It is interesting to note that the treatment with Mucuna gray without nitrogen fertilization obtained a soil carbon content of 30.5% more than the treatment with the use of nitrogen fertilization. Possibly these values are related to the decomposition characteristics of the species in question, together with the smaller amount of decomposing organisms in the soil. Additional, possibly the plots with cover crops and nitrogen fertilization export more nutrients because was obtained more grain production of maize.

Keywords: cover crops; nitrogen fertilization; carbon stock

(9490 - 1787) Water retention, non-saturated hydraulic conductivity and soil porosity under different preparation systems and cultivation plans

Cícero Ortigara[1]; Lucas Aquino Alves[1]; Henrique Debiasi[2]; Vanderlei Rodrigues da Silva[3]
Universidade Federal do Rio Grande do Sul[1]; Embrapa Soja[2]; Universidade Federal de Santa Maria[3]

The aim of this work was to evaluate the effect of no-tillage system and conventional tillage and different soil cultivation plans in the distribution of pore size and water flow and indicate the use of new methodology to evaluate the porosity continuity in a very clayey Rhodic Eutrudox. The study was carried out in a long-term experiment, implemented in 1993, on a very clayey Rhodic Eutrudox. The experiment presents a 2x3 factorial scheme (soil preparation system *versus* rotation planes), in a randomized block design with four replications. The soil preparation system consists of: I) Conventional tillage system (CT); And II) No-till system (NT). The cultivation plans factor is composed of: I) wheat/soybean (WS) succession; II) rotation lupine/corn-oats/soybean-wheat /soybean-wheat/soybean (ROT) and III) corn + brachiaria/soybean (CS). Soil samples with preserved structure were collected in eight soil layers (0.00-0.05, 0.05-0.10, 0.10-0.20, 0.20-0.30, 0.30- 0.40, 0.40-0.60, 0.60-0.80 and 0.80-1.00 m) for each plot. The available water fraction, hydraulic conductivity of unsaturated soil, frequency and volume of pores and uniformity of distribution of pore classes were obtained from the adjustment of the Van Genuchten model. The no-tillage system (NT), despite having a lower moisture amplitude in the retention curves and water availability in some layers, presented less restrictive layers to the water flow in the soil, and presented better distribution uniformity of larger pores along the profile compared to the conventional tillage system. The cultivation plans influenced the frequency of soil pore classes and the uniformity of distribution of soil pore classes (UDP), the other parameters are less influenced by this factor. The UDP attribute presents potential for the estimation of soil pore continuity.

(2789 - 2017) Assessment of fertilization efficiency in a vineyard at the Maule region, central Chile

Priscila Tapia[1]; Osvaldo Salazar[2]; Ranvir Singh[3]; Helena Ponstein[4]
Programa de Magíster en Manejo de Suelos y Aguas, Universidad de Chile, Casilla 1004, Santiago, Chile (priscila.tapia@ug.uchile.cl)[1]; Departamento de Ingeniería y Suelos, Facultad de Ciencias Agronómicas, Universidad de Chile[2]; School of Agriculture and Environment, Massey University[3]; Deutsches Institut für Nachhaltige Entwicklung e.V.[4]

One of the major problems caused by agriculture nowadays is water pollution which stems from traditional practices such as the excess use of inorganic fertilizers and irrigation water. The main goal of this study is to assess practices and efficiency of the current fertilizer program and its potential improvement in a vineyard located at the Maule Region of Central Chile. A comprehensive field experiment is established to assess effects of different amounts of water and fertilizer applied by fertigation, on grape yield and quality, fertilizer use efficiency, and N-lixiviation in the vineyard (*Vitis vinifera* L). The experiment includes a control treatment, that receives the amount of water and fertilizer supplied on the current management program, the second treatment that receives 75% of both the current irrigation and fertilizer amounts, the third treatment that receives 75% of the current irrigation volume and 85% of the current fertilizer dose, and a fourth treatment that receives 50% of the current irrigation volume and 75% of the current fertilizer dose. The soil $N\text{-}NO_3$ and $N\text{-}NH_4$ concentrations are being monitored three times along the season (October to May), at two soil depth intervals (0-25 cm and 25-50 cm) to compare changes in N accumulated in the soil profile. In addition, soil water samples are being taken fortnightly to measure $N\text{-}NO_3$ and $N\text{-}NH_4$ concentrations at a soil depth of 50 cm in each treatment. At the end of the growing season the grape yield and some quality grape-juice parameters will be measured for each treatment. The soil solution samples started to be taken with the first application of N fertilizer, which was on December 30, 2017, around six weeks after blooming. The initial measurements showed a higher concentration of $N\text{-}NO_3$ in the soil water for the control treatment, with a mean value of 7.23 mg/L, as compared to the other treatments that showed mean values from 1.57 to 3.95 mgL^{-1}. This paper will present a comprehensive analysis of the data being collected for the complete growing season, assessing and making recommendations for optimal N use efficiency for vineyards in the study region.

C3.3.10 - Beneficial management practices for sustaining soil fertility

(5669 - 2077) Aggregate stability in a Oxisol ustox under different management practices in State of Bahia, Brazil

Paloma Cunha Saraiva[1]; Cácio Luiz Boechat[1]; Adaílton Conceição do Santos[2]; Marcela Rebouças Bomfim[2]; Jorge Antonio Gonzaga Santos[2]
Federal University of Piauí[1]; Federal University of Recôncavo da Bahia[2]

The aggregate stability (AS) affects the erodibility being used as an indicator of the process, besides being a synthetic soil parameter, and it is linked to several factors, such as organic matter content, bulk density, porosity, pH, texture, mineralogy and crop. The aim of this study was to evaluate the influence of different soil management practices on AS in a semiarid region. Treatments were: AL10 – Area with 10-year old orange trees, hand weeding under the canopy and management of weeds between rows, receives annual fertilizer correction and, acidity is corrected by liming, which was done only at planting; AFMA - Consortium (two years tobacco, one cassava and one year peanuts). Conventionally tilled with a disk harrow and disk arrow and fertilized when tobacco is planted with correction of the soil pH; AL30 - Area with thirty-year old orange trees, hand weeding under the canopy and between the lines without any management of weeds. The area receives fertilizer maintenance, and this was only done after planting in conventional tillage with a harrow pass, followed by liming and incorporation, and AFA - Consortium (tobacco for two years, followed by peanuts). Conventional tillage with disk harrow. Thus, 25 g of the selected aggregates were air-dried, the weight was corrected to oven-dry weight and then pre-moistened by spraying with distilled water. The separation of the size of aggregates as well as their stability was determined in three replicates and, consisted of the diameter classes of >2.00, < 2.00 < 1.00 < 0.50 < 0.25 < 0.05 and <0.053 mm, vertically agitated for 4 minutes in a container with water. The AS was expressed as the percentage of stable aggregates (PAE). In the 0-10 and 10-20 cm layer, AL10 and AL30 showed a higher PAE. The relationship with the perennial crop and soil tillage is not followed in the 0-10 cm layer of the AFMA and the AFA layer 10-20 cm. In the 0-20 cm layer the proportion of aggregates larger than 0.50 mm were between 53.4 (AL30) to 68.7% (AFA). Therefore, in the 10-20 cm layer, the ratios were between 59.1 (AL10) to 71.2% (AFA). At the depth of 20-40 cm there are differences in the proportion of stable aggregates, as this layer is not affected by tillage implements and particularly harrowing, so there is an increase in the percentage of aggregates larger than 0.50 mm, indicating more aggregation, while the AFA showed 82.06%, even under intensive soil compaction and with bulk density values above the critical limit.

(7254 - 473) Agricultural land application of sanitary sludge

Arrarte Gimena[1]; Takata Virginia[2]; Arló, Laura[2]; Casanova Omar[3]; del Pino Amabelia[2]
Facultad de Agronomía, UDELAR, Av. Garzón 780, Montevideo, 12900, Uruguay (garrarte@fagro.edu.uy)[1]; Facultad de Agronomía, UDELAR, Av. Garzón 780, Montevideo, 12900, Uruguay[2]; Facultad de Agonomía, UDELAR, Av. Garzón 780, Montevideo, 12900, Uruguay[3]

Sewwage sludge obtained in wastewater treatment plants is result of a biologic process. This sludge forms a substrate of high humidity and organic matter, with variable contents of nutrients, heavy metals and presence of pathogens. These characteristics make it suitable as a soil improver for agriculture, but it also implies a risk at a sanitary and environmental level. In order to reduce pathogens, there are various mechanisms for hygienization and stabilization of the sewage sludge; among the most widespread are the addition of lime and composting. To date, in Uruguay there are only some preliminary studies on the application of sludge in cultivated soils which showed positive results in the production obtained. The objective of this work was to quantify the response to the application of sanitary sludge on forage crops of ryegrass and sorghum in a typical soil from the south of the country. Another aim was to evaluate if the application of this type of material modifies certain soil physicochemical properties. Before planting ryegrass, 2 doses of fresh sludge, limed sludge and composted sludge were applied in 2x4 m plots, leaving control plots without

amendments and a commercial fertilizer was used as a chemical control. The second crop of the rotation (sorghum) was planted without further sludge addition. By means of two cuts per crop, the aerial biomass and its nutrient content (N, P, K, Ca, Mg, Na, Cu, Fe, Zn, Mn) were determined. The soil was analyzed at the harvest of each crop (pH, exchangeable bases, available P). The application of fresh, limed and composted sludge produced significant increases in plant growth compared to the control, especially in the ryegrass crop. It highlights the contribution of nutrients, especially N and P, although it also increased the absorption of other nutrients. It should be noticed that the effect of the composted sludge was of lesser magnitude compared to the others. The observed effect of different amendment rates on the biomass production will contribute, to the adjustment of the doses to be applied in production situations. A relatively low residual effect of the amendments was observed in the second crop (sorghum), except for the case of the higher rate of limed sludge. Regarding the effects of the amendments on the soil properties analyzed, there were few changes after one year of application, which is important to assure the sustainability of the sludge utilization at farm level.

(2675 - 2917) Agroindustrial Residues to Improve Water Consumption and Productivity of *Lolium perenne* in a Sandy Soil

M. Cristina Diez[1]; Juan Curiqueo[2]; Marcela Levío[2]; Felipe Gallardo[3]
Chemical Engineering Department and Biotechnological Research Center Applied to the Environment (CIBAMA-BIOREN). University of La Frontera[1]; Biotechnological Research Center Applied to the Environment (CIBAMA-BIOREN). University of La Frontera[2]; Chemical Sciences and Natural Resources and Biotechnological Research Center Applied to the Environment (CIBAMA-BIOREN). University of La Frontera[3]

Sandy soils have a wide range of limiting factors for agricultural use, between them nutrient deficiencies, acidity, water stress and poor physical properties. In these conditions, nutrient decline, erosion, leaching, salinity, and acidification could occur. To improve these soils, organic and inorganic amendments are commonly added for improving its physical and chemical characteristics which promoting plants productivity. We studied different combinations of diatomite earth (D) from brewery production, biochar (B) from biomass boiler and sawdust (Sw) from wood process industry, as amendment to improve the water holding capacity (WHC) and productivity of *Lolium perenne* (ryegrass) in a Sandy soil (S). The soil contains 58.3% sand, 32.6% silt and 9.1% clay, with low organic matter content (3.0%). Also, we used an organic soil (Trumao) (37.1% sand, 34.2% silt and 28.7% clay) with high organic matter content (12%) for comparative purposes. For *L. perenne* productivity assay, pots of 4 kg of the soil amended with the residues in different combinations were used and maintained in greenhouse conditions. The assay consisted of three periods in which water was added to the pots corresponding to 100, 75 and 50% of the soil WHC. Chemical, biological and physical paremeters of the amended soil were measured at initial and final time (240 days). TDR-100 equipment was used to water volumetric content evaluation and, water loss by gravimetry. Vegetal biomass was evaluated four times during the assay and chlorophyle content at the end of the assay. The WHC of Sandy soil without amendment was low (30-32%) compared with Trumao soil (60-65%). The addition of all materials (1%) increased WHC in both soils. The cumulativy productivity (240 days) of ryegrass increased in SSwD, SSwDD and SBD treatments, respect to the control soil (S), obtaining more than 80% of productivity in the soil amended with B + D. However, the SSw and SSwB treatments showed cumulative productivity less than the control soil, probably by the type of sawdust wood and the alcalinity associated with biochar. Biological (urease, phosphatase and dehydrogenase activities) and chemical properties of the Sandy soil were also improved by addition of the different combinations of agroindustrial wastes. The chlorophyl content was the highest in SBD treatment and the lowest in the control soil. On the other hand, no differences ($p<0.05$) were found between SSwD, SSwBD SB SBD SSwB treatments.

(2853 - 1395) Ammonium and nitrate in yellow latosol in chronosequence of crops under no-tillage in the eastern Amazon

Letícia Cunha da Hungria[1]; Edilson Carvalho Brasil[2]; Rúbia Carla Ribeiro Dantas[1]; Jamil Chaar El Husny[2]; Mário Lopes da Silva Júnior[1]; Sidney Daniel Araújo da Costa[1]
Universidade Federal Rural da Amazônia[1]; Embrapa Amazônia Oriental[2]

The time of use of the soil conservation management systems can to influence ammonium ($N\text{-}NH_4^+$) and nitrate ($N\text{-}NO_3^-$) dynamics, during the process of nitrogen (N) organic mineralization in the soil. In the Amazon, especially in the state of Pará, there are few studies that evaluate impacts caused by changes of soil management and system adoption time on the dynamics N inorganic forms ($N\text{-}NH_4^+$ e $N\text{-}NO_3^-$) in soil. The objective was to evaluate the influence of no-tillage (NT) on the $N\text{-}NH_4^+$ and $N\text{-}NO_3^-$ dynamics in a Yellow Latosol (Oxisol) in the Eastern Amazon. The study was carried out in the Paragominas city, southeast of the state of Pará, where soil samples were collected at depths of 0-5, 5-10 and 10-20 cm during the rainy period of the region. The experimental design was completely randomized, in subdivided plots, with four replications. The treatments consisted of a chronosequence of crops under no-tillage with four (NT4), six (NT6) and ten years (NT10) of adoption, besides an area under conventional tillage (CT) and another with native forest (NF). The $N\text{-}NO_3^-$ and $N\text{-}NH_4^+$ contents were determined by extraction with KCl 1,0 $mol.L^{-1}$ solution and further reading through the spectrophotometer. According to the results, the $N\text{-}NO_3^-$ contents obtained in the 0-5 and 5-10 cm layers were, respectively, 21,2 and 15,4 mg kg^{-1} in NT4; 23,0 and 17,0 mg kg^{-1} in NT6 and 24,1 and 18,7 mg kg^{-1} in NT10, demonstrating that throughout the time of adoption the NT promoted increases in $N\text{-}NO_3^-$ contents at these depths. Regardless of the time of adoption, the NT promoted $N\text{-}NO_3^-$ stratification, while the CT promoted a more homogeneous distribution between the depths. In all depths, the highest $N\text{-}NH_4^+$ contents were obtained in NT6 (14,8 mg kg^{-1}) and CT (15,3 mg kg^{-1}), which did not differ among themselves, but were highest than NT4 (10,0 mg kg^{-1}) and NT10 (10,4 mg kg^{-1}), which did not differ between them either. Evaluating the individualized layers was found that in the 0-5 cm layer, the $N\text{-}NH_4^+$ content of the NT6 (21,4 mg kg^{-1}) was higher than CT (15,2 mg kg^{-1}). The NT was efficient in increasing the $N\text{-}NO_3^-$ contents in the soil, during the time of adoption, indicating its capacity to maintain the N in the system.

(3213 - 2674) Anaerobic incubation as an estimate for the nitrogen mineralization rate in organic wastes

Jessica Zuanazzi Fioritti Corbo[1]; Aline Renée Coscione[1]; Adriana

Marlene Moreno Pires[2]; Ruan Carnier[1]
Agronomic Institute[1]; Embrapa[2]

The agricultural use of organic wastes is based on the supply of nitrogen (N) to crops, as it is usually the most limiting nutrient in soils. The nitrogen mineralization rate (NMR) of organic wastes and fertilizers can be estimated by several methods. However, but the most used and widely accepted is the long-term aerobic incubation (AE). This is a laborious, costly and time-consuming method. The anaerobic incubation (AI) method can be an alternative to the standard procedure since it is robust, faster and cheaper. The aim of this work was to compare the NMR of anaerobic and aerobic methods, using 10 organic waste samples. For this, hen manure (HM), coffee silverskin (CS), chicken manure (CM), sugar cane filter cake (FC), cattle manure (BM), expired coffee powder (CP), castor bean cake (CB), dry sewage sludge (SS), peat (PT) and poultry litter (PL) were incubated aerobically according to the standard aerobic and the an aerobically procedures, in triplicate. The anaerobic incubation occurred under water saturation for 7 days, at 40^{O}C. The incubations were performed using a Rhodic Ferralsol at pH 4.1. Three doses of wastes were used in the incubations, corresponding to 150, 300 and 450 g kg^{-1} of N-Kjeldahl (NK), summing 30 incubation units plus a soil reference without nitrogen addition. The amounts of mineralized N were determined in extracts obtained with saline solution after steam distillation with the addition of MgO and Devarda alloy. The calculate NMR obtained for both methods were submitted to the correlation analysis ($p<0.05$). The recovered N by the anaerobic incubation represent 56% of the incubation aerobic, by obtaining the following equation: (TMN_{ai} = 0,559*TMN_{ae} - 3,9418; r^2 = 0.66; $p<0.01$). For both methods, the higher NMR was found for CB and SS (6.3% of NK, C/N=7 and 5.4% of NK, C/N=5.8, respectively). On the other hand, the lower NMR was found for FC in both methods (0.12% of NK, C/N=46). Besides FC, the CS and CP wastes presented N immobilization in the AI, probably due to the characteristics of these material, that have amounts of toxic polifenols. These composts may have affected the decomposition of the wastes by microorganisms. Nevertheless, such results indicate that the anaerobic method can be used alternatively to estimate NMR at organic wastes.

(4488 - 2688) Analysis of quantitative parameters of the meso and macro edaphic fauna found in corn culture under different forms of fertilization.

Domenico Marcelo Rafaele[1]; Alexandre Pozzato[1]; Daniel Fontanive[1]; Marco Antonio De Oliveira[1]; Patrick Gustavo Dunke[1]; Danni Maisa Silva[1]; Bárbara Clasen[1]
UERGS[1]

Soil fauna organisms play an important role in the soil. Techniques that favor the increase of the edaphic organisms are of great importance. The use of Liquid Swine Manure (LSM) as an alternative source for mineral fertilization is widely used in regions that share agricultural activities and pig farms. This work had as objective to analyze the classes of organisms of the meso and macro edaphic fauna found in corn crop under different forms of fertilization. This work was carried out on private property located in Tenente Portela - RS. In order to conduct a survey of soil fauna, Provid-type traps was used (Antoniolli et al., 2006), were installed in a R7-stage maize experiment with seven treatments with four replications in a randomized block design (RBD), (16m^2 each treatmen), they was: CFR, chemical fertilization as recommended for corn crop in latosol by the Manual of Liming and Fertilization for the RS and SC states described in publications (CQFS-RS / SC, 2017); MTR, Dose of 31.875 m^3 / ha of LSM stabilized according to its nitrogen concentration equals the same as CFR; MT-10, which is equivalent to MTR less 10% of recommended N; MT0, without fertilization; MT10, which is equivalent to MTR plus 10% of recommended N; MT20 equivalent to MTR plus 20% of recommended nitrogen and NFT, native forest. The evolution of the addition of LSM increased considerably abundance of organisms such as some species of Collembola that provided greater abundance in all the treatments that received LSM compared to NFT that demonstrated greater diversity of groups which is expected in natural environments. Similar results were also obtained by Sauer et al. (1996), who verified that colembolla populations increase with the increase of the organic matter content in the soil surface. 31753 organisms were collected and classified into 15 different groups of which 30336 belonged to the Colembolla group and 1417 organisms divided into the other groups. The results showed that natural environments (NFT) preserve greater diversity (0.75 Diversity of Simpson), while environments that provide food favorable to organisms concentrate higher amounts of these, raising the dominance (0.97 Simpson dominance) as is the case of the MT20 which received high doses of DLS and favored the dominance of Collembola (18023 out of 18276 organisms). The meso and the macro edaphic fauna showed variable abundance and diversity under different fertilizations in the maize crop.

(3630 - 1918) Analysis of soil chemical fertility level under cashew trees (*Anacardium occcidentale*) in North of Côte d'Ivoire (West Africa)

Diomande Loua Barthélémy[1]; Coulibaly Fanlégué Lacina[2]; Diabate Donourou[3]; Soro Sibirina[1]
Université Peleforo GON COULIBALY, Institut de Gestion Agropastorale, Filière Economie et Gestion Agropastorale[1]; Université Peleforo GON COULIBALY, UFR Sciences Biologiques, Département de Biologie Végétale[2]; Université Félix Houphouët-Boigny, UFR SSMT, Laboratoire de chimie physique[3]

Côte d'Ivoire is the first producer and exporter country of brute cashew nut. But, the yield by orchard is very low with 350 kg.ha^{-1} against 1000 kg.ha-1 in India and 2000 kg.ha^{-1} in Vietnam. For explaining the low yield of cashew orchard in Côte d'Ivoire, influence of soil pH and essential nutrients content under orchards of cashew trees were evaluated in Korhogo, Ferkessédougou and Bondoukou departments in Côte d'Ivoire. Ten (10) orchards old more than 15 years were selected randomly in each department. Under each orchard, one composite sample from thirty two (32) elementary samples was collected by auger to a depth of 0-30 cm on one (1) ha. These samples were sent to laboratory in order to evaluate pH and nitrogen, phosphorus, potassium, calcium, magnesium, iron, zinc and copper content. The values from analysis were compared to critical levels. The results of analysis showed that soils under orchards are moderately acid and nitrogen, phosphorus, calcium and zinc contents are strongly low. Concerning magnesium and potassium contents, the level varies between strongly low and low. In contrast, iron, copper and manganese have got high level. The cashew trees studied suffers from serious nutritional deficiency in major, secondary and trace nutrients. For increasing the yield of cashew nut in north of Côte d'Ivoire, adjustment fertilisation is necessary which must put at normal level the soil pH and all deficient nutrients following an appropriate fertilisation plan.

(2655 - 899) Analytical quality program of soil fertility laboratories that adopt Embrapa methods in Brazil – 2016/2017 results

Daniel Vidal Perez[1]; Marcelo Francisco Costa Saldanha[2]

Embrapa Soios[1]; Embrapa Meio Ambiente[2]

Accuracy and precision of soil fertility results is constantly questioned by customers. To promote its credibility, laboratories generally participated of external performance testing programs. The analytical quality program of soil fertility laboratories that adopt the Embrapa methods (PAQLF) is a voluntary sample-exchange program established since 1992. PAQLF is managed by Embrapa Solos and evaluate P and K extracted by Mehlich1 solution; Al, Ca, and Mg by KCl 1 mol L^{-1} solution; H + Al by Ca Acetate 0.5 mol L^{-1} ; soil pH in water; and organic C by wet combustion. Accuracy is based on a confidence interval: average ± a.SD; where, SD = standard deviation; a = 1, when CV> 50%; a = 1.5, when 20%> CV <50%; and a = 2.0, when CV <20% (CV means coefficient of variation). Precision is determined by the average CV of the analytical results of two samples sent in triplicate. Inaccuracy and imprecision composes an Index of Excellency rank: A for IE> 91; B for 71> IE <91; and C for IE <71. Only A and B laboratories are considered approved by PAQLF. In the 2016/2017 program, 122 laboratories from all Brazilian states had participated. The Midwest region contained the largest number of participants (37%). Southeast, Northeast, North and South regions comprises, respectively, 25%, 17%, 11% and 9% of the laboratories. Only 66% of the 122 laboratories reached the A and B ranks of IE classification. However, Midwest laboratories were by far the ones that presented the best performance, with 87 percent being approved. Northeast laboratories showed the worst results with 38% approval. These findings highlighted the different laboratories profiles of each region. The laboratories of the Midwest are in its most private and possess the greater analytical capacity, some of them exceeding 100,000 yearly analyses. The permanence in the market of soil analysis is clearly dependent on its ability to demonstrate its analytical quality to the customers. And this occurs through its results in quality programs like PAQLF. On the other hand, laboratories in the Northeast region are mostly public and, therefore, dependent on government resources. In this way, due to the weakness of the Brazilian economy in recent years, it's easy to understand why they have the lowest performance. Considering the last seven years, although the number of participants has been growing annually (34%), there is no evidence of lowering of the percentage of approved laboratories.

(3582 - 746) Availability of phosphorus in soils amended with dairy manure, urban and industrial sludge.

Amabelia del Pino[1]; Lucía Bentancur[1]; Nadia Freire[1]; Melina Fernández[1]; Omar Casanova[1]

Facultad de Agronomía - Universidad de la República[1]

Dairy manure, urban and industrial sludges can provide important amounts of nutrients when used as soil amendments for pasture and crop production. However, management difficulties arise due to uncertainties regarding to the dosage of these materials. An important proportion of P in manures and sludges is in organic form, and from the inorganic fraction not all is water soluble. This study was aimed to: 1) Assess the soil P availability for crops of three amendments: dairy manure (DyM), sludge from dairy industry (SDI) and urban sanitary sludge (SU). 2) Evaluate the residual available P in soils amended with these materials. A greenhouse experiment was conducted with ryegrass as the test crop, in a soil representative of dairy production region in Uruguay (A horizon texture: silty clay loam). Two rates of each amendment were compared to P fertilizer (K_2HPO_4), plus a control without any addition. The application rates of the amendments and fertilizer, based on total P content, corresponded to 40 and 80 mg kg^{-1} of soil. The amendments and fertilizer were mixed with the soil, transferred to plastic pots (3 per treatment), and ten pre-germinated ryegrass seeds were planted in each pot. Three months after planting the aerial biomass of ryegrass was cut, weighed, dried and ground for P concentration analysis. Soil samples from each pot were collected to evaluate residual P availability (Bray 1). The biomass production of the treatments SDI and SU represented 2.7 and 1.6 folds the yield of the control (average of two rates). In contrast for DyM ryegrass yield was lower than control, while in the fertilized pots biomass production was slightly above the control. The absorbed P showed similar trends, with the highest values for sludge amended soils. But also ryegrass in DyM and fertilized pots more than doubled the P absorption of the control. For SDI, SU and fertilizer significant differences were found between application rates, in biomass production and absorbed P. The residual soil P was higher for SDI and fertilizer compared to SU and DM. The reasons for these results could be linked to the slow decomposition of DyM, which presented a higher C/N ratio compared to sludges. In the case of SU, higher soil P retention was attributed to the addition of $FeCl_3$ during sludge processing. It was concluded that the dosage of DyM and sludges should take into consideration not only total P content, but also other characteristics that affect their reaction with the soil.

(9764 - 2852) Biosolid microbial stabilization for potential use as soil improver in Costa Rica.

Fabiola Segura[1]; Andrea Quesada[1]; Federico Masís[1]

Costa Rica Institute of Technology[1]

Phosphorus, nitrogen and potassium are key elements in plant growth. Therefore, essential to accelerate land use recovery and food security improvements. The projected increase in the demand for fertilizers in Latin America and the Caribbean, between 2005 and 2050, is estimated to be 180%. In Costa Rica, nitrogen is considered a generalized limiting factor and 74% of agricultural soils present phosphorus deficiencies. On the other hand, septic waste, depending on its origin and dewatering degree, contains varied but significant amounts of nutrients such as nitrogen, phosphorus and potassium. By 2017, domestic wastewater treatment in Costa Rica was covered using septic tanks at 75.8%, indicating an increasing generation of domestic sewage sludge, which can contain large number of pathogenic bacteria, viruses and parasites eggs. Thus, the need for appropriate disposal and treatment. Up to now, there are countries that have already attained management and disposition strategies of biosolids in soils, for example: U.S.A and Canada. So far, production of biosolids derived from domestic sewage sludge comprehend three phases: microbiological stabilization, physical-chemical stabilization and storage or final disposal of treated biosolids. From laboratory-scale to pilot-scale, this research seeks to establish three sanitary treatments to cover the first phase and to minimize potential risk of biosolids land application. Three approaches are undertaken: lactic acid fermentation, liming and biosolid solarization. To improve handling disposal and reduce public concern regarding the recycling of domestic sewage sludge in soils, this research aims to show the usefulness of “faster and unexpansive techniques” to reduce microbial pathogens during biosolids production. Therefore, in accordance with related legislation, the microorganisms of focus are intestinal nematodes and fecal coliforms. The high content of organic matter and nutrients of biosolids make them excellent substrates to produce soil improvers. Furthermore, soil physical properties like water holding capacity and total porosity are enhanced when biosolids are mixed with materials such as biochar.

amendments using sanitation alternatives to the recovery and conserve of soil.

(6955 - 1305) Boron content as a function of N rates in Oxisol cultivated with coffee

Danilo Marcelo Aires dos Santos[1]; Michele Ribeiro Ramos[1]; Enes Furlani Junior[2]; Talita Maia Freire[1]; Thalline Rodrigues da Silva[1]; Lorena dos Santos Campos[1]; Dara Chaves Paixão[1]; Dione Joaquim Pereira[1]; Sebastiana Patricia Alves Coelho[1]

Universidade Estadual do Tocantins[1]; Universidade Estadual de São Paulo[2]

The addition of N to agricultural crops is usually accomplished through the application of fertilizers. In many cases, the requirements of the crop and the dynamics of the availability of this nutrient in the soil are not known, thus opting to apply a greater amount of fertilizers to guarantee high yields that can cause imbalance of the soil fertility, being able to decrease the availability of micronutrients. In order to study the influence of nitrogen rates and different application systems, in the soil B levels this study was carried out. The work was installed in FE / UNESP Campus of Ilha Solteira, in the municipality of Selvíria-MS, in a Oxisol Dystrophic cultivated Catuaí red cv. The experimental design was a randomized block design in a 5x3 factorial scheme with 4 replications, 5 nitrogen doses (0, 50, 150, 250 and 350 kg ha-1) and three application modes (single, split twice, split three times), source used was urea. Soil collection was performed after coffee harvesting at depths of 0 to 40 cm and the determination of boron levels were obtained through the methodology described by Raij & Quaggio (1983, 1987), Raij et al (2001) and Embrapa (1999). There was a significant effect for interaction between doses and the N application system, with linear adjustment for single and split application mode in two moments, but the adjustment was negative, that is, the higher the N dose the lower the B content in the soil, this fact can be explained by the acidification of the soil by the use of nitrogen fertilizer inhibiting the absorption of micronutrients, which requires the pH between 6.0 to 7.0, for greater availability. Single and piecewise application at two N times decreases soil B contents.

(4037 - 1519) Boron release from different fertilizer sources in two soil types

Gabriel Barth[1]; Helio Antonio Wood Joris[1]; Marcel Barbier[2]; Fabiano Silvestrin[2]

Fundação ABC[1]; Rio Tinto[2]

Boron (B) is an essential element for plants, participating of several physiological processes. The known effects on crop yield have resulted in efforts to provide the right B source, especially considering its solubility. The higher the source solubility, the greater the theoretical amount of B released in soil solution. In order to determine B release after application of different sources, an experiment was established in soil columns, by testing two soils with contrasting texture and B content: Sandy (299 g kg^{-1} of clay and 0.2 mg dm^{-3} of B) and clayey (727 g kg^{-1} of clay and 0.4 mg dm^{-3} of B). The B sources were the treatments, consisting of two sources of low solubility (ulexites) and three sources of high solubility (one boric acid and two sodium tetraborate). Experimental design was complete randomized block with four repetitions. Each experimental unit was a 0.0157 m^3 PVC column pipe (0.7 m height by 0.1 m diameter). Soils in columns were saturated at 60% of water filled pore space, then B sources were applied to soils surface. Next, dripping of deionized water initiated on a weekly basis, at rates of 0.5 ml and 0.8 ml on sandy and clayey soils, respectively. At the end of each week, B content was analyzed in percolated solution. This study was carried out through 40 weeks. Analysis of percolated solutions showed an intense B release from highly soluble sources, with more than 90% of B released during the first 10 weeks of the study on both soils. After 30 weeks, B released reached more than 95% of the total B that was applied to these columns. On average, during the first 10 weeks, an amount of 9.3 mm of water for each percent point of released B was estimated. On the other hand the less soluble B sources, in average for both soils, showed a maximum of 47% of total B released, after 40 weeks. At the end of the experiment, the soil B content was analyzed. In sandy soil, was found that B was higher on soils where the less soluble sources were applied, while in clayey soil, all treatments exhibited higher B than in the untreated control, but indicated no differences between sources. The high solubility B sources released almost 100% of B, while less soluble sources released less than 50% of B. The remaining boron in soil from low solubility was not released through a great amount of percolated water (average of 3300 mm). In order to improve B availability, the right B source and application time are an important aspect to keep in mind.

Teak (*Tectona grandis* L.f.) is one of the most cultivated forest species in the State of Mato Grosso, which requires a large amount of substrates, such as subsoil, to produce seedlings. Currently, alternative substrates have been requested for the productive process, such as the use of forages, especially the brachiaria brizantha (*Urochloa brizantha*), which is widely cultivated in the State. The objective of this work was to evaluate the effect of the brachiaria substrate on the growth in height and lap diameter of seminal teak seedlings. The experimental design was in randomized blocks and with four replications, the experimental plot consisting of two teak plants. The seedlings were produced in pots and the substrate used was subsoil. The treatments consisted of aerial part and the roots of the brachiaria, which after being harvested and ground, is incorporated into the substrate at the concentrations of 0, 5, 10, 20, 33 and 50% of its volume. At 60 days after repication, the height and diameter of the lap of the teak seedlings were evaluated. The growth in height was not influenced by the aerial part of the brachiaria, whereas lap diameter was influenced by the concentrations above 20% of the substrate volume, and these averages did not differentiate between each other

($p < 0.05$). In the treatment with 50% concentration of brachiaria roots, a lower height ($p<0.05$) was observed for the others. For the diameter, the effect was more pronounced at concentrations above 20%. As the forage concentration in the substrate composition was increased, teak growth decreases, which demonstrates inhibitory effect, either by allelopathy or by immobilization of nutrients, the object of further studies. The brachiaria influences less the growth in height than the lap diameter of seminal teak seedlings. The roots of brachiaria interfere more and negatively in the growth in height and lap diameter when compared to aerial part. Brachiaria has potential for use as a substrate at lower concentrations.

(4915 - 3100) Carbon stock in fine roots of agroforestry-based oil palm productionin eastern Amazon, Brazil

Saime Rodrigues[1]; Steel Vasconcelos[2]; Daniel Markewitz[3]; Alzinei Simor[4]; Sandro Chaves[5]; Roberto Paiva[6]; Debora castellani[7]; Alessa Costa[2]; Osvaldo Kato[2]
Federal Rural University of Amazon, 2501 Tancredo Neves, Belem, 66.077-830, Brazil (saimecrodrigues@gmail.com)[1]; Embrapa Eastern Amazon[2]; University of Georgia[3]; College Estacio of Belem[4]; Federal University of Para[5]; Para State University[6]; Natura Innovation and Product Technology Ltda[7]

Agroforestry systems (AFS) can be an alternative to monocultures for oil palm production that can improve both above and below ground species diversity. A potentially positive benefit of diversification in oil palm cultivation is the possibility of increasing the soil carbon stock due to increased below ground competition and niche differentiation in fine roots. The biomass of fine roots (<2 mm) is important for the carbon cycle of ecosystems since this pool often accounts for a substantial portion primary production (up to 30%) in forested ecosystem, is a fast cycling pool, and can increase the soil carbon reservoir. In AFS, particularly in oil palm, little is known about fine root biomass. Working in the eastern Amazon of Brazil, we measured the spatial variation of the carbon stock in fine roots within an AFS containing oil palm and other species (herbaceous, shrubs, and trees). Carbon stocks were also quantified in fine roots of a 20-year-old secondary forest as a benchmark for comparison with the oil palm based AFS. Oil palm seedlings were planted in double rows interspersed with strips consisting of nine rows of herbaceous, shrub, and tree species. Organic fertilization was carried out quarterly with residues of palm oil fruit and from semi-annual pruning of some species in the AFS planting lines. Root samples were collected at a depth of 0-0.01 m on the palm planting line at two distances from the trunk (0.06 and 2.5 m) and at different sites (frond pile, between plants, and random spots within the AFS). In general, the stock of carbon in the fine roots was higher in the secondary forest than in the oil palm AFS, showing that even with the diversification of oil palm production, the potential of carbon accumulation in the root biomass is lower than within secondary forest. Carbon stocks in the fine roots (<2 mm) were higher nearer to the palm trunk (0.06 m) and at the frond pile, possibly due to the oil palm architecture and the accumulation of organic nutrient at the frond pile. Under the conditions of the current study, the conversion of a secondary forest into oil palm cultivation in organic agroforestry systems is not an efficient alternative for carbon storage in the biomass of fine roots.

(2980 - 963) Changes in nutrient cycling processes due to the introduction of exotic species in Cerrado native areas

Jonas Inkotte[1]; Marco Bruno Xavier Valadao[1]; Sarah Camelo da Silva[1]; Karla Monique Silva Carneiro Valadão[2]; Alcides Gatto[1]; Reginaldo Sérgio Pereira[1]
University of Brasília[1]; Mato Grosso's Estate University[2]

Exotic species have been used for the recovery of degraded areas because they have rapid growth and a cover of exposed soil, which promotes the reduction of erosion, and consequently the recovery and stabilization of soils. However, little is known about the impacts of this practice on the balance of edaphic processes. This issue has been gaining more attention in recent years due to the amendment of the 1965 Forest Code by Law No. 12,651 of May 25, 2012, in Article 61-A, paragraph 13, item IV admits the restoration of permanent preservation areas - borders of watercourses like gallery forests, mangroves, hill tops - by planting exotic species interspersed with native species in up to 50% of the total area to be surveyed. Therefore, the objective of this study was to evaluate the speed of eucalyptus leaf decomposition in a commercial plantation area and in a gallery forest Cerrado area, in order to verify if there is a difference in the speed of eucalypt leaf decomposition between the two areas of study, which may indicate a possible disequilibrium in edaphic processes.The work was conducted at the Água Limpa farm, which belongs to the University of Brasília, located in the Federal District - DF (15 ° 56'-15 59 'S and 47 ° 55'-47 58' WGr.), In a planting area of Eucalyptus clonal hybrid: Eucalyptus grandis x urophylla with 49 months of age and spacing of 3x2m, where the soil was characterized as Red Latosol, and a native area of gallery forest in an Organosol. Thirty litterbags with 20cm² of size were then allocated in each area, with 20g of eucalyptus leaves in each bag. These were then randomly allocated to each study area and rescued after 30 and 60 days of field exposure. The foliar decomposition was estimated by means of the initial and final mass difference after each exposure time, by the expression: remaining mass (%) = (final mass / initial mass) × 100. The two areas were compared by means of the t-test independent. Leaf masses after 30 days of field exposure showed a significant difference, being the fastest decomposition in the gallery forest area (5.83g decomposed) in comparison with the eucalyptus area (1.86g).The same occurred at the time of 60 days, being decomposed 4.64 g to the area of eucalyptus and 9.96 g decomposed in the gallery forest. The results showed that there is a difference in the speed of leaf decomposition between the areas and that this may indicate a possible imbalance in soil processes of nutrient cycling.

(7322 - 2348) Characterization of residual substratum originated by leaf cutting ants, used in the restoration of soils in colombian tropical dry forest

Yury Alexandra Fonseca[1]; Miguel Eugenio Cadena[1]
Universidad Distrital Francisco José de Caldas[1]

In the region of Quimbo Dam, located in southwestern-central Colombia, with Entisols and Inceptisols soils, a process of restoration of the area of damping is under development. This process requires to afforest the delimited damping area with native forest species, that need for their rapid establishment of a management of fertilization. The residual substratum originated of refuse of the leaf cutting ants (*Atta colombica*, Hymenoptera: Formicidae) can be used like natural fertilizer in the propagation of forest species. The aim of this study was to characterize the chemical properties of the residual substratum of ants. Three representative anthills in each one of the following vegetal cover were selected: Dense Forest (DF), Open Grassland (OG) and Dense Shrub (DS). The study was carried out at three depths in the external piles of the anthills (top TD, medium MD, and low LD), and at

two climatic seasons (dry and wet). The pH, C:N ratio, and concentrations of P, K, Ca, Mg, B, and Cu in the substratum were determined. The variables were analyzed by means of a Combined Analysis of Variance, a Randomized Complete Block Design with factorial arrangement (3 anthill depths x 3 vegetal covers) in series of experiments (equal place – different season), where the blockade form corresponded to three intervals of time during the day (6 to 9 am, 11 am to 2 pm, and 4 to 7 pm). The results showed that pH of substrates changes with the depth of the anthill, 6.47 for top, 7.34 for medium and 7.17 for low depth. The C:N ratio ranged between 3.9 and 12.0, showing that the lowest value is obtained for the interaction of Dry Season (DS) with Open Grassland (OG) and Low Depth (LD). Likewise, in the existing interaction DS:OG:LD, the elements P (11.29 mg/kg), Ca (5.43% dm), Mg (0.89% dm), B (84.57 mg/kg) and Cu (17.77 mg/kg) presented the highest concentrations. The K presented its biggest concentration (1.90% dm) for the Wet Season in the Open Grassland and Top Depth. In Dry Season, the same concentration of K was found, but for Dense Shrub and same depth (TD). It is recommended for the propagation of species in its seedling stage in nursery and open field, to use the refuse that comes from low stratum of pile anthill, collected at dry station and under Open Grassland, mixed with a proportion of the refuse of top stratum, to provide a substratum with the better nutritional content.

(1500 - 1280) Characterization of soil fertility variables cocoa planting indifferent areas in the State of Bahia

Thainara Brenda Lameira das Neves[1]; Joicelene Costa de Moraes[1]; Eduardo Cezar Medeiros Saldanha[2]; Marluce Reis Souza Santa Brígida[3]

Universidade Federal Rural da Amazônia-UFRA, Belém-PA[1]; Yara Brasil Fertilizantes, BR[2]; Universidade Federal Rural da Amazônia, Capitão Poço-PA[3]

The cocoa tree originates from regions of rain forests of Tropical America, where even today is found so Silvestre (CEPLAC, 2010). The cultivation of the cocoa in Brazil began in 1679, when Royal Chanter authorized the planting. With the growth in consumption as raw material for chocolate, the cocoa crop a expansion, where the mined-18th century, was implement in the South and Southeast of Bahia, witch concentrates most of the area cultivated with cocoa in Brazil (Soares, 2013), by presenting relevant productivity especially amongst the largest producers (FAO, 2009). Due to environmental conditions in tropical and humid areas with predominantly acidic soils, it is necessary to fix fertility for proper nutritional balance to achieve satisfactory productivity. In the context, the present study aimed to characterize the variability of fertility in different areas of cultivation. The samples were collected in large production area in six municipalities in the State of Bahia, kept in sixteen farms, with 15 simple sample collected with the help of Dutch Auger, 0-20 cm and 20-40 cm depth, forming composite samples taken a in front of plants another two on the sides (right and left) of these. The collection was made in zigzag for a better use of the area. The samples were taken to private lab for chemical analysis and the results were described in a spreadsheet and treated by the described statistics. The attributes were evaluated; Hydrogen potential (pH), Cationic Exchange Capacity (CTC), Base Saturation (v%), Aluminum Saturation (m), Phosphorous (P), Potassium (K), Magnesium (Mg), Sulfur (S), Boron (B), Copper (Cu), Iron (Fe), Manganese (Mn), Zinc (Zn). The results of the analysis showed that the attributes P, K, Mg, Cu, Mn and Zn had an imbalance of distribution in the cultivated areas, which required a fertility adjustment under the planting of cocoa, homogenizing the spatially of the cultivation areas balancing these elements for greats inefficiency and raise productivity.

(3239 - 2495) Characterization of the structure and analysis of microbial diversity in soil exposed to long-term nitrogen fertilization under contrasting agricultural stubble situations

Mónica Boccolini[1]
Instituto Nacional de Tecnología Agropecuaria. Marcos Juárez, Córdoba, Argentina.[1]

Agronomic practices involve changes in soil physical chemical properties which modify the function and structure of microbial communities. Molecular methods allow us to quickly and accurately evaluated changes in the structures of these communities. The aim was to characterize the structure and to estimate microbial community diversity of soil with long-term urea application and under two contrasting residues. The field experiment established in 1993 is located in INTA Marcos Juárez. It presents a design in completely randomized blocks with three treatments and three repetitions: A: without fertilization; B: 90 Kg ha^{-1} of N and C: 165 Kg ha^{-1} of N as urea. In 2010 and 2011 two samplings were carried out on stubble of soybean and corn respectively. Soil samples were collected from 0 to 10 cm depth. Were amplified DNAr of fungi and bacteria. The products of amplification were separated in gels of polyacrylamide denaturing. The Shannon index diversity was estimated and analyzed by ANOVA. The molecular profiles were analyzed by cluster analysis (CA). The variation in the composition of the communities was visualized by multidimensional scaling (MDS). The diversity of bacteria did not change with the treatments for both residues, whereas the diversity of fungi of the treatments B and C was significantly lower ($p< 0,05$) under soybean. In the CA of bacteria the separation was observed A and B to C for both residues, whereas in fungi, A it separated of B and C in both residues. The analysis MDS showed that the microbial communities of the soil changed depending on the rate of urea applied. The bacterial communities of A and B they were located united and separated of C in both residues; whereas in fungi only under soybean differences between communities were observed, separated A of C. In general, the pH correlated significantly ($p< 0,05$) with the variation in the composition of the microbial communities in both types of residues. Therefore, the fungi diversity of the soil it was more sensitively to the urea application. The urea caused changes in the composition of species and the structure of the communities. This would be determined principally by the variations in the pH of the soil and might be influenced by the type of residue in surface.

(2203 - 2145) Chemical and microbiological attributes in different areas of agriculture and fragment of native forest

Leopoldo Sussumu Matsumoto[1]; Leandro Mazo Rocha[1]; Rodrigo Domiciano Marques[1]; Teresinha Esteves da Silveira Reis[1]
State University of North Paraná[1]

Soil is one of the main basic resources whose function is to support several species on the planet and also acts as a substrate for plants, providing them with water and nutrients, which ensures the maintenance of life on earth. Therefore, different systems and techniques of soil management act directly in the physical, chemical and biological properties, since the preparation is directly associated with the quality and availability of nutrients to the plants. The objective was to evaluate chemical and microbiological parameters of soil quality in areas of cultivation and forest fragment in the winter and summer. The study was carried out in the city of Bandeirantes – PR/Brazil, considering areas of soybean, maize, sugarcane, pasture, around the forest fragment and four areas located in the central portion, border one and border two and in reforested area of the

fragment. Among the soil chemical parameters, organic matter, total organic carbon, hydrogenation potential, calcium, magnesium, aluminum, phosphorus, potassium, base sum and cation exchange capacity were evaluated, and the microbial biomass carbon was determined in the microbiological biomass, soil basal respiration, metabolic quotient and microbial quotient. The experimental design was completely randomized, arranged in an 8 x 2 factorial scheme. The data were submitted to analysis of variance and the means were compared by the Tukey test ($p < 0.05$). The chemical and microbiological attributes were submitted to multivariate analysis by main components separately. The results obtained in the native vegetation areas presented in most parameters analyzed, greater microbial community, organic matter content, lower stress, better efficiency in the availability of nutrients when compared to the areas of agriculture. Thus, in the different areas of study, soil management can influence the activity of the microbiota. The agrosystems presented good soil fertility, it was observed that soybean and maize presented better fertility when compared to the agricultural areas, with better P, K, Ca, Mg and CTC indexes, as well as sugarcane and pasture obtained lower levels of fertility. Soil management and vegetation substitution may favor changes in chemical and biological attributes. Studies aimed at this line of research may be of great help to the producer in choosing soil quality monitoring techniques, being more efficient and sustainable, aiming at the conservation and increase of organic matter in the soil.

(5810 - 680) Chemical attributes of an Oxisol submitted to management and organic fertilization in the system of crop-livestock integration in the western Amazon

Rodrigo Maciel Nunes[1]; Weder Vinícius de Oliveira Silva[1]; Fabio Régis de Souza[1]; Anderson Cristian Bergamin[1]; Jairo Rafael Machado Dias[1]; Luciana Sônia da Silva[1]; Cauandrey Deyverson Fagundes[1]; Júnior Antônio Rodrigues Mello[1]; Wesley Santana Ferreira[1]
Fundação Universidade Federal de Rondônia[1]

The livestock, for milk or beef, be part of the major source of income for the rural producers in the state of Rondônia, however, the inappropriate management in formation and development of the pasture promote a rise in the pasture degraded and soil, and consequently cause changes in the quality of the chemical attributes. The system o crop-livestock integration comes to be a promising alternative to recuperate de degraded pasture and promotes a higher input of waste vegetables, that improve the physical, chemical and biological quality of the soil when it is compare with conventional system of production. The objective of this work was evaluate the chemical attributes of an Oxisol submitted to a crop-livestock integration using an organic fertilization and management with limestone application. The experiment was conducted in the municipally of Pimenta Bueno-RO in the property of Alto Alegre Farm at RO 010 Km 30 area of pasture degraded. The delineation was randomized blocks in arrangement of subdivided parcels. Soil management treatment was implemented in February 2015. Principal parcel consists the management of soil: application limestone in surface on *Brachiaria* with no turn over of soil (CS), application limestone incorporated with harrowing (CIG), application limestone incorporated with an subsoiling followed by a harrowing (CIS), no limestone, just prepared with harrowing (G), no limestone, just prepared with subsoiling and harrowing (SG). The subparcels were constituted by source of fertilization: organic fertilization (manure of laying birds) and mineral fertilization. Application with mineral fertilization and organic happen in the moment of corn sowing, being the mineral in the furrow and the organic in surface. Was applied 300 $kg.ha^{-1}$ of NPK 04-30-16 formulation of mineral fertilizer an 5,5 $t.ha^{-1}$ of organic fertilizer. The properties chemical evaluate was pH in $CaCl_2$ 0,01 mol. L^{-1}, Al^{3+}, P, K^+, Ca^{2+}, Mg^{2+}, M.O, $H^+ + Al^{3+}$, effective CTC, CTC at pH 7,0, SB and V%. The best results for chemical attributes were obtained when realized the limestone application, independent of application mode. The fertilization with manure of lying birds rise the chemical attributes of the soil with pH, M.O, K^+, Ca^{2+}, Mg^{2+}, effective CTC and V% reduce the levels of toxic aluminium. For the P levels in the soil, is obtained the higher value with limestone incorporated application with the aid of harrow and organic fertilization with manure of laying birds.

(6745 - 2296) Clay dispersion in a Ferralsol under raw sugarcane management system

Lucas Augusto de Assis Moraes[1]; Thiago Ometto Zorzenoni[1]; Jean Carlos Santos de Oliveira[1]; Thadeu Rodrigues de Melo[1]; Alex Figueiredo[1]; Gislaine Silva Pereira[1]; Cláudia Maria do Prado Furquim[1]; Adriana Pereira da Silva[1]; Cristiane de Conti Medina[1]; João Tavares Filho[1]
Universidade Estadual de Londrina[1]

In the State of Paraná, the raw sugarcane harvesting method (SCC) has been ascending which has contributed to the mitigation of the fires and guaranteed the permanent maintenance of vegetal cover. However, with the encouragement of straw gathering, a scenario of return to the post-harvest straw removal was established. The objective of this work was to evaluate the clay dispersion in different periods without burning and three types of straw management. The work was carried out in an experiment implemented in August 2010, in an area submitted with a burned sugarcane harvesting system since 1960. The design was a randomized block design, with three replications and the soil of the area classified as a clayey Ferralsol. The treatments evaluated were: A) 2 years without burning (SQ) + no harvesting of straw (HS); B) 6 years SQ + no HS; C) 6 years SQ + partial HS and, D) 6 years SQ + total HS. Samples were collected at 60 and 160 days after the 2015/16 harvest at 0.00 - 0.05 m, 0.05 - 0.10 m and, 0.10 - 0.15 m depth. The evaluated attributes were water-dispersible clay (WDC), total organic carbon (TOC), pH_{H2O}, pH_{KCl}, ΔpH, PCZ, Ca^{2+}, Mg^{2+} and K^+. The results obtained allowed us to infer there were no significant difference between the treatments and that the variables with the highest correlation for WDC at 60DAC were ΔpH, PCZ and Mg^{2+}. For 160 CAD, there was a negative correlation between WDC and TOC. Therefore, it is concluded that, regardless of SQ time and straw management, there were no significant changes on clay dispersion.

(9615 - 1404) Colorimetric dosage of phosphorus by the phospho-molybdic complex reduced in extracts of Mehlich-3

Victor Hugo Alvarez V[1]; Carlos Antonio da Fonseca[1]; Reinaldo Bertola Cantarutti[1]
Universidade Federal de Viçosa[1]

The reduced phospho-molybdic complex with vitamin C (cPMoVitC) method used to determine P in the Mehlich-1 (M1) extract has low spectrophotometric efficiency for the determination of P in Mehlich-3 (M3) extracts. To improve this efficiency, the amounts of bismuth subcarbonate (ScBi), ammonium molybdate (MoAm) and sulfuric acid

(AcSu) in the composition of reagent 725 (R725) were adjusted. In addition, the amounts of ascorbic acid (VitC) in the working reagent composition (WR) were adjusted. In addition, the WR should be adjusted according to the volume of the M3 extract aliquot.We studied 17 WR_i initially working with calibration curves for the dosing method (DM) using 5.0 mL of M3 extract and 5.0 mL of WR (DM: 5 + 5). The composition of each WR_i studied was according to the Baconian matrix (5 + 5 + 5 + 5). The first three factors are the R725 components, which correspond to five doses of ScBi (0.6, 0.8, 1.0, 1.3 and 1.7 g L^{-1}), five of the MoAm (16, 18, 20, 25 and 30 g L^{-1}) and five doses of AcSu (120, 130, 138, 160 and 180 mL L^{-1}). The last factor was VitC with doses of 1.2; 1.4; 1.6; 2.0 and 2.4 g L^{-1}. To prepare each WR_i, initially, 1 L of each of R725i was prepared. Then to prepare each of the WR_i, 200 ml of the R725i were taken with the respective doses of VitC and the volume was completed to 1 L. In the sequence, WR was defined for DM with 2 mL of extract M3 plus 8 mL of RT and with 8 mL of the extract 2 mL of WR, (2 + 8) and (8 + 2), respectively. The spectrophotometric efficiency of the DM was evaluated by the slope of the calibration curves and by the sensitivity, limit of detection and precision. Higher slope, better sensitivity, better detection limit and high precision were achieved with the R725 composed of 2.0 g L^{-1} ScBi, 30.0 g L^{-1} MoAm and 138 ml L^{-1} AcSu. Thus, it has been defined that 125, 200 and 500 mL of this R725 and 1.0, 1, 2, and 5 are required to prepare 1 L of WR for DM (2 + 8), (5 + 5) and (8 + 6 and 4.0 g of VitC, respectively.

(2307 - 2900) Compositional analysis of cations and potential acidity of soil for Marandu palisadegrass fertilized with nitrogen sources

Elisângela Dupas[1]; Salatiér Buzetti[2]; Tárik Cazeiro El Kadri[1]; Maílson Vieira Jesus[1]; Marlene Estevão Marchetti[1]; Marcelo Carvalho Minhoto Teixeira Filho[2]

UFGD[1]; UNESP[2]

The objective of this work was to perform the compositional analysis of the cations ($N\text{-}NH_4^+$, K^+, Ca^{2+}, Mg^{2+}) and the potential acidity (H+Al) of the soil in the 0-20 cm layer, in Marandu palisadegrass (*Urochloa brizantha* cv. Marandu) in response to sources of nitrogen - N (urea, urea with urease inhibitor, polymer coated urea, ammonium sulfate, ammonium nitrate, ammonium sulphonitrate and without N) in five harvests in Ilha Solteira, SP, Brazil (20^o 21′ S, 51^o 22′ W and 226 m), applied 100 kg ha^{-1} of N per harvest. The compositional analysis was made based on the following sequential binary partitions of the *isometric log ratio* (*ilr*), where *ilr-1* = [$N\text{-}NH_4^+$, K^+, Ca^{2+}, Mg^{2+}|H+Al] and *ilr-2* = [$N\text{-}NH_4^+$|H+Al]. The *ilr-1* contrast was used to evaluate the balance between cations and soil acidity, and the *ilr-2* evaluated the effects of the addition of N sources on soil acidity, that is, the decrease in the value of pH and, consequently, increase in Al^{3+} content due to nitrification. The experimental design was a randomized complete block with four replications. There was significant effect isolated for N sources and cuts for *ilr-1* and *ilr-2*. The treatment without N presented higher value and positive of *ilr-1*, not differing from treatments urea with urease inhibitor and polymer coated urea, demonstrating a lower *isometric log* ratio of cations in soil than H+Al, responsible for soil acidity. The treatment with ammonium sulfate obtained the lowest value of *ilr-1*, not differing from the treatments urea, ammonium nitrate, polymer coated urea and ammonium sulphonitrate, indicating a higher proportion of cations than H+Al. In the first and third harvests, the *ilr-1* presented a negative value, demonstrating that there was a higher proportion of cations than H+Al, and these values did not differ from the fifth harvest. For the second and fourth harvests, the highest proportion of cations occurred in relation to H+Al, not differing from the fifth harvest. The *ilr*-2 not showed difference between N sources, however, for all N sources, the H+Al ratio was higher than $N\text{-}NH_4^+$. In relation to the harvests, the second was the only one that expressed negative value and differed from all other observations, meaning that the proportion of $N\text{-}NH_4^+$ was higher than H+Al. The highest values were from the first and fifth harvests, which differed from the third and fourth harvests. There were higher proportions of H+Al than $N\text{-}NH_4^+$, indicating that nitrogen fertilizers acidified the soil.

Keywords: acidity of soil, ammonium sulphonitrate, isometric log ratio (ilr), polymer coated urea, urea with urease inhibitor

(2541 - 1049) Corn inoculated with *Azospirillum brasiliense* grown under cover crops and ash

Jonas Guerra[1]; Gabriela Naibo[2]; Rodrigo Roani[2]; Cristiane Pain[2]; Wilson Galli[3]; Cristiano Nunes Nesi[4]; Mauricio Vicente Alves[4]

University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê, Zip Code: 89820-000, Brazil (guerraagronomia88@gmail.com);[1]; University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê, Zip Code: 89820-000, Brazil[2]; University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê, Zip Code: 89820-000.[3]; Professor, University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê, Zip Code: 89820-000.[4]

The aim of this study was to evaluate the effect of soil management in winter, the use of ash and nitrogen supply on yield and yield components in the corn. The experiment was carried out at the experimental plant of Unoesc - Xanxerê / SC, from May 2016 to April 2017. The soil of the experimental area is classified as dystrophic Red Latosol (Oxisoil), and the climate classified as Cfb. The experimental design was randomized in blocks with four replications under the arrangement in sub-divided plots. In the plots the winter management treatments were randomized: fallow, fallow with ash application, black oats / common vetch mixtures and black oats / common vetch / ash residues mixtures. No-tillage was the system used for sowing, with intercropping between vetch (40 kg ha^{-1}) and oats (50 kg ha^{-1}) and fertilization according to soil analysis and crop requirements. The ash dose was indicated according to the potassium content of the ash and the required by the culture. After the end of the cover crop cycle, the area was desiccated and the ashes reappeared (23.81 t ha^{-1}), starting the second step of the experiment (November, 2016 to March, 2017). Fertilizers were calculated according to the interpretation of the soil analysis, for a production expectation of 12 t ha^{-1} of grain. The subplot was corn seeded with and without inoculation with *Azospirillum brasiliensis*, with the inoculant being applied to the seeds at the dose of 500 ml ha^{-1}. In the sub-subplot, the application of mineral nitrogen (within or without) at a dose of 200 kg / N ha^{-1}, was been spread at 21, 33 and 44 days after emergence of the corn. Upon reaching the stage of physiological maturation, a thousand grain weight (TGW), number of grains, number of rows per cob and productivity. Sample datas were submitted to analysis of variance using F test, with 95% confidence. The results showed no statistical difference of the biological fixation for the number of rows per cob, number of grains per spike and TGW. However, for the yield of the corn culture, a positive statistical difference was obtained for the use of *Azospirilum brasiliensis* (11.596 kg ha^{-1}) when compared to treatments without

inoculation (10.447 kg ha^{-1}). This result demonstrated the potential of inoculation with *Azospirillum brasiliensis* as an alternative source to increase corn crop yield. The use of ash did not change any variables.

(1013 - 1034) Corn nutrition cultivated with organic and mineral fertilization

Eric Victor De Oliveira Ferreira[1]; Luis Artur Batista de Andrade[2]; Jennifer Alves Camilo[2]; Elizete dos Reis Lima Carvalho[2]; Greice Leal Pereira[3]; Samuel Petraccone Caixeta[2]
Universidade Federal Rural da Amazônia[1]; Universidade Federal de São João Del Rei[2]; Universidade Federal de Viçosa[3]

Under natural conditions, most of the tropical soils present high acidity and low availability of nutrients, mainly macronutrients, which reduces their uptake by plants. Such scenario requires correction and fertilization of these soils to obtain high yields. The objective of this work was to evaluate the macronutrient contents of the silage corn shoot (hybrid RB 9004 VT PRO) by the substitution (partial and total) of the mineral fertilization by organic fertilization via barn compound. An experiment was carried out at Barreiro Alto Farm (Sete Lagoas, Minas Gerais State, Brazil), from November 2016 to February 2017, in soil cultivated under no tillage system. Before the installation of the experiment, the soil (0-20 cm) presented pH (H_2O)= 5.5; organic matter= 2.0 %; P and K (Mehlich 1)= 26 and 135 mg/dm³ respectively; base saturation= 51 % and clay= 70 %. It were evaluated nine treatments in a randomized complete block design, with four replications (15 m² each plot). The treatments consisted of combinations of mineral fertilization (200 to 400 kg/ha of 30-0-10) and organic (4 to 8 t/ha) in the topdressing, applied on the soil surface near the planting line, besides the control (without fertilization). At planting, all treatments (except for the control) received 230 kg/ha of 9-44-0 (N-P_2O_5-K_2O) and 70 kg/ha of 0-0-60. There was a treatment with only organic fertilization, being applied 6 t/ha of the barn compound in both the planting and the topdressing. Barn compound (C/N= 16, organic matter= 43.5 %, CEC= 64.5 $cmol_c$/kg, P and K= 2.49 and 2.48 % respectively) consisted of waste (manure and urine) of dairy cows mixed with pieces of eucalyptus wood, being this material mixed twice by day. At the end of the experiment (90 days), were randomly collected the shoot (stem, leaves and ears) of ten plants within each plot, being three of them dried (70 ºC/96 h), ground and sent to the laboratory for determination of macronutrients. The results were submitted to analysis of variance ($p<0.05$) and to the Tukey test in the Sisvar software. There was no statistically significant difference between treatments on nutrient content in corn shoot, with mean values (g/kg) of N= 12.1; P= 1.4; K= 8.9; Ca= 2.2; Mg= 1.5 and S= 0.8, probably due to the initial good soil fertility. Under such conditions, the barn compound provides corn nutrition similar to mineral fertilization.
Keywords: macronutrients; tropical soils; silage corn; *Zea mays*

(3319 - 2063) Correction of soil acidity and nutrient availability in a Oxisol

Luis Felipe Rodrigues de Aquino Sousa[1]; Ricardo Miranda dos Santos[2]; Carlos Alberto Kenji Taniguchi[3]; Márcio Cleber de Medeiros Corrêa[1]; William Natale[1]
Universidade Federal do Ceará[1]; Universidade Federal de Viçosa[2]; Empresa Brasileira de Pesquisa Agropecuária - Embrapa[3]

Brazilian soils are mostly characterized by being acidic reaction and low natural fertility. Several factors affect the availability of nutrients, one of them is pH. Liming is a practice widely used for soil acidity correction. Its main effects are the increase of pH, decrease of acidity, increase of Ca and Mg concentrations and, increase of the availability of P. Thus, the objective of this work was to evaluate the effect of liming on the availability of P, K, Ca and Mg in acid soil. For this, samples of Oxisol were collected in the municipality of Maracanaú-CE, Brazil, with the following chemical properties: pH(water) 4,6; 5.4 mg dm^{-3} of P; exchangeable contents of K, Ca, Mg, Na, H + Al, Al, cation exchange capacity (CEC) of 1.1, 1,3, 2.5, 0.3, 38.8, 10.0, 43.9 mmolc dm^{-3} respectively; base saturation (V%) of 12%. The soil was incubated with increasing amounts of limestone, CaO = 32% and MgO = 15%, in amounts sufficient to raise the base saturation (V%) to: 25%, 35%, 45%, 55%, 65%, 75% and 85%; with four replicates, in a completely randomized design. The amounts of limestone were calculated by the base saturation method. After thirty days of incubation soils were removed from the vessel and sent to the laboratory for chemical analysis of pH, P, K, Ca and Mg, to evaluate the availability of these elements. at end, the regression method was applied to evaluate the data, relating them to V%. Based on the results it was found that there was an increase in pH, in the concentrations of P, K, Ca and Mg so in linear trend ($P<0.05$). The pH increase (pH = 4.03 + 0.03V% R^2 = 95%) is the result of the reaction of the H + ions with the hydroxide produced by the limestone reaction. The elevation of Ca (Ca = 1.52 + 0.224V% R^2 = 97%) and Mg (Mg = 0.82 + 0.151 V% R^2 = 93%) results from the application of limestone, which is composed of carbonates of Ca and Mg. The same applies to P, which had its availability increases at P = 5.93 + 0.013V% R^2 = 86%. This increase is due to the release of P adsorbed to the oxides, which become more soluble with increasing pH. The availability of K increased by K = 1.03 + 0.001V% R^2 = 31%. This low effect on the availability of K can be explained by the low initial concentration of K in the soil. It is concluded that liming, in fact, reduces the acidity and increases the availability of nutrients in the soil.

(4817 - 2051) Cover Crop Cocktails as N and P Source in the Brazilian Semiarid

Antonio Pereira Filho[1]; José Teixeira Filho[2]; Tamires Santos de Jesus[3]; Vanderlise Giongo[4]
Universidade Federal do Vale do São Francisco[1]; Universidade Estadual de Campinas[2]; Universidade de Pernambuco[3]; Empresa Brasileira de Pesquisa Agropecuária - Embrapa Semiárido[4]

Many studies have shown the benefits of the single cultivation, but the value of varied cover crop plant cocktails has received less attention. The objective was to evaluate the availability of N and P by plant cocktails used as cover crop and green manure in the semiarid. The treatments were arranged in four blocks in a split-plot design with two soil management systems (tillage and no-till) and three cropping systems (Plant Cocktail 1 - 75% legumes + 25% non-legumes; Plant Cocktail 2 - 25% of legumes + 75% non-legumes; and Natural Vegetation). Fourteen species were included in the composition, comprised legumes, oilseeds and grasses. Dry biomass production and decomposition, nutrients accumulation and mineralization by plant cocktails and natural vegetation were evaluated. Decomposition and release of N and P was monitored by the litterbag-method. Plant cocktails reached a Dry Biomass production (~9.0 t ha^{-1}) twice higher than Natural Vegetation, essential for adoption of no-tillage systems in the region. Natural Vegetation showed less accumulation of N and P due to lower production of biomass in relation to Plant Cocktail 1 and 2. Dry biomass production and P and N accumulation by Plant Cocktail 1 and 2 had no significant differences. The decomposition of

50% of plant cocktails takes approximately 116 days by no-till system and 100 days by tillage system, showing a small difference between the types of soil management. The 50% of N mineralization occurred during the first 3 months which the higher N release ranged from 163.2 to 171.6 kg ha^{-1} with Plant Cocktail 1, varying with the type of soil tillage. P mineralization was influenced by soil management. Plant Cocktail 2 took 105 days to release 50% of P while no-tillage system took about 135 days. Plant Cocktail 2 released a mean of 29.8 kg ha^{-1} P during the first 3 months by conventional tillage. The use of Plant Cocktail was more effective than Natural Vegetation and proved possible alternative to supply the nutritional demands of N and P for a successional crop.

(2814 - 2844) Cowpea: spacing and density of plants in cerrado soil.

Mauro Gomes dos Santos[1]; Weslany Silva Rocha[1]; Rogel Galvão Prates[1]; Ana Paula Ribeiro Barros[1]; Marcelo Alves Ribeiro[1]; Tânia Rodrigues Peixoto Sakay[1]; Eduarda Fernanda Gomes Viegas[2]; Raimundo Laerton de Lima Leite[2]; Rodrigo Ribeiro Fidelis[1]; Manoel Mota dos Santos[1]
Universidade Federal do Tocantins[1]; Instituto Federal do Tocantins[2]

The cowpea presents for planting, high adaptability to adverse conditions of the environment, such as climate, soils, as well as water deficit. Plant population and spacing have been emphasized among many farmers, as they are directly related to increased productivity; are key points to obtain good results in the production of grains. The objective of this study was to evaluate the behavior of cowpea, cultivar BRS Sempre Verde, on the spacing and density of plants in Cerrado soil, in the 2013/2014 harvest. The experiment was carried out at the Experimental Farm of the Federal University of Tocantins – Gurupi, on a Dystrophic Yellow Red Latosol. The experimental design was a randomized complete block design, with a 2 x 3 factorial scheme, with four replications of 4 m in length, spacings of 0.35 and 0.70 m between rows and three densities (4, 8 and 12 plants / m), the results were submitted to the Tukey test at the 5% level. The evaluated characteristics were flowering, stem diameter, mass of one hundred grains, total chlorophyll and productivity. There was interaction of plant densities per linear meter with the spacings between rows for the stem diameter characteristic; and line spacings and plant densities per linear meter did not influence productivity.

(1059 - 723) Critical limits for microbial indicators in tropical clayey Oxisols: towards the FERTBIO soil sample concept

Ieda de Carvalho Mendes[1]; Leandro Moraes de Souza[2]; Djalma Martinhão Gomes de Sousa[1]; André Alves de Castro Lopes[2]; Fábio Bueno dos Reis Junior[1]; Marilusa Pinto Coelho Lacerda[2]
Embrapa Cerrados[1]; Universidade de Brasilia[2]

The FERTBIO soil sample concept considers the advantages that the unification of the time of sampling and of the sample pretreatment procedures for soil chemical fertility (FERT) and microbiological (BIO) analyses, would bring for farmers and commercial laboratories. This study examined the effects of two soil sampling/handling strategies (flowering stage /field-moist soil samples (FFM) and post-harvest stage/air-dried soil samples (PHAD)) on the critical limits (CLs) for microbial biomass carbon (MBC), and soil enzymes β-glucosidase, arylsulfatase, acid phosphatase and dehydrogenase. Soil samples (0 to 10 cm depth) were collected in the years 2013 and 2015, from 24 treatments from three long-term experiments, on a Cerrado clayey Red Oxisol, in which P fertilization management was used to modulate crop yields and soil organic carbon (SOC). Linear regressions showed that the PHAD sampling was representative of the FFM. In spite of significant reductions of MBC (19%), β-glucosidase (62%), arylsulfatase (56%), acid phosphatase (64%) and dehydrogenase (63%), the PHAD sampling preserved the ranking of the treatments and did not alter the adjustment of regression models between SOC and the microbial indicators. Adequacy classes for each microbial indicator as a function of SOC were established based on the following criteria: ≤40%: low; 41 to 80%: moderate; and >80%: adequate. At the PHAD, the CLs equivalent to 80% of the SOC for MBC, β-glucosidase, arylsulfatase, acid phosphatase and dehydrogenase were: 325 mg C kg^{-1}, 116 µg p-nitrophenol g^{-1} h^{-1}, 71 µg p-nitrophenol g^{-1} h^{-1}, 495 µg p-nitrophenol g^{-1} h^{-1} and 41 mg TPF kg^{-1}soil $24h^{-1}$. The interpretative tables generated using the FERTBIO soil sample concept represent an important step towards the research efforts to incorporate microbial indicators in routine commercial soil analyses in Brazil.

(4957 - 2106) Crop residues amendments shaped the N transformation processes in soil during solarization

Chen Wang[1]; Guitiong Li[1]; Kun Zhu[1]
College of Resources and Environmental Sciences, China Agricultural University[1]

Biosolarization, where soil is amended with organic residues prior to solarization, can accelerate pest suppression, compress the solarization timetable, and facilitate effective treatment in relatively short time periods. The advanced understanding of N transformations in soil during solarization would be crucial for the optimization of biosolarization strategies. However, the N transformations in soil during solarization is rarely investigated. A greenhouse trial was employed in this study to examine the effects of crop residues amendment on soil heating, pH,microbial biomass carbon and nitrogen （MBC and MBN）, enzyme activity dynamics during biosolarization. Four treatments were designed in greenhouse in Shunyi, Beijing.We used wheat straw as the organic amendments. Control treatment had no amendments. To study the impact of pre-immobilizaton of NO_3-, another treatment was added with wheat straw 5 days earlier. Biochar was co-incorporated with wheat straw as the last treatment. We were aiming to verify microbial biomass carbon and nitrogen dynamic changes in soil during biosolarization period. Stable isotope tracing technique was applied to study the key N transformation processes during solarization. The current results suggested that wheat straw is an effective organic amendments for biosolarization, Furthermroe, earlier addition of wheat strawcould substantially reduce N loss and increase MBN and MBC, co-application of biochar could enhance the N retain in soil during the biosolarization process.

(5338 - 2370) Determination of the degree of humification of organic matter in production systems by laser-induced fluorescence spectroscopy (LIFS)

Jean Carlos de Almeida Ramos[1]; Jaqueline Bonfim de Carvalho[1]; Diego dos Santos Pereira[1]; Christtiane Fernandes Oliveira[1]; Deise Cristina Santos Nogueira[1]; Paulo Alexandre da Silva[1]; Ludhanna

Marinho Veras[1]; Maria Elisa Vicentini[1]; Debora Marcondes Bastos Pereira Milori[2]; Alan Rodrigo Panosso[1]
Paulista State University[1]; Embrapa Instrumentação[2]

The quantity and quality of soil organic matter (SOM) are influenced by climate, soil type and agricultural practices. Humic substances account for about 80% of the soil MOS content formed by a combination of polyelectrolytes from the biological action of microorganisms on plant and animal remains that are more stable fractions of MOS that remain for a long period in the soil. HLIFS is used as an index to evaluate how stable or humidified MOS is, since the more humidified the MOS is, the more durable it will be. Therefore the determination of HLIFS is an important indication of the stability of this component in soil. The objective of this work was to evaluate the influence of five different production systems on the degree of organic matter humification (HLIFS), in the municipality of Selvíria - MS. The data were collected in areas of native forest (MN), eucalyptus forest (EU), no - tillage (PD), pinus forest (PI) and silvopastoral system (SI), located in the municipality of Selvíria - MS, in the year 2017. For the determination of HLIFS, the laser-induced fluorescence (LIFS) analyzes were used. The LIFS technique has as basic principle the excitation of the soil samples with a laser, resulting in the fluorescence of functional groups of the organic matter, related to the humification process (MILORI et al., 2006). Samples were analyzed with 2 replicates per pellet, totaling 4 replicates per sample, in order to remove the mean of the HLIFS from each pellet. The highest HLIFS index was found in the PI, while the MN and SI had the lowest HLIFS in the depth of 0.0-0.1 cm. The difference in HLIFS among all evaluated areas shows how this attribute is influenced by management systems. This result evidences that the SI for integrating two crops in the same area promotes the accumulation of labile organic material similar to the MN area, so it is a system that most imitates native ecosystems, that is, it aims to reduce the effects of anthropic interference , therefore it is less labile, presenting a behavior similar to MN, thus being an important system for use in environmental and economic sustainability.

Keywords: degree of humification of organic matter, conservation systems, quality of organic matter.

(1319 - 1214) Development of new predictive models to estimate lime requirement of soils from Minas Gerais state, Brazil.

Welldy Gonçalves Teixeira[1]; Víctor Hugo Alvarez V[1]; Júlio César Lima Neves[1]; Rodrigo Bazzarella Paulúcio[1]
Universidade Federal de Viçosa[1]

Numerous methods have been developed to estimate lime requirement (LR) in Brazil, but discrepancies exist in relation to their efficiency in this determination. This study aimed to develop new models for LR estimation, in order to achieve target pH values on a wide range of soils from Minas Gerais state, Brazil. Treatments derived from a factorial with 22 soils and 10 lime rates. Soil samples (0 - 20 cm) were collected throughout Minas Gerais state, in native areas under forest and savanna (Cerrado) that had never been limed. These soils were incubated for 60 d with lime rates determined by seven LR methods traditionally used in Brazil: exchangeable acidity; base saturation; exchangeable acidity and Ca + Mg contents (two versions); SMP buffer pH; potential acidity, and soil pH and organic matter (OM) content. In addition, a non-limed treatment and other two lime rates were included. Soil pH_{H2O} measured at the end of incubation period was plotted as a function of lime rates. Then LR needed to attain pHs 5.8 and 6.0 (incubation LR) were estimated. Incubation LRs were plotted against relevant chemical and physico-chemical properties of unlimed soils. As a result, four nonlinear regression models for estimating LR to pHs 5.8 and 6.0 were fitted. The new LR methods developed in this study consist in models relating incubation LR with ΔpH (target pH_{H2O} - initial pH_{H2O}) multiplied by either OM or potential acidity (HAl). Predictive models based on OM to pHs 5.8 (R^2 = 0.86) and 6.0 (R^2 = 0.89) showed nearly identical goodness of fit, which was higher than the models based on HAl to pHs 5.8 (R^2 = 0.76) and 6.0 (R^2 = 0.84). Nevertheless, the four predictive models have high R^2 values and are similar at providing good LR predictions. LRs as predicted by traditional and new methods were related to incubation LR through linear regression analysis. We observed that traditional LR methods were less correlated ($r \geq 0.67$, $p < 0.05$) with the standard incubation method than the new predictive models ($r \geq 0.87$, $p < 0.01$). All traditional LR methods under or overestimated LR to pHs 5.8 and 6.0, as indicated by intercepts > 0 and slopes < 1. However, intercept and slope values of the regression lines for the new predictive models were not significantly different ($p > 0.05$) from 0 and 1, respectively. Thus, the new predictive models were found to be better than the traditional LR methods as they efficiently predict the amount of lime needed to achieve the desired target pH

(4688 - 829) Distribution of C and N in mineral-associated and particulate organic matter within aggregates in a calcareous silty clay loam soil under high-input agro-ecosystems

Xueping Wu[1]; Jing Li[1]
Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences[1]

Multiple studies on the formation of soil aggregates and occlusion of organic matter therein have provided valuable insights into the nature and stability of management-induced organic carbon (OC) and nitrogen (N) storage. However, the intensified agro-ecosystems in North China with large mineral fertilizer and organic manure inputs are not represented by past field experiments. We applied a combined soil aggregate size, and particle density and size fractionation procedure to obtain physical fractions including free and occluded particulate organic matter (fPOM and oPOM) and mineral associated fractions ($Mineral_{>53}$ and $Mineral_{<53}$) within three aggregate sizes (> 2 mm, 0.25-2 mm and < 0.25 mm). Soils were collected from a medium-term field trial involved 4 fertilization treatments: no fertilizer, CK; nitrogen (N) and phosphorus (P) fertilizer, NP; maize straw combined with NP fertilizer, NPS; manure plus straw and NP fertilizers, NPSM. The application of N and P fertilizer alone was not capable of increasing the OC and N in the three aggregates investigated, while the application of NPSM and NPS significantly and evenly augmented OC and N sequestration in all aggregates. NPS and NPSM led to higher amounts of organic C and total N accumulated in unprotected fPOM, and this process predominantly took place in > 2 mm and 0.25-2 mm macroaggregates. NPS and NPSM application also resulted in larger OC and N storage of physically protected oPOM, which explained the highest portion of newly loaded C and N. Furthermore, at least 50% of increased oPOM was stored within 0.25-2 mm aggregates. Extra manure application on top of straw did not further increase the storage of $Mineral_{<53}$-OC or -N, indicating these fractions appeared to be saturated. Thus, we concluded that the increased C and N inputs due to organic fertilizers are predominately stored as fPOM and oPOM in macroaggregates, which would be easily lost again by continuous tillage practices. These have to be carefully taken into account when setting realistic and effective goals for long-term sequestration of OC in intensively agricultural ecosystems.

(3179 - 2428) Do biowastes change the essential oil quality and quantity?

S. Seyedalikhani[1]; J. Esperschuetz[1]; N.M. Dickinson[2]; R. Hofmann[1]; J. Breitmeyer[1]; J. Horswell[3]; B.H. Robinson[4]
Lincoln University - Faculty of Agriculture and Life Sciences, Department of Soil and Physical Sciences, P O Box 84, Lincoln 7647, New Zealand[1]; Lincoln University - Faculty of Agriculture and Life Sciences, Department of Ecology, PO Box 84, Lincoln 7647, New Zealand[2]; The Institute of Environmental Science and Research Limited, Kenepuru Science Centre, PO Box 50-348, Porirua 5240, New Zealand[3]; School of Physical and Chemical Sciences, University of Canterbury, Christchurch 8041, New Zealand[4]

Biowastes are unwanted materials of biological origin, including biosolids and dairy shed effluent. Potentially, these wastes are low-cost sources of plant nutrients. However, they can also contain contaminations such as pathogens, heavy metals, and xenobiotics. Biowastes are widely used to improve plant growth on degraded or low-fertility soils, with a view to producing non-food products such as essential oils. We sought to determine the effect of biowastes on the quantity and quality of essential oils produced by lavender (*Lavandula angustifolia*), rosemary (*Rosmarinus officinalis*), and thyme (*Thymus vulgaris*). In a greenhouse experiment we grew the plants in a low fertility soil (Lismore stony silt loam) amended with either biosolids (1000 kg ha^{-1} N equiv.) or dairy shed effluent (200 kg ha^{-1} N equiv.). The maximum increase of the biomass was related to the thyme by biosolids addition (62%). Biosolids generally augmented the oil production of all three plants more than dairy shed effluent. The essential oil production of lavender, rosemary, and thyme increased by 71%, 39%, and 102% when biosolids were applied. Although biosolids increased the concentration of Zn, Cu, and Cd in the plant leaves, the levels were below than what can make a risk to ecosystems or human health. As a result, biosolids could be diverted from landfill to low-fertility lands, where they can enhance the essential oil production using lavender, rosemary, and thyme. To evaluate production economics and ecological variables field trials are essential.

(8059 - 262) Do Land Characteristics Affect Farmers' Soil Fertility Management?

Shuhao Tan[1]
Renmin University of China[1]

Soil fertility management (SFM) has important implications for sustaining agricultural development and food self-sufficiency. Better understanding the determinants of farmers鈥 SFM can be a great help to the adoption of effective SFM practices. Based on a dataset of 315 plots collected from a typical rice growing area of South China, this study applied statistical method and econometric models to examine the impacts of land characteristics on farmers鈥 SFM practices at plot scale. Main results showed that in general land characteristics affected SFM behaviors. Securer land tenure arrangements facilitated effective practices of SFM through more diversified and more soil-friendly cropping pattern choices. Plot size significantly reduced the intensities of phosphorus and potassium fertilizer application. Given other factors, one hectare increase in plot size might reduce 3.0 kg ha-1 P2O5 and 1.8 kg ha-1 K2O. Plots far from the homestead were paid less attention in terms of both chemical fertilizers and manure applications. Besides, plots with better quality were put more efforts on management by applying more nitrogen and manure, and by planting green manure crops. Significant differences existed in SFM practices between the surveyed villages with different socio-economic conditions. The findings are expected to provide important references to the policy-making incentive for improving soil quality and crop productivity.

(9770 - 1206) Dynamics of nutrients in maize cultivation under application of various organic fertilizers with different C/N ratios.

R. Tamele[1]; H. Ueno[1]; Y. Toma[1]; N. Morita[1]
Ehime University[1]

The rising cost of inorganic fertilizers coupled with their inability to condition the soil in a long term application has directed attention to organic fertilizers in recent times. The application of organic materials (OMs) to soil is considered as a good management practices in any agricultural production system because it improves plant quality and soil fertility. The results below mentioned are products of a study on effect of different OMs with different C/N ratios on corn (*Zea mays*, dent corn) nutrients dynamics and soil properties. The study was conducted on a sandy-loam soil in Ehime University, Japan. Six treatments applied with chemical fertilizer (CF), rapeseed waste (RW), chicken manure, cow manure, bamboo compost (BC) and bamboo tealeaf compost were used in a randomized complete block design (RCBD) with five replications. Dynamics of N was also analyzed by application of ^{15}N tracer. The major distribution of N in all treatments trended as following: grains > leaves > stem, root. RW took up half of N compare with CF in spite of same yield, suggesting that the N use efficiency in RW is two times higher than that in CF. Corn mainly took up N from the fertilizers, and the amount of N was correlated with N mineralization rate (R^2 = 0.6724). The plant in CF took up the highest amount of N, in contrary plants in BC treatment took up the lowest amount of N derived from soil due to its high C/N ratio and low nitrogen immobilization rate during the cultivation. Moreover, almost of the soil N was accumulated in grain. It is assumed that the soil N taken up at the early stage accumulate in stem, then the N was translocated into grains at ripening stage of the experiment. The concentration of mineral nutrients in corn grains, in all treatments showed a trend: K > P > Mg > Ca. There is no significant difference in Ca and P concentrations among the treatments ($P < 0.05$). However, K and Mg concentrations in BC was significantly lower than those in CF. The lower concentrations of total nutrients in BC, may be due to the low growth.

(5371 - 206) Dynamics of the decomposition of sugarcane straw in the function of different levels maintained on the surface of the soil

Zigomar Menezes de Souza[1]; Camila Viana Vieira Farhate[1]; José Luiz Rodrigues Torres[2]; Ana Paula Guimarães Santos[1]
State University of Campinas (Unicamp), Agricultural Engineering (Feagri)[1]; Federal Institute of Triângulo Mineiro Campus Uberaba[2]

In the current scenario, the large volume of straw produced resulting from mechanized sugarcane harvesting may have two destinations: i) be kept in the field to decompose naturally, or ii) be removed to be use in bioenergy. The idea which naturally prevails is the partial collection of this field material for industrial use. However, the question of how much straw can be removed from sugarcane fields still needs to be scientifically clarified. Thus, we aimed at assessing the

dynamics of sugarcane straw decomposition as function of different levels maintenance on soil surface under different edaphoclimatic conditions. Our experimental design was a randomized block with four levels of dry biomass (straw) maintained on the soil surface: 0, 5, 10 and 15 Mg ha^{-1} in two areas with different conditions granulometric of soils (sandy and clay) and four replicates. We assessed sugarcane straw decomposition by using decomposition bags at days 90, 180, 270 and 360 after field distribution. When analyzing the rate of decomposition of sugarcane cultural residues at different soil straw levels (5, 10 and 15 Mg ha^{-1}), we observed a proportional increase to straw levels rise for two types of soil present in this study. Probably, a higher amount of straw resulted in higher soil moisture associated with lower thermal amplitude, which favored an increase in microbial biomass activity and consequently residue decomposition. The values of decomposition constant (k) and time half-life (T½) of the cultural residues calculated confirm the results presented for the decomposition rate, in which for both types of soil assessed, T½ of sugarcane straw decreased with an increase in biomass amount in the soil. Thus, we conclude that the maintenance of higher straw levels on the soil surface (10 and 15 Mg ha^{-1}) promotes decomposition acceleration regardless the type of soil.

Keywords: Bioenergy production; straw removal; decomposition constant.

(8622 - 1008) Effect of different weed control methods on soil properties on a young teak stand in Costa Rica

Paola Hernández Rodríguez[1]; Edwin A. Esquivel Segura[1]; Mario Guevara_Bonilla[1]
TEC[1]

Weed control is a fundamental practice in plantation forestry. Null or inadequate plantation management can lead to growth reduction and economic losses. Several techniques are used in tropical forest plantations, however, few evidence exists on the effect of these methods on soil properties. The objective of the work was to evaluate the effects of different weed control methods in soil properties in a young teak stand. To perform the experiment, a trial was carried out in a randomized complete block design consisting of 7 treatments: Control, Chemical Control, Manual Control, Canavalia ensiformis cover crop, Vigna radiata cover crop, mix of Pueraria phaseloides with V. radiata, Crotalaria juncea cover crop and three repetitions. Changes in time of organic matter, soil carbon, soil fertility and nutrient content at foliar level were evaluated. No statistical differences were found in organic matter content and soil carbon. Soil fertility and nutrient content at foliar level were constant at 6 and 12 months. Significant differences were found in the nutritional concentration in soil of the elements Cu, Fe and Mn, as well as for K and P in the foliar analysis.

Keywords: soil fertility, cover crops, nitrogen, leguminous plants, forest production

(2925 - 275) Effect of glyphosate application on biological variables in soils with different agronomic practices

Sterren Maria Alejandra[1]; Benintende, Silvia[1]; Uhrich, Walter[1]; Barbagelata, Pedro[1]
FCA-UNER[1]

Glyphosate is a broad-spectrum herbicide which use has increased since 2002, and the environmental consequences of its application are not clearly elucidated. There is no regional information available about the effects of the use of glyphosate on soils under different management practices. The aim of this study was to evaluate the effect of glyphosate herbicide after 2 days of its application, on some biological variables in Vertisol and Mollisol soils with good and deficient agronomic practices. The research was conducted on a long-term fields trials in a Vertisol and Molisol soil: continuous soybean (deficient agronomic practice, DAP) and sequence wheat/soybean-corn (good agronomic practice, GAP). Samples were taken from 0-2,5 cm in both soils types and management. We applied 2.14 L. ha^{-1} of active principle of glyphosate in each sample. We evaluated the following variables after 2 days of glyphosate application: Microbial Biomass C (MBC), respiration activity (RA) and hydrolysis of fluorescein diacetate (FDA). We performed Student' t- test to compare glyphosate application effect. In the Mollisol the effect of glyphosate application inhibited the RA in GAP (p=0,0172) and DAP (p=0,673). Microbial Biomass C also showed a lower level in both management practices (GAP: p=<0,0001 and DAP: p=0,0006). Glyphosate application provoked a decrease of 34 % in MBC in GAP, while in DAP, the decrease was of 62%. In the FDA variable, similar effects were observed although no significant differences were found. The enzymatic activity was 11% lower in GAP and 3% in DAP. In the Vertisol, the effect of glyphosate application decreased the RA only in DAP (p=0,0031), while in GAP, both treatments behaved in a similar way. In this soil order, differences between managements caused marked diminutions in organic matter content (11.3% in GAP and 8.7% in DAP). The clays content and differences of organic matter probably had a protector effect on biota activity (RA and FDA). However, MBC showed a lower level in GAP when the herbicide was applied. Glyphosate application provoked a decrease of 48 % in GAP (p=0,0001). In DAP no differences were found in MBC.

(8728 - 3064) Effect of manganese in a transgenic maize crop in sandy and clay soils

Daniele Scudeletti[1]; Leontino De Oliveira Neto[1]; Jader Luis Nantes Garcia[1]; Murilo de Souza[1]; Rafael Do Val Müller[1]; Dirceu Maximino Fernandes[1]; Leonardo Theodoro Bull[1]
São Paulo State University, School of Agricultural Sciences[1]

Maize (*Zea mays* L.), has a worldwide economic importance, being high productivity as a consequence of the adoption of technologies such as using transgenic plants for insect resistance and tolerance to herbicides such as glyphosate. In soybean plants, glyphosate interferes in mineral nutrition due to its action on shikimic acid metabolism, which may show lower efficiency in Mn accumulation than conventional materials. Our aim was to evaluate Mn behavior in the soil and absorption of $Mn2^{+}$ by the transgenic maize plant under the effect of glyphosate in soils with different water retention capacities, in manganese presence and absence. Our trial was carried out in a greenhouse at the University of Agronomic Sciences FCA / UNESP, Botucatu (SP, Brazil) with a genetic material of transgenic maize hybrid from Syngenta, cultivated in sandy soil and clayey soil with levels close to Mn in a water stresses of 60 and 90% of the water retention capacity, in Mn absence and presence. Daily weighing maintained the humidity and it was carried out until its vegetative stage V4. We analyzed height, stem diameter, shoot dry mass accumulation per pot and leaf content of Fe, Mn, Cu, and Zn. Soils were sampled and analyzed for Mn content.The experimental design was a randomized complete block with 2x2 double factorial, two values of water stresses, retention capacity of 60% and 90%, and Mn presence and absence. We performed a Tukey test at 5% by SAS software. Manganese sulfate in sandy soil provided higher manganese content on leaves, however, there was no difference for stem diameter, height and dry mass of shoot. Nevertheless, manganese sulfate in clay soil did not show a difference for the variables analyzed. As for the water slides, in sandy soil, the smallest blade provided higher dry matter mass and plant height, but the higher micronutrient contents were obtained when the largest water

blade was applied. In clay soil, the higher water depth provided higher plant height, stem diameter and higher manganese content in the top growth, but there was no difference between variables analyzed in the lowest water depth.

(8468 - 366) Effect of the application of olive mill waste on some chemical properties of a soil of the Souhtwest of Buenos Aires, Argentina.

Minoldo Gabriela[1]; Laurent Gabriela[1]; Suñer Liliana[2]
Universidad Nacional del Sur[1]; Universidad Nacional del Sur, Comisión de Investigaciones Científicas[2]

The southwestern area of Buenos Aires Province on Argentina has suitable ecological conditions for growing olive trees. Is for that, several oil mills in the area next to Coronel Dorrego city have been established. Since oil is extracted by two-phase system, an olive mill waste composed of pomace plus waste water is obtained (Spanish "alperujo"). For the year 2017, the olive production was about 20000 t, which represents around 15000 t of wastes. Alperujo could be used as soil amendment due to its fertilizing properties. The objective of this experiment was to study the effect of alperujo on some chemical soil properties of a 50 years old olive orchard. The soil in which the experiment was performed classify as *Petrocalcic Paleudolls*. Two laboratory experiments were conducted: one, was carried out on soil columns, where the horizons were placed following sequence and thickness of horizons at profile (Ap-A2-Bt-BC) within acrylic tubes. Alperujo was mixed with soil of the Ap horizon at a rate of 0, 20, 40 and 80 t ha^{-1}. Four irrigations were performed totalizing 669 mm. Cation exchange capacity (CEC), exchangeable cations; Ca^{2+}+ Mg^{2+}, Na^{+} y K^{+} and exchangeable sodium percent (ESP) were determined before and after application of alperujo. The other experiment consisted of soil + alperujo (0-5-10-20-40 t ha^{-1}) incubations for 75 days. Soil organic matter (SOM), total nitrogen (Nt), extractable and inorganic phosphorous (Pe and Pi, respectively) and pH were determined. Soil CEC of the Ap horizon increased from 17,10 to 24,35 meq $100g^{-1}$ as alperujo doses increased. At the same time, the Ca^{2+}+ Mg^{2+} increased from 13,0 to 18,10 meq $100g^{-1}$ and K^{+} from 2,66 to 4.91 meq $100g^{-1}$. Exchangeable sodium increased significantly for doses 40 and 80 t alperujo ha^{-1}, however the ESP did not step up to risky values (highest value 5.39% at 40 t ha^{-1}). In leachates the electrical conductivity (EC) diminished from 1.90 dS m^{-1} (L1) to 0.42 dS m^{-1} (L4). The pH values were variable. The cations showed the following tendency to leaching: Ca^{2+}+Mg^{2+} > Na^{+} > K^{+}. The Ca^{2+}+Mg^{2+} fell from 17.63 me L^{-1} (L1) to 5.22 me L^{-1} (L4). Na^{+} decreased after L4 (1.66 – 1.01 me L^{-1}) and K^{+} stayed between 0.42-0.73 me L^{-1}. After the mineralization process, the greater differences for SOM, Nt and Pi were observed for the dose of 40 t ha^{-1}. This increase in Pi is explained by a pronounced increase in Pe at the beginning of the incubation together with a drop in pH. The latter stabilized after 75 days.

(8369 - 3018) Effect of the K-N application levels on two oil palm genotypes in nursery stage

Maria do Rosário Lobato Rodrigues[1]; Emmanuelle Lamade[2]; Jean Ollivier[2]; Bernard Dubos[2]; Ricardo Lopes[3]; Wenceslau Geraldes Teixeira[3]
Brazilian Agricultural Research Corporation – Embrapa Western Amazon[1]; CIRAD[2]; Brazilian Agricultural Research Corporation[3]

Recently some researchers focus on the identification of planting material presenting a better efficiency towards nutrient applications and consumptions. Our work is focusing on the internal functioning of the mineral reserves of the plant, especially the absorption processes and the remobilization of some nutrients essential to oil palm as potassium, in addition with nitrogen. An experimental has been conducted in controlled conditions, with the objectives to study the effect of K-N gradient on the mineral allocation at the plant scale and to compare two progenies (G1 and G2), presenting contrasting leaf potassium content (G1 will be characterized as K- - and G2 as K++). Pre-germinated seeds, after 3 months of pre-nursery, were transferred to plastic pots (6 kg) with a growing medium composed of 50 % sand and 50 % vegetal commercial compost. The plants were submitted to four potassium levels (K0, K1, K2, K3) and two levels of nitrogen (N1, N2) in a block design with three repetition. A first set of measurements started with three months, a second eight months on 36 plants by progeny (G1 and G2) belonging to N1K0, N1K1, N1K2, N1K3, N2K0 and N2K3 treatments. The results concerning foliar mineral analyses show out high levels for nitrogen (N), potassium (K) and magnesium (Mg) for G2 genotype. The levels were N%=2.26 (±0.17), K%=1.64 (±0.21), Mg%=0.476 (±0.04) for G2. For Genotype G1 the foliar levels were N%=1.89 (±0.20), K%=1.478 (±0.24), Mg%=0.394 (±0.04). The evaluations of chlorophyl content, using SPAD 502 (Minolta, Japan) on the three youngest leaves of each plant, showed an increase of the chlorophyll content from leaf rank one to leaf rank three. The chlorophyll content was higher in K- of leaves than in K+ ones for the two measurement dates. The results concerning the biomass showed differences between genotypes in all evaluations. Leaf and and roots biomass were higher for G1 in both dates of measurments. G1 and G2 showed contrasted "above ground/roots" ratios that increased during plant growth (first sampling of G1=1.65 (±0.21) and G2=1.80 (±0.19), second sampling G1=2.18 (±0.40) and G2=2.63 (±0.78). Significant differences were observed for starch between G1 and G2 with higher concentration for G1 compared to G2. The first investigations undertaken just after germination stage for the two genotypes do confirm their potassium characterization K- - for G1 and K++ for G2. This difference could be a genetic characteristic plant?.

(6666 - 257) Effectiveness of a micronutrient delivery system fertilizer in jatropha plants is related to enhanced photosynthesis, gas exchange and biomass allocation

Alexandre Bosco de Oliveira[1]; Wagner A. Vendrame[2]
Federal University of Ceará[1]; University of Florida[2]

This study aimed to compare the growth and physiological changes in *Jatropha curcas* L. (jatropha or physic nut) young plants fertilized or not with a commercial product based on a micronutrient delivery system (MDS), under different doses of NPK. Measurements of growth, chlorophyll content and leaf gas exchange were performed in the greenhouse, where plants were arranged in a split-split plot design. Plants were grown for 120 days in 3.9 L pots containing local soil, with or without MDS (main plot), combined with NPK doses (0; 1.8; 4.7 and 7.4 g L^{-1}) in subplots. Dose-response curves showed that most variables were positively responsive to NPK doses in plants growing without MDS, whereas slight responses or even opposite behavior was observed in MDS-fertilized plants. MDS application under low NPK doses resulted in higher biomass allocation in leaves and roots, increases in number of leaves and chlorophyll content, plant height, stem diameter, shoot and root dry weight, stomatal

conductance, photosynthesis, leaf transpiration, and water use efficiency, as well as decreases in intercellular CO_2 in the leaf and vapor-pressure deficit. The enhanced biomass allocation, photosynthesis and gas exchange in MDS-supplemented plants indicates the relevant role played by this fertilizer in jatropha metabolism, resulting in more vigorous plants.

(7242 - 428) Effects of Agricultural wastes on Potassium Quantity – Intensity parameters of some soils in Ogun – state, South – Western, Nigeria

Taiwo, Adebimpe Abidemi[1]; Adetunji, M.T[2]; Elemo, K.T[2]; Azeez, J.O[2]
Moshood Abiola Polytechnic, Abeokuta,Ogun state Nigeria[1]; The Federal of University Agriculture, Abeokuta[2]

The study was conducted to investigate the effects of three agricultural wastes, namely poultry, cattle and goat manure on the quantity- intensity of potassium and uptake as it relates to maize cultivation in some soils of Ogun –state, South-western Nigeria. The research was carried out at Moshood Abiola Polytechnic, research and teaching farm; the treatments were arranged in completely randomized design. The agricultural wastes were applied at following rates; 0.49 t ha^{-1}, 0.94 t ha^{-1}, 1.41 t ha^{-1} and 1.88 t ha^{-1}. Results of the study showed that the studied soils were predominantly sandy and slightly acidic. Large portion of K in the studied soils occurred in non –exchangeable form. The quantity - intensity parameters in the soil samples were low initially but higher values were observed after manuring, a reduction in energy of exchange (ΔG) was observed in all treatments these enhanced the K supplying power of the studied soils. leaf area, dry matter yield and K – uptake by maize increased with increase in rates of manure. Hence, higher concentration of organic manure can be employed where considerable quantities of K are required and high crop yields are needed. Two weeks after planting the maize plant were thinned to one plant per pot. At the end of each cycle, whole plant tops were harvested, oven dried at $60^{o}c$ for 48 hours. 5 gm of the plant tissue was milled digested with H_2SO_4-H_2O_2 mixture and K content was determined by flame photometry.

(8242 - 2328) Effects of the use of agricultural gypsum on the concentration of calcium, magnesium and aluminum in soils of southern Brazil.

Carla Fernanda Ferreira[1]; Antônio Carlos Vargas Motta[1]; Marcos Vinícius Martins Bassaco[1]; Cleiton Frigo[1]
UFPR[1]

The reactions that occur in soils after the application of agricultural gypsum are dependent on the solubility of this product and it acts in a different way between the layers in the soil. The main changes in the sorption complex after the application of gypsum are related to the increase of the Ca^{2+} and SO_4^{2-} ions, available to the soil solution, forming new ionic pairs such as $CaSO_4$, $MgSO_4$ and KSO_4, complexes that have high mobility and translocate to the deeper layers. The objective of this work was to quantify the concentrations of Aluminum (Al), Calcium (Ca), Magnesium (Mg) and other parameters of the sorghum complex of Dystrophic Red-Yellow Latosol by effect of different dosages of gypsum applied to the surface under hybrid cultivation Eucalyptus urophylla x Eucalyptus grandis (E. urograndis). This experiment was installed in two forest areas located in subtropical Brazilian conditions, in the municipality of Jaguariaíva and in the municipality of Ventania, Moquem district, and state of Paraná. Seven doses of agricultural gypsum 0, 300, 600, 1200, 2400, 4800 and 9600 kg ha^{-1} were applied to the haul. Soil collection was carried out every 6 (six) months, at depths between 0 and 0,20 m; 0,20 to 0,40 m; 0,40 to 0,60 m; 0,60 to 0,80 m and 0,80 to 1,00 m. In the samples collected at 6 (six) the pH ($CaCl_2$), Al^{3+}, $H^+ + Al^{3+}$, Ca^{2+}, Mg^{2+}, K^+, P (Mehlich), $C_{organic}$ acid were determined to quantify the Basal Sum (SB), Substitution of Cations (T), Basal Saturation (V%) and Saturation by Aluminum (m%). Already at 6 (six); 12 (twelve); 18 (eighteen) and 24 (twenty-four) months soil chemical parameters were quantified by determining the levels of Al^{3+}, Ca^{2+} and Mg^{2+}. An effect of the gypsum on pH ($CaCl_2$) was not expressed in absolute values. The agricultural gypsum did not interfere on the levels of K, P and Organic Carbon. The sum of the bases and the saturation of the bases presented higher indices in the deeper layers and responded to the addition of gypsum. The saturation by Al (m%) presented significance in practically all the layers of the evaluated soil. Agricultural gypsum reduced Al^{3+} contents, but concentrations remained very high in the soil. Ca^{+2} remained below the desired rates for crop development, although the percentage of increment of this element was high. On the other hand, the Mg^{2+} contents presented indices ranging from low to medium. For these parameters, the effects of gypsum were more significant in the evaluations at 6 and 12 months.

(7849 - 1042) Effects of Tillage and Crop Residue Management on Soil Organic Carbon Stock Under Four Different Soil Types in Sudan-Savanna of West Africa

Eeusha Nafi[1]; Isaac Danso[2]; Thomas Gaiser[1]
Institute of Crop Science and Resource Conservation, University of Bonn, Germany[1]; CSIR-Oil Palm Research Institute, Kusi, Ghana[2]

Erosion of topsoil from agricultural lands due to increasingly intense rainfall and improper soil management practices has become one of the most crucial threats to crop productivity in Sudan-Savanna of West Africa, causing removal of soil organic carbon and loss of soil inherent fertility. To counteract the problem, a alternative management practices (a combination of tillage, crop residue incorporation and nutrient management) is proposed that has potential to prevent and/or reduce the severity of soil nutrient loss, sustain soil quality as well as improve crop productivity. The objective of this research is to evaluate the single and combined effects of tillage and crop residue management on soil organic carbon (SOC) stock in five-year, multiple site experiment (2012-2016) with maize-cotton rotation under four different soil types in Sudan-Savanna of West Africa. The study was established in 2012 at two different soil types (Eutric Plinthosol and Ferric Lixisol) in Tambiri (Dano watershed), Burkina Faso, and two other soil types (Plinthic Lixisol and Haplic Lixisol) in Ouriyouri (Dassari watershed), Republic of Benin. The experimental setup was a strip-split-plot design with four replicates comprising two tillage systems (contour ridge, CR and reduced, RT) in main plots, and two levels of crop residue (with, R1 and without, R0) and three mineral nitrogen fertilizer rates (0, 60, 120 kg/ha) randomised within the sub-plots. After five years, we sampled soil from different depths and measured soil organic carbon stock. The result showed that SOC stock was always higher under contour ridge tillage condition than the reduced tillage for all four soil types. The highest amount of SOC stock was observed for the Ferric Lixisol under contour tillage practice. On the contrary, the lowest content of SOC stock was recorded for the Haplic Lixisol under reduced tillage practice. Incorporation of crop residue had additive effects on SOC

stock. The results indicate that contour ridge tillage along with crop residue incorporation has potential to better preserve SOC stocks in the Sudan Savanna of West Africa.

(4585 - 1168) Efficiency of soil-applied ^{67}Zn-enriched fertilisers in three consecutive crops

Edson M. Mattiello[1]; Eduardo L. Cancellier[2]; Rodrigo C. da Silva[3]; Fien Degryse[3]; Roslyn Baird[3]; Mike J. McLaughlin[3]
Universidade Federal de Viçosa[1]; Universidade Federal de Lavras[2]; Univesity of Adelaide[3]

A very small amount of applied Zn is taken up by crops, resulting in low apparent recovery by plants. Adding elemental sulphur to ZnO fertilisers could potentially improve Zn solubilisation and provide a higher residual effect for crops than soluble sources. We produced and evaluated the performance of an isotope-labelled Zn-elemental sulphur fertiliser for a sequential crop cultivation. Three ^{67}Zn-labelled fertilisers: ZnO, $ZnSO_4$ and ZnO cogranulated with elemental sulfur ($ZnOS^0$) were produced. Their contribution to the uptake of Zn by three consecutive crops of wheat, ryegrass and corn was assessed in a pot trial with a total experimental duration of 294 days. The contribution of fertiliser Zn followed the order: $ZnSO_4$>ZnO³ $ZnOS^0$. The relative contribution of fertiliser Zn was lower in the first crop than in the consecutive crops. The overall recovery of applied Zn by the three crops was higher for $ZnSO_4$ than for ZnO and $ZnOS^0$, reaching values of 1.56, 0.45 and 0.33%, respectively. Residual effects existed for all Zn fertilisers, including soluble source. The ES-Zn-containing fertilisers were ineffective in supplying Zn in the first crop cultivations, but their efficiency improved over time. However, these products were still much less effective than $ZnSO_4$ in supplying Zn to plants both initially, and over an extended time. Furthermore, fertilisers based on ZnO and ES have higher nutrient concentrations and lower costs compared to traditional soluble sources of S or Zn. Our study using labelled ^{67}Zn sources help us understand that soil Zn application has an important residual effect regardless Zn source.

(3666 - 3069) Emission of N_2O from urine and feces of cattle grazing *Brachiaria brizantha* pasture fertilized with N or mixed with the forage legume *Desmodium ovalifolium*

Camila Almeida dos Santos[1]; Claudia de Paula Rezende[2]; Robert Michael Boddey[3]; Segundo Urquiaga[3]; Claudia Pozzi Jantalia[3]; Bruno José Rodrigues Alves[3]
Soils Department, IA, UFRRJ[1]; ESSUL, CEPLAC[2]; Embrapa Agrobiologia[3]

Bovine excreta (feces and urine) contribute to the increase of greenhouse gases (GHG), mainly nitrous oxide (N_2O), but there is a lack of information to estimate these emissions in pasture areas in Brazil. The objective of this study was to determine the fraction of N in urine or feces of Nelore cattle that is converted to N_2O. Excreta were taken from animals grazing pastures of *Brachiaria brizantha* cv Marandu fertilized (50 kg N ha^{-1} applied every four months) with urea (FP) or mixed with *Desmodium ovalifolium* (MP), apart from a control. The experimental design was a 3 x 3 factorial in randomized blocks, with 2 replicates. The main treatment corresponded to the pasture management, and the subplot, to the addition of excreta (urine, feces or without excreta). In each pasture, exclusion areas were set up to allow grazing but not trampling or dejection, in with static chambers were installed. In the area of each chamber, 1 L of urine or 1 kg of fresh feces were added. A third chamber were left without excreta as the control. The highest N_2O fluxes were observed with the addition of urine derived from the animals of FP, and the lowest when derived from the control. The fractions of the added N emitted as N_2O were 0.45%, 0.23% and 0.16% of the total N applied as urine, respectively for the treatments FP, MP and control. For feces, the fractions of the existing N that was emitted as N_2O were 0.008%, 0.011% and 0.018 % respectively for FP, MP and control. Urine was the main source of N_2O, but either for urine or feces emissions were lower than the 2% of any excreta N as described in the IPCC methodology for GHG inventories. The disaggregation of excreta type is fundamental for more accurate GHG inventories. N_2O emissions from excreta produced from animals grazing mixed pastures with *D. ovalifolium* is less impacting than that from N-fertilized pasture, although an analysis involving stocking rate and excreta production is required to a more accurate conclusion on this respect.

(6520 - 2496) Eucalyptus yields response to the conditioning of a tropical Brazilian Cerrado soil

Leonardus Vergütz[1]; Rodrigo Nogueira de Sousa[1]; Bernardo Amorim Silva[1]; Vanderlayne Verônica Costa[1]; Lucas Vinícius Torres Lima[1]; Reinaldo Frederico de Siqueira Montalvão[2]; Ivo Ribeiro da Silva[1]
Universidade Federal de Viçosa[1]; MetalSider Florestal[2]

Most of Brazilian tropical soils are acidic, high in Al^{3+}, poor in nutrients and with high P fixation capacity, especially in the Cerrado, the greatest and most important agricultural and forestry frontier in the country. The fairly high yields achieved in these soils are due to the use of fertilizers and soil conditioners. The fate of gypsum in tropical soils is well known. It is an important tool to improve soil chemical conditions in depth in tropical soils and to improve crops nutrients and water use, increasing productivity. However, its benefits are rather underestimated and it is use is only marginal. Recently, the Brazilian Soybean Strategic Committee (CESB) has shown that even for an annual crop like soybean it is mandatory to have Ca in deeper soil layers in order to achieve high yields. In their annual soybean productivity contest, the only soil property constant in all high yield areas (≥ 97 bags/ha) was high Ca content down to 110 cm (≥ to 1 $cmolc/dm^3$), which increased root growth and distribution, improving plants water and nutrients use. Even though eucalyptus is known for its tolerance to drought stress and to acidic and low fertility soils, it is also responsive to fertilization. Thus, the aim of this work was to evaluate the productivity of eucalyptus in response to gypsum, among other soil conditioners, on a Brazilian Cerrado soil commonly used for eucalyptus plantation. Without any soil conditioner and only receiving 200 kg/ha of MAP at planting, the productivity of a 7 years old eucalyptus plantation was 212.0 m^3/ha. When the MAP was replaced by 500 kg/ha of a natural rock phosphate (Bayóvar), the productivity increased to 241.9 m^3/ha. When lime was applied (3,000 kg/ha), the best result came when it was applied banded as a 70 cm wide band and incorporated into the topsoil, that way the productivity increased to 302.8 m^3/ha. When lime was applied (2,400 kg/ha) with gypsum (1,000 kg/ha), allowing Ca to descend into the soil profile, the

productivity reached 334.1 m^3/ha, an increase of 57.6 % comparing to the control and 10.3 % comparing to highest productivity without gypsum. This increase is related to the better growth and distribution of the root system throughout the soil profile, giving more access to nutrients and water to the plants. Even though eucalyptus is a plant tolerant to low fertility soils, it responds to soil fertility buildup in the soil profile. In that sense, eucalyptus fertilization programs should be rethought.

(3872 - 1122) Evaluation of coffee ground influence on the soil pH

Cleberson Tiago de Souza[1]; Jonas Guerra[1]; Jaqueline Gaio Spricigo[1]; Augusto Henrique Debiasi Orsatto[1]; Cristiane Pain[1]; Cristiano Nunes Nesi[2]; Mauricio Vicente Alves[2]
University of West of Santa Catarina[1]; Professor, University of West of Santa Catarina[2]

The disposal waste in the soil has historically been considered a solution for the most diverse sectors of society, materials that can provide improvements in chemical properties of soil, correcting acidity. The coffee grounds are generated from roasting and milling of the coffee in the industrial process, and have a low value and abundant waste, and can bring great benefits to the soil if applied correctly. Thus, the objective of this study was to evaluate the effects of coffee grounds on soil pH. The experiment was carried out at the University of Western Santa Catarina – UNOESC, campus Xanxerê at Xanxerê/SC, Brazil, from September to December, 2017. During the period of 105 days, the soil characterized as Dystrophic Red Latosol/Oxisoil was incubated in plastic bags with 2 kg of soil and percentages of coffee grounds. The experimental design was completely randomized, with six treatments: 0, 1, 2, 4, 8 and 16% (v/v) of coffee grounds in soil mixtures and five replicates. The soil moisture was maintained at 60% of the field capacity and at 105 days the water pH (1: 1) was evaluated. The data were submitted to regression analysis and the Mitscherlich model was the one that matched the data. The analyses have been done with R program (R Core Team, 2015). The water soil pH increases according to the dose of coffee grounds, stabilizing from the 10.85% (v / v) dose, the dose that ensured 99% of the maximum asymptote to pH was 8.79% (v / v), increasing soil pH from 5.1 to 5.9. Regarding for the characterization of the residue used, it was observed that it presents in its composition considerable amount of nutrients enhancing the plant nutrition besides conditioning the pH of the soil.

(6989 - 2896) Evaluation of dispersant solutions for the determination of available phosphorus in Particule Size fractions in a Brazilian Sandy Soil

David Vilas Boas de Campos[1]; Livia da Silva Chaves[2]; Bianca Braz Mattos[1]; Fabiano de Carvalho Balieiro[1]
Embrapa Solos[1]; Embrapa Solos / Universidade Severino Sombra[2]

Due to the complexity of soil organic matter, it is necessary to identify the components that are homogeneous in relation to properties, dynamics and function. Using the particle size fractionation it is possible to obtain fractions that serve as indicative of the quality and quantity of organic matter in soils. The objective of this work was to evaluate different dispersant solutions for subsequent soil fractionation, and analysis of available P in particulate organic matter and in the heavy fraction. The granulometric fractionation was performed, according to Cambardella and Elliot et al. (1992), in brazilian sandy soil samples. 10 g soil sample was placed in contact with 100 mL dispersing solution, with stirring at 130 rpm for 15 h. Were used the dispersion in water, with sodium hexametaphosphate (HMP), NaOH 1 mol L^{-1} solution, $Ca(OH)_2$ 0,01 mol L^{-1} solution and ultrasonic dispersion (400 J mL). After dispersion, the material was passed through a 0.053 mm sieve. The material retained in the sieve was dried and weighed, called particulate organic matter (MOP). The heavy fraction (PF), which passed through the sieve, was also dry and heavy. The available P of the granulometric fractions obtained with the different dispersants was determined. From the results obtained, the dispersing solutions with HMP and NaOH were the most efficient with obtaining 129 and 120 g of clay per kg of soil, respectively. The dispersants $Ca(OH)_2$, water and ultrasonic application were not efficient for dispersion of the sandy soil sample. Samples with HMP dispersant showed phosphorus contamination in both granulometric fractions. There was no statistical difference on the levels of P between the different extractive solutions. The available P contents varied between 0.17 and 3.77 mg kg^{-1} in particulate organic matter, and between 2.90 and 5.97 mg kg^{-1} in the heavy fraction. The extractive solution NaOH 1 mol L^{-1} can replace the solution with HMP in granulometric fractionation studies in sandy soils, when it is desired to determine the available P in the fractions.

(9567 - 1792) Evaluation of organic and inorganic residues for organic production systems and small properties of paraguay

Carlos Leguizamón Rojas[1]; Marcos Sanabria Franco[1]; Silvia Bobadilla Galeano[1]; Celeste Saucedo Valverde[1]; Alicia Rivas Mendieta[1]; Astrid Reichert Duarte[1]; Pedro Morinigo Ferreira[1]; Doralicia Zacarias Servin[1]; Alba González[1]
Universidad Nacional de Asunción - Facultad de Ciencias Agrarias[1]

Organic or inorganic residues can be used as inputs to maintain or improve soil fertility in organic production and in the 250,000 small properties (<20 ha) with limited capital for access to inputs and responsible in the prevailing food production in the country. The objective of this study was to evaluate the effect of organic and inorganic residues in the soil and agricultural products of the small property. Were evaluated doses of ash obtained from the soybean processing industry, doses of compost made from residues of the sugar industry and dose of bovine manure from the farm itself. The nine doses of ash were evaluated in a Rhodic Paleudult with a sandy texture and in a Rhodic Kandiudox with a clay loam texture, in pots. Two types and seven doses of compost were evaluated in pots, in a Typic Paleudalf of the area of influence of the sugar industry, using wheat (*Triticum vulgare*) as an indicator plant. Three doses of bovine manure were evaluated in a small property on a Rhodic Paleudult with sandy texture in a sequence of *Manihot esculenta* - *Zea mays* L. Ash doses produced pH increases in sandy soil from 3.88 to 5.79 and in clay loam soil, from 4.3 to 5.60 with 2.5 and 7.5 t ha-1 of ash, as well as allowed to neutralize exchangeable acidity; the pH even reached 9.19 in the sandy soil. The ash also increase the available phosphorus, low to high level, in both soils; increased levels of exchangeable potassium, going from low to high level in sandy soil and increased the exchangeable magnesium concentration in both soils. The two compost evaluated increased the aerial and radicular dry matter of the wheat, they did not produce significant increases in interchangeable calcium, magnesium and potassium levels and had differentiated effects on the pH levels and available phosphorus. The application of bovine manure produced a significant increase in the production of the cassava-corn sequence. The yield of commercial roots of cassava (in kg ha-1) was adjusted to an equation y=6,956.5 x + 29,189.6 with R2=0.92, in the range of 0 to 30 Mg ha-1 of manure

applied. In the corn yield there were successive increases of 0.64 to 2.92 and 3.86 Mg ha-1 with the doses of 0, 7.5 and 15 Mg ha-1 of bovine manure, respectively. These results indicate the potential of organic and inorganic residues processed or not in the process of organic production and low input agriculture. Furthermore, the use of each residue should be evaluated in the soils in which it will be used.

(5020 - 2159) Evaluation of soil physical attributes in cover crops grown under fly ash applicatio

Matheus Antonio Arcego Filipin[1]; Gabriela Naibo[2]; Cleberson Tiago de Souza[2]; Augusto Henrique Debiasi Orsatto[2]; Juliano Marcarini Bordin[2]; Mauro Porto Colli[3]; Mauricio Vicente Alves[3]

University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê/SC, Zip Code: 89820-000, Brazil (matheusfilipin@yahoo.com)[1]; University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê/SC, Zip Code: 89820-000, Brazil[2]; Professors, University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê/SC, Zip Code: 89820-000, Brazil[3]

Evaluation and quantification of the physical quality in the management of the soil with new fertilization alternatives in off season are fundamental to development of sustainable agricultural systems. This study aimed to evaluate the effect of fly ash application using different soil managements in the winter on the soil physical attributes. The experiment was carried out at the experimental plant in Unoesc - Xanxerê, from July 2016 to March 2017. The soil of the region has been classified as a dystrophic Red Latosoil/Oxisoil, under a Cfb climate classification, according to Koppen. The experimental design was randomized in blocks with four replicates. Four treatments was carried out in the winter: 1) Fallow (without cover plants and without application of ash); 2) Fallow + ash; 3) Cover crops without ash application (CC); and 4) CC within ash application (CCA). In the CC plots, a consortium was used between vetch (40 kg ha^{-1}) and oat (50 kg ha^{-1}), grown under no-tillage system. In the treatments with ash application, the applied dose was 10.500 kg ha^{-1}, being calculated according to the potassium content present in the ash along with the required for the cover crops. After the end of the cover crop cycle, the area was desiccated and ash was again applied (23.81 t ha^{-1}) for sowing of the corn in no-tillage. The fertilizers of the corn crop were calculated according by interpretation of the soil analysis, for a production expectation of 12 t ha^{-1} grains (according to Liming and Fertilization Manual for RS and SC Brazilian states). The both application of ash used was sampled from a boiler of a pulp and paper plant. Soil samples were taken before winter cover crops cultivation and after corn cultivation in summer, using 1 sample per plot at 0 to 10 cm depth. Soil density (SD); particle density (PD); mean weight diameter (MWD) and geometric mean diameter (GMD) was evaluated using the volumetric ring method (EMBRAPA, 1997). Data were submitted to analysis of variance using F test, with 95% confidence. All analyzes were computed using the R Core Team program (2016). There was no statistical difference in any physical attributes of the treatments within each season evaluated. The time factor had statistical difference found in the SD, MWD and GMD variables, decreasing them in the general mean of all treatments. Regarding for the PD variable, the values were only decreased in the CC and CCA treatments between the two evaluation periods.

(2822 - 1438) Evaluation of the composting of municipal biosolids with eucalyptus bark and sugarcane bagasse.

Marianne Fidalgo de Faria[1]; Iraê Amaral Guerrini[1]; Roberto Lyra Villas Boas[1]; Caroline de Moura D'Andrea Mateus[1]; Caio Vilela Cruz[1]; Raquel Gonçalves Silva[1]; Roseli Vicentin[1]; Rosemary Marques de Almeida Bertani[1]; Robert Boyd Harrison[2]

Universidade Estadual Paulista "Júlio de Mesquita Filho" – UNESP, Departament of Soils and Environmental Resources, Box 237, Botucatu/SP, 18610307, Brazil[1]; University of Washington, School of Environmental and Forest Sciences, Box 352100, Seattle/WA, 98195-2100, U.S.A.[2]

Biosolids is a residue from the wastewater treatment that contains organic matter and nutrients in its composition and when applied in agriculture ensures to the soil fertility maintenance and greater resistance to erosion. However, in some countries, such as Brazil, the final disposal of sewage sludge is still inappropriate, often being deposited in landfills. Composting is a process of bio-oxidation of a solid organic substrate where there is decomposition and release of organic matter after maturation. The addition of a carbon source adjusts the Carbon / Nitrogen ratio (C/N) and improves the physical characteristics of the organic compost. The objective of this study was to evaluate the composting process of municipal biosolids mixture with two different sources of carbon – eucalyptus bark and sugarcane bagasse – and to determine if the process is effective in terms of temperature and moisture, as well as the final composting time. The experiment was installed and performed in the city of Botucatu, State of São Paulo, Brazil, inside a greenhouse located at the Wastewater Treatment Plant (WWTP) of the company SABESP. A compost pile was set up for each mixture with dimensions 1.5m x 3m x 16m, with a total volume of 36m³ per pile. The mixture ratio of biosolids:carbon source was 1:1. The temperature in the compost pile was monitored hourly by Decagon 5TM and Decagon RT1 temperature sensors, which were installed at five points of each pile at different depths. The samples for moisture analysis were collected weekly in five points of different depths, forming a composite sample for each pile. Once collected, the samples were incubated at 65ºC for 72h. In both materials the average daily temperature remained between 50ºC and 70ºC, which can be considered ideal for composting. The sugar cane bagasse was the one that retained better the moisture throughout the process, which ended up with moisture in the range between 40 and 50%. In the pile with eucalyptus bark, the moisture decreased faster in the same period, being the final product with moisture below 30%. Due to the difference in moisture, the composting time of the two materials were different, with 45 days for mixture with eucalyptus bark and 60 days for mixture with sugarcane bagasse. It is possible to conclude that both mixtures of biosolids with eucalyptus bark and sugarcane bagasse in the ratio 1:1 are viable and present ideal temperature and moisture indexes for an effective composting process.

(9732 - 1638) Experiences with oil palm (Elaeis guineensis Jacq) biomass use at replanting

Floria Ramírez[1]; Andy Arguedas[1]; Eder Jiménez[2]; Montserrat Ulloa[3]; María Araya[3]

Palma Tica[1]; Palmosur[2]; [3]

Yield intensification and monoculture are prone to have less biodiversity at every level (vegetation, macro fauna, micro fauna and microorganisms), condition, which can difficult efficient nutrient recycling, and the maintenance and accumulation of organic matter (OM). The kind of fertility conferred by the organic fraction of the soil

cannot be substituted by inorganic fertilizer applications, hence the required complementary use of organic and inorganic sources of nutrients. The oil palm has certain advantage, since it produces a great amount of biomass at the mill (shredded empty fruit bunches) and in the field (recycling of leaves at every harvest; leaves, roots and trunks at replant). Incorporation of the crop´s biomass sources in the fertilizer programs calculations maximizes its use; in order to enrich the organic fraction of the soil, reduce the fertilizer bill and contribute to carbon neutrality. Oil palm replanting constitutes a great agronomic opportunity, which well accomplished, allows general land preparation, drainage upgrade and the addition of massive amounts of organic matter, which will help soil´s chemical and physical fertility, in order to secure the sustainability of the crop for the next 40 years (when using compact materials). Experiences documented, up to date in Palma Tica S.A., show significant improvement during the plant establishment period, when organic amendments (OA) produced by the same crop are applied. Results show more vegetative biomass development and hence higher yields during the first harvest months, besides an important reduction of inorganic fertilizer required. The space-time synchronization between the OA decomposition and the nutrient uptake of the new palm, explains the best response of replants where shredded empty fruit bunches or chips of the previous crop were within the reach of the new plant, compared with replants with no OA, or where OA was out of the weeded circle area. Best management practices, as is the use of OA, are essential in the first three years of a new plantation, in order to assure high yields during the lifetime of a palm generation. Poorly managed plantations cannot develop the amount of biomass required to achieve optimum yields, a close target must be to collect 60 tons of fresh fruit bunches per hectare (t FFB/ha) during the first 60 months after planting.

(8790 - 2895) Forms of fertilizer application for coppice in Eucalyptus urophylla

Vitor Augusto Cordeiro Milagres[1]; Francisco Sérgio Gomes[1]

Gerdau Aços Longos[1]

Although Brazil leads the global ranking of forest productivity for eucalyptus, reaching an average of 35.7 m³ / ha / year, the productivity of forests managed by coppice is considerably inferior comparing it with the regime of high forests. In addition to the climatic factors that have negatively affected productivity in recent years, nutritional deficiency has also played a role in this outcome. One of the difficulties faced by the forestry sector has been the limited studies aimed at developing sowing fertilization techniques in order to optimize the growth of eucalyptus stands and reduce input costs. One of the difficulties faced by the forestry sector has been the limited studies aimed at developing techniques of fertilization of eucalyptus shoots in order to optimize the growth of eucalyptus stands and reduce input costs. Therefore, in this experiment, the following forms of fertilizer application were compared in a stand of a clone of Eucalyptus urophylla with Limestone in total area (LT), incorporated Limestone (IL), phosphorus in the total area (FT), phosphorus in groove (FG), potassium in total area (PT) and potassium in groove (PG) using three different inputs. The inputs are Araxá Phosphate (29% P2O5 and 36% CaO), Northwest Limestone (27% CaO and 14% MgO) and Potassium Chloride (60% K2O), and eight treatments: T1: LT + FT + PT; T2: LT+FG+PT; T3: LT+FT+PG; T4: LT+FG+PG; T5: IL + FT + PG; T6: IL + FG + PG; T7: IL + FG + PT; T8: IL + FT + PT. The test was carried out in the municipality of Três Marias, central region of Minas Gerais, in sandy loam soil with average precipitation of 1390 mm/year. The results show the importance of CaO top dressing application. The mean annual increment obtained IMA was 38.06 m³/ha/year, that is, 90% of the IMA obtained in the first rotation.

(8177 - 1070) Forms of limestone application for the elevation of base saturation

Júnior Antônio Rodrigues Mello[1]; Junior Barbosa dos Santos[1]; Fábio Régis de Souza[1]; Anderson Cristian Bergamin[1]; Jairo Rafael Machado Dias[1]; Cauandrey Deyverson Fagundes[1]; Rodrigo Maciel Nunes[1]; Wesley Santana Ferreira[1]

Fundação Universidade Federal de Rondônia[1]

Brazil is among the world's largest producers and exporters of grain, being this one of the main bases of the national economy. It is necessary to boost production by area, because the crops are restricted to areas already deforested and the demand for food grows annually. In this way, it is necessary to reduce the limiting factors of production, such as soil acidity. The soils of the Amazon region present good physical quality, exceptional for agricultural cultivation, but are predominantly acidic. The practice of liming is the most recommended and necessary for good production. However there are doubts about recommending the application of limestone in surface or embedded and the answer the form of application are scarce in the region of Zona da Mata in the state of Rondônia. The objective of this experiment was to evaluate the application of limestone and the elevation of base saturation as a function of the doses, in the Zona da Mata of Rondônia. The work was conducted experimental campus of the Federal University of Rondônia, municipality of Rolim de Moura, at the geographical coordinates of latitude 11º34'58.60"S and longitude 61º46'22.30"W, in 277 meters of height. The design used was the randomized of blocks in a 2 x 6 factorial arrangement with four replications, being the factors, the forms of limestone applications on surface or embedded and the second factor elevation of V%, with application of increasing doses of limestone to raise the V% for (V0, V60, V80, V100, V120 and V140%). The antecedent base saturation was 56%. The experiment was implemented in November 2014. The data were collected in January 2016, in layers of 0.0-0.10m and 0.10-0.20m. The following variables were evaluated: Ca, Mg, K, P, effective CEC, CEC at pH 7.0, sum of bases, Al, Al + H, pH 7.0, pH in CaCl and V%. Among the obtained results, there was highlight in the limestone applied on the surface, which provided higher values in Ca, effective CEC, potential CEC, Mg, SB, pH 7.0, pH in CaCl, compared to the incorporated, in the layers of 0,0-0,10m and 0,10-0,20m. It was also observed that the P content in the soil increased linearly as a function of the V% increase, of 0.0-0.10 m, even with non-significant pH values. Only Al and Al + H were significant in relation to the increase in saturation by bases of 0,10-0,20 of depth. Al linearly decreased with the V% increase, Al + H had quadratic response presenting lower potential acidity with elevation from V% to 80.

(6480 - 2745) Growth and yield of sugarcane as function of soil preparation and liming rates in sandy soil in two consecutive seasons

Ariani Garcia[1]; Gabriela Ferraz de Siqueira[1]; Jorge Martinelli Martello[1]; Tiara Moraes Guimarães[1]; Ciro Pozzi Garcia[1]; Daniele Scudeletti[1]; Murilo Campos[1]; Carlos Alexandre Costa Crusciol[1]; Juliano Carlos Calonego[1]

São Paulo State University, School of Agricultural Sciences[1]

Intense mechanization of harvest and planting now occurs in sugarcane production systems as a result of the abandonment of pre-harvest sugarcane burning practices, causing strong soil compaction, reduced root growth, and decrease the productivity and longevity of the cane field. Due to the new system of preparation and maintenance of the straw in the soil, more research is necessary to evaluate the interaction between the soil preparation systems and liming. The

official recommendations for liming for São Paulo State are no longer sufficient for the new system, which may limit sugarcane yield to lower values than the crop yield potential. Therefore, the aim of this study was to evaluate the effect of deep soil tillage compared with conventional tillage and liming rates on the sugarcane growth and yield in two years of production. The experiment was installed in 2015 in a Red-Yellow Latosol with a sandy texture, in the municipality of Borebi, SP, Brazil. The experimental design was a randomized block with split-plot design with four replications, where the plots consisted of three systems of soil tillage: conventional soil preparation (CSP); deep soil tillage (DST) with lime application spread in the entire area; and modified deep soil tillage (MDST) with lime application in the surface of the planting row, with ¼ of the dose in depth; and the subplots consisted of liming rates: 0, 1, 2 and 3 times the recommended dose (RD) for sugarcane production in São Paulo State, based on soil samples of 0.0-0.20 and 0.20-0.40 m. For the deep tillage treatments, all the machines were equipped with GPS equipment in order to control the traffic, allowing the definition of the plant growth and traffic zone. There was no significant difference between the soil preparation used and limestone rates for all the variables analyzed in the first year due to a frost that caused sugarcane yield reduction and an early harvest before full maturity. Yet, in the second year, CSP provided plants with longer stalk length compared to DST and MDST. However, MDST provided larger stalk diameter at all doses used. In relation to the stalks (TSH) and sugar production (TPH), the CSP system provided higher values of TSH and TPH at doses 2 and 3 x RD, higher than DST and MDST treatments.

(2272 - 403) Growth of pre-sprouted sugarcane seedlings as a function of organomineral compost

Rodolfo Lizcano Toledo[1]; Leonardo Correia COsta[2]; Vera Lucia da Silva[2]; Mirela Peroni[2]; Mara Cristina Pessoa da Cruz[2]; Dilier Olivera Viciedo[3]
University of the Amazon[1]; UNESP[2]; UNISS[3]

The use of fertilizers is considered of great importance to achieving positive results in productivity; however, the mineral fertilizer has suffered price increase affecting the cost of production in the sugarcane industry. Thus, with prospective reduce dependence, reduce costs and optimize the use of fertilizers, researchers seek alternatives to boost the productivity of sugarcane. In this context it took place this work to evaluate the effect of applying organic-compound in pre-sprouted seedlings of cane sugar Quartzipsamment. The experiment was conducted in a greenhouse in FCAV / UNESP belonging to the land department. The experimental design was completely randomized in a 2x5 factorial design, with two ways of applying organic-mineral compost in transplanting seedlings of sugarcane and five evaluation periods, with 5 replicates. The application forms of the compost and interaction of the application form with the timing, does not have significant effect on any of the variables studied pre-sprouted seedlings of sugarcane. The timing, the evaluation shows significant effect for all variables, with linear fit for phosphorus and potassium and quadratic for the other variables in pre-sprouting of sugarcane seedlings.

(1866 - 917) Growth patterns and nutrient extraction by *Eucalyptus globulus* Labill in the eastern region of Uruguay

Alejandro Gonzalez[1]; Jose Pedro Ualde[1]; Jorge Hernandez[2]; Amabelia del Pino[2]
UPM[1]; UdelaR[2]

Sustainability of forest production in the long term depends to a large extent on the dynamics of nutrients in forest ecosystems. For this it is important to know throughout the cycle, the evolution of the biomass produced as well as the nutrients retained in the different fractions of the tree. This work quantifies the biomass production and extraction of nutrients by *Eucalyptus globulus* trees at ages 5, 7, 9 and 12 years, in the eastern region of Uruguay. In each of the 4 plantations, 9 trees were harvested with average height and diameter. The different fractions were separated and weighed (leaves, wood, bark and branches), taking samples for analysis. In the laboratory the samples were dried at 60ºC, ground and N, P, Ca, Mg and K were determined. The aerial biomass increased with the age of the forest, explained mainly by the wood fraction, although there were also increases in bark and branches. For the leaves fraction, there were no significant biomass increases after 7 years of the forest, representing only 3 % of the total aerial biomass in the 12 year plantation. The total of nutrients in the aerial biomass, increased with the age of the forest, and the wood fraction showed greater accumulation of N, P and K; while for Ca and Mg bark had the highest amount. For all ages, and all nutrients, the sum of the fractions that correspond to harvest residues (leaves, branches and bark) showed greater accumulation, compared with the nutrients in wood. The nutrient accumulation in aerial biomass increased until 7 years stabilizing from there on (up to 12 years), with the only exception of P, where the accumulation increased up to 9 years. For all the ages studied, the order of absorption of nutrients was: Ca> N> K> Mg> P. In reference to the concentrations, in general terms, no important differences were observed for each nutrient in the different ages for each fraction. The leaf fraction presented the highest concentration of nutrients in all ages, except for Ca, where the highest concentration occurred in bark. The fraction with the lowest concentration of nutrients was wood, except for P, because also the thick branches showed a low concentration. The exchangeable Ca, K and Mg contents in the soil upper horizon of the sites evaluated showed relationship with the concentrations of these nutrients in the wood and leaf fractions, indicating that soils with greater nutrient richness promote higher nutrient absorption by *E. globulus*.

(8823 - 1672) Growth, yield and quality of hydroponically-grown Pineapple plants supplied with different potassium sources

Esteban Loria-Solano[1]; Marco V. Gutiérrez-Soto[2]
ACCS, Agrocontrol, Guápiles, Limón, Costa Rica (erloso@hotmail.com)[1]; University of Costa Rica, Dept of Agronomy, Fabio Baudrit Experimental Station, Alajuela, Costa Rica[2]

Pineapple nutrient uptake, particularly of K and N, is far superior than most tropical crops, but only a small fraction is retained in the fleshy fruits. In the field, most of K uptake occurs during vegetative development, when nutrients are applied mostly to the foliage, but substantial amounts of K are also applied during fruit development under the belief that this nutrient is essential for high fruit quality, particularly sweetness and fruit mechanical integrity. It is important to know the content and distribution of K in the whole plant to improve fertilizer use and administration, and to produce well-nourished plants capable of sustaining higher fruit yield and quality. In this work, we present the content and distribution of essential nutrients in all organs of whole vegetative and reproductive pineapple plants grown in a greenhouse in Costa Rica (10^{O}N, 840 m elev.), under optimal nutrient and water supply compared to pineapples grown in K-deficient solutions. To achieve this, we suspended K addition to the nutrient solution three months after planting, after which K was supplied to the foliage using KCl and K citrate. Both sources of K were applied at different concentrations: 600Kgha^{-1} and 200 Kgha^{-1}

respectively. The results showed no differences in plant growth and phenology, the time required for plants to achieve appropriate weight for flower induction, fruit yield and quality, and slip number and fresh weight among treatments, suggesting that K uptake during the first three months was enough to produce high quality plants and fruits, and point to the root system as the main organ responsible for nutrient uptake in pineapples. No evidence of increased fruit deterioration, such as translucency and mechanical damage was obtained, under different K sources. However, general nutrient content, especially K, was lower in plant grown in deficient solutions. Because of the significant differences in the amount of K supplied from diverse sources (KCl and K citrate), we conclude that K uptake and use efficiency is substantially increased when K is supplied through organic sources such as K citrate. We conclude with recommendations regarding fertilizer use strategies to maximize nutrient use efficiency and reduce water consumption in field-grown plants.

(1444 - 2804) Impact of conversion of land use on granulometric composition of soil in the maranhense Amazon, Brazil

Maria Karoline de Carvalho Rodrigues de Sousa[1]; Victor Roberto Ribeiro Reis[1]; Luciano Cavalcante Muniz[1]; Elimilton Pereira Brasil[1]; Diana Signor Deon[2]; Ilka South de Lima Cantanhêde[3]
UEMA[1]; EMBRAPA[2]; IFMA[3]

In the Amazon region, the practice of converting native forest to tradicional ranching, which commonly has poorly maneged pastures and the potential risk of soil degradation, is predominant. The identification of soil attributes that may be sensitive to changes in the conservation status of an environment is indispensable for the development of a more productive and sustainable livestock. The objective of this study was to evaluate the changes in the soil granulometric composition, as an indicator of soil quality, in different land uses in the Maranhense Amazon. The samples were collected in four environments in the municipality of Pindaré Mirim, Maranhão: Native forest with babassu (Attalea speciosa Mart.); Capoeira; Degraded pasture (with Urochloa brizantha cv. Marandu) and CLFI System (in the first year of the maize consortium, Marandu grass and eucalyptus). The samples were collected at seven dephts: 0-10, 10-20, 20-30, 30-40, 40-60, 60-80 and 80-100 cm. The granulometric analysis was performed according to the method of sieving and pipetting in standard fractions: sand, silt and clay. The means were submitted to analysis of variance by the Kruskal-Wallis method, followed by the comparison of means by the Bonferroni test (Dunn) at 95% confidence level. At dephts 0-10 and 10-20 cm, the soils under degraded pasture and CLFI system presented lower sand and higher clay content compared to other uses. The highest clay content in these layers, in a native forest and capoeira environment, probably occurred due to the greater protection of the soil to the process of erosion by the vegetation cover of the forest. A decrease in sand and an increase in clay content in depth were observed for areas with native forest with babassu and capoeira. In all layers evalueted, the silt content in the CLFI system was significantly higher than those with native forest and capoeira, and similar to degraded pasture. The samples in the different uses showed similar silt contents, except in the native forest with babassu. The granulometric composition of the soil is affected as a result of conversion of the forest or capoeira into pasture, which can result from the trampling of animals and the traffic of machines and implements, in addition to the loss of biomass. However, after the first year of implementation of the CLFI system, replacing the degraded pasture, no differences in granulometric were observed between these two uses.

(7278 - 782) Impact of potassium application on sown pastures and natural grassland in northern Uruguay

Maximiliano Cattani[1]; Monica Barbazán[1]; Teresa Rodriguez[1]
Facultad de Agronomia UDELAR[1]

In Uruguay, potassium (K) has recently been found as one of the factors that limits production in annual crops, but in sown pastures or natural grassland there is little information. This study evaluated the response in forage production of sown pastures to fertilizer K application from 2015 to 2017. Field trials were established at two sites on basaltic soils located in northern Uruguay, which had no history of K fertilization. At Site 1, the pasture was a mixture of white clover (*Trifolium repens* L.), red clover (*Trifolium pretense* L.), and perennial ryegrass (*Lolium perenne* L.). At Site 2, the pasture was Tall Fescue (*Festuca arundinacea*) and spontaneous species. The experiment was design with three repetitions and five treatments, each is an application rate (0, 30, 60, 120 and 240 kg K_2O ha^{-1}), applied as KCl, using a completely random block design with three repetitions, and P and S in non-limiting quantities. Plant K concentration and dry matter production were measured by periodic cuts with mower, eliminating crop residues from the plots and separating by hand grass species from legumes. At the beginning of the experiment, the soil K test (determined by the AcNH4 method) at 0- 15 cm depth were 0.45 and 0.32 $cmol_c$ kg^{-1} at the Site 1 and 2, respectively. In both sites, the fertilized plots tended to have higher total dry matter yield than the controls treatment, but significant differences among treatments were observed after the third cut at Site 1 and after the second at Site 2. The total amount of K extracted by pastures after two years varied from 365 to 553 kg K ha^{-1} at Site 1, and from 97 to 148 at Site 2. The soil K test after the first cut, increased 0.07 and 0.10 cmolc kg^{-1} in plots fertilized with 240 kg ha^{-1} of K_2O respect to the control plots, at Site 1 and 2, respectively. More research is needed to understand the K dynamic in these production systems.

(5342 - 3201) Increase of the production of potatoes (*Solanum tuberosum* L.) in two localities of the Peruvian highlands by the application of nitrogen mixtures and humic acids

Edgardo Marcelino Alaluna Gutierrez[1]; Juan Miguel Guerrero Lazaro[2]; Silvia Aguero Aguilar[3]
Technical Area. Molinos & Cia. S.A.[1]; Technical Area. Laspaf. Univerisdad Nacional Agraria La Molina[2]; Univerisdad Nacional Agraria La Molina[3]

The dose of fertilization should be based on the demand for nutrients, soil quality and timely supply to achieve the expected productivity. The objective of the research was to compare the increase in production of potatoes (*Solanum tuberosum* L.) in two localities of the Peruvian highlands by the application of nitrogen mixtures and humic acids. The study localities were Huancas-Junín (3571 ma.sl) and Sacsara-Ayacucho (2994 ma.sl). A CRB with a factorial arrangement of 6 treatments with three replications was applied. Three commercial mixtures (A: NPK 15-25-15 + 2MgO + 3S, Urea, B : NPK2 12-24-12 + 3 MgO + S, Ammonium sulphate and C: NPK 10-24-12 + 3 MgO + 8S Urea and ammonium sulfate) were evaluated combining these with and without humic acids (300 $kg.ha^{-1}$) in plots of 24 m^2. The tubers of each of the treatments were harvested, selected and weighed. The production and quality of tubers for first and second class in Huancas (33.72 and 30.64 $t.ha^{-1}$) were higher than those of Sacsara (23.81 and

8.33 t.ha^{-1}) according to the statistical analyzes ($p < 0.05$) showed significant differences. The total production in Huancas (64.36 t ha^{-1}) was 100% higher than Sacsara (32.13 t ha^{-1}). With humic acid mixture, the yields of first class tubers were increased by 20% in Huancas and 17% in Sacsara. Likewise, in both locations, the interactions of the three mixtures with humic acid showed similar results, however the C mixture with humic acid was higher than the application of the mixtures alone.

(1292 - 2953) Influence of agrominerals on chemical attributes of two soils of Rio Grande do Sul State, Brazil.

Milena Moreira Peres[1]; Carlos Augusto Posser Silveira[2]; Adilson Luís Bamberg[2]; Ivan dos Santos Pereira[2]; Rosane Martinazzo[2]; Rogério Oliveira de Sousa[1]

Universidade Federal de Pelotas[1]; Embrapa Clima Temperado[2]

The agricultural use of rocks with minerals that contain available nutrients for crops (Agrominerals) has been the focus of new and recent research in Brazil, aimed at reducing production costs, to create alternatives for market niches and to reduce the Brazilian external dependence of inputs. In Brazil, the Law N. 13,891 / 2013 included the "remineralizers" as a new class of agricultural inputs. This Law also enables the use of mining wastes, especially those that are rich in calcium, magnesium, potassium (K) and silicon (Si), but only if they have solely passed by physical processes to reduce the size of particles or separate them. In some cases, certain rocks may also have the potential to correct or elevate the soil acidity. The objective was to evaluate the influence of three rock types on pH and electrical conductivity (EC) of two representative soils from the Rio Grande do Sul State, Brazil. The experiment was conducted with monitored environmental conditions at Embrapa Clima Temperado, Pelotas/RS/Brazil. The treatments were: T1 - Control, T2 - Fonolite, T3 - Dacite and T4 - Dacite (90%) + Basalt (10%) and the soil types were: Quartzarenic Neosol and Red Nitosol. The rate of each rock was dimensioned and applied to raise the available K content of each soil up to the high level, according to local recommendation, being the rocks samples with 100% passing through a 140 mesh (0.105 mm) sieve. The experiment was conducted in a randomized block design with three replicates. At 180 days, samples of each treatment were collected and determined the pH and EC in the soil:water (1:2.5) ratio. Data were submitted to analysis of variance and, when a significant effect was observed, the Tukey test was performed at 5% of probability error. For soil pH, no significant effects were observed for the studied treatment factors, indicating that the evaluated rocks did not change the soil acidity levels. In relation to EC, only between the two soil types a significant difference was observed, however, the addition of the three types of rocks did not significantly affect the EC in both soils. In general, the rates and the types of the studied rocks did not influence the soil acidity nor presented risk of salinization for the studied soils until 180 days after rock incorporation.

(1975 - 2090) Influence of limestone and phosphogypsum on eucalypt productivity in Curvelo - MG

Rodrigo Nogueira de Sousa[1]; Vanderlayne Verônica Costa[1]; Lucas Vinícius Torres Lima[1]; Bernardo Amorim da Silva[1]; Leonardus Vergutz[1]; Ivo Ribeiro da Silva[1]; Samuel Vasconcelos Valadares[1]; Fernando Antonio Vieira Rodrigues[2]

Universidade Federal de Viçosa[1]; CEFET-CURVELO[2]

The Eucalyptus plantations are increasing mainly due to economic viability and need to reduce demands for native species. The liming in the eucalyptus is made to reach base saturation around 50%, also to provide Ca and Mg for the plants. However, Ca and Mg applied by limestone have little mobility in soil profile. To increase their availability in depth and reduce phytotoxic forms of Al^{3+}, many studies have shown that phosphogypsum (CaSO4.2H2O) has great effectiveness. Thus, the main objective of the authors with this work was to determine the influence of limestone and phosphogypsum on eucalyptus growth and productivity. The Eucalypt planting is already in pre-harvest step (74 months). The experiment was setted up in december of 2010 on oxisoil with 62,5 % of clay in Curvelo–MG. The experiment was arranged in a factorial ($2^3 - 1$) + 2 + 2 with randomized blocks and four replicates, totaling 44 experimental units. In this abstract we focused in four treatments, the treatment +L+P (with limestone and phosphogympsum), in which limestone was applied in total area and gypsum in strip; the +L+P, with limestone and phosphogympsum applied in total area; the +L, just limestone in total area and the control treatment, -L-P (without limestone and phosphogympsum). The amount of limestone used was 3 Mg ha^{-1} and phosphogympsum (when applied) was 1 Mg ha^{-1}. The planting was done seven days after limestone and phosphogympsum application. The +L+P applied in strip showed productivity of 370 m^3 ha^{-1}, 33,7% higher than the control treatment, which it was 281 m^3 ha^{-1}. The +L+P applied in total area had productivity of 341 m^3 ha^{-1} (21,5% higher than control). The aplication of limestone (+L) promoted 14% more productivity than the reference. Our findings are explained by the fact that, Ca and Mg provided by the liming (mainly) and gypsum, improved the nutritional and chemical characteristics of the soil, pH increase, cation exchange capacity (cec), (Zambrosi et al., 2007). The phosphogympsum probably promoted more roots growth, consequently contributed to higher development of the trees leading to high productivity. Thus, we conclued the effectiveness of limestone and gypsum, mainly applied in strip, on eucalypt productivity.

(9322 - 2940) Initial growing of *acacia mangiumin* in soil classes incorporated with carnauba straw (*copernica prunifera*)

Brito, Ana Clecia Campos[1]; Damasceno, Ayrton Senna da Silva[1]; Boechat, Cácio Luiz[1]; Morais, Joacir[1]; Gonçalves, Breendon Patrick da Silva[1]; Arauco, Adriana Miranda de Santana[1]; Baiano Júnior, Denir da Silva[1]

UFPI[1]

Acácia mangium has been used for recuperating degraded areas. This paper aims to evaluate the *Acacia mangium* seedlings nutrition with the incorporation of commercial fertilizer and organic residue in different soil classes. Soil samples were classified as Quartzenic Neosol, Yellow Red Latosol, Yellow Argisol, and Haplic Gleysol. Five samples of carnauba straw (0.25%, 50%, 75%, and 100%), treatment with soil with mineral fertilization, and four classes of soil, arranged in fully randomized blocks (FRB). At the ninetieth day, Ca, K, Mg, Zn, Cu, and Mn contents in the aerial part were evaluated. Was observed for calcium (Ca) in the aerial part (AP), and the higher Ca (8.6 g kg^{-1}) amount was observed in the substrate contained 100% carnauba straw within the Argisol, no difference among the other treatments. On the Gleysol, were observed in the 0% and 50%, while in the Latosol in all treatments, and in the Neosol, in the soil treatment with N-P-K (17.2 g kg^{-1}). Ca content in AP of cultivated plants in the Neosol stands out from others, except for 100% treatment. For Argisol and Latosol, there was increase in Ca content as the carnauba straw percentage was increased. The magnesium content (Mg) in the aerial part was higher in the pure soil; the worst result was in the soil treatment with

N-P-K in the Argisol class, except in the Neosol, in which there was no significant difference. Among the soil classes, the best results inside each treatment were observed in the Latosol, except in the treatment with 100% that did not differ among the soil classes. Potassium (K) with maximum mean of 216.6 g kg^{-1} in the substrate with 50% of carnauba straw with Latosol. Except the means of the Gleisol treatment, it is able to realize that there was K decrease with the increase of carnauba straw doses. Among the soil classes, the lowest concentrations in the Gleisol treatments were observed. The highest K contents were observed in the aerial part of cultivated plants in substrate with Neosol and Latosol. In this study, there was little variation among treatments inside the four soil classes for the Cu content in the aerial part of *A. mangium*. Zn presented range from 7.16 to 20.70 mg kg^{-1} with 75% carnauba straw, and in the only soil treatment inside the Latosol. Considering the micronutrients, Mn was the most absorbed by the *A. mangium* seedlings, presenting maximum AP content (144.42 mg kg-1). All the four soil classes can be used in the *Acacia mangium* seedlings production.

(8731 - 2893) Inorganic phosphorus in soil after four years of integrated systems of crop-livestock-forest

Gessica de Carvalho[1]; Maurel Behling[2]; Anderson Lange[3]; Diego Camargo[3]; Jaqueline Bento Farias[3]; Leticia Helena Campos de Souza[3]
UFV[1]; Embrapa Agrossilvipastoril[2]; UFMT[3]

The study was conducted in the 2015/2016 harvest at Embrapa Agrosilvopastoral in Sinop, MT. The evaluated systems were: eucalypt planted forest (F); exclusive crop (soybean) (L); pasture with brachiaria (P); and integrated systems of crop-livestock-forest (ICLF) established with eucalyptus provisions in triple lines ((3,5 x 3,0) x 30 m East-West orientation) with soybean crop annually. The experiment used a randomized block design with four replications. Soil samples were taken at the layers of 0-5, 5-10, 10-20, 20-30 cm. In the ICLF system, samples were collected in four equidistant transects per treatment in the transverse direction of the lines of forest species, at the distances of 1.5; 3; 6; 10 and 15 m on both sides (north and south faces). In the determination of Pi, Air-dried soil (0.5g) was weighed and placed in tubes with sodium carbonate solution ($NaHCO_3$ 0.5 mol L^{-1}) for agitation. The quantification was realized by the blue molybdate method and the reading was realized by spectrophotometer. After meeting the assumptions (normality and homoscedasticity) the data were submitted to analysis of variance, the effects of the treatments unfolded by contrast and the distances in relation to the row of the trees compared through the standard error of the mean. Pi differs between the ICLF and the exclusive systems (F, L and P), in the depth up to 10 cm. The same occurs between the contrasts F vs (L+P), the L vs P. The contrast ICLF-L vs L differs only in the superficial layer of the soil (0-5cm) and the contrast F vs L only occurs difference in layer 0-20cm. The Pi has higher availability in the crop of the ICLF system and in the exclusive crop up to 10 cm of soil. In the ICLF, the levels of Pi in the superficial layers were smaller in the position 1.5 m away from the trees in the south and north face. Thus, up to the fourth year, in the ICLF there is still no pronounced effect of the forest component on the subsurface layers of the soil. However, it acts as a drain of Pi in the range of crops near the trees reducing the availability of P to the agricultural crop

(7253 - 2834) Integral use of pineapple plant residues for biorefinery and production of an organic soil amendment

Mariana Murillo[1]; Paola Fuentes[2]; Carolina Hernández[3]; Wei Liao[4]; Lidieth Uribe[5]
Instituto Nacional de Innovación y Transferencia en Tecnología Agropecuaria[1]; Centro de Electroquímica y Energía Química[2]; Instituto Costarricense de Electricidad[3]; Michigan State University[4]; Centro de Investigaciones Agronómicas[5]

Agricultural residual biomass can be used as a source for biorefinery. In Costa Rica, pineapple production generates over 250 tons of residual biomass per harvested hectare, which are left in the field to decompose. During the degradation process, aromatic compounds are released, attracting the hematophagous fly *Stomoxys calcitrans*. This insect feeds on cattle, causing great losses to nearby ranchers. With the aim of reducing the impacts of pineapple production and finding an integral utilization of the residues, a double-purpose approach was studied. Pineapple plants were separated into two fractions; solid and liquid, which were used for fatty-acid methyl esters (FAMEs) and biogas production, respectively. The solid fraction was pretreated for one hour at 121 °C and exposed to 17 FPU cellulase (Sigma C2370) and 37 U xylanase (Sigma X2753) per gram of cellulose. The hydrolyzed material was then used to grow the oleaginous fungus *Umbelopsis isabellina*. By controlling the nutrient content in the culture media, the accumulation of lipids in the fungal cells was encouraged. Using the Bligh & Dyer extraction protocol, the lipids were separated from the fungal biomass, and thereafter, where transesterified to FAMEs. A yield of 3.5 g biomass / kg of solid fraction of pineapple plants was obtained. The residues generated throughout the FAME production process, in combination with the liquid fraction of the pineapple plants, were used to produce biogas in anaerobic digester systems. With the obtained results in lab-scale assays, an electric potential of 4145 KW/m^3 of liquid residues was estimated. Finally, the digested material from the anaerobic reactors could be incorporated to the pineapple plantations to increase the organic matter input to the system.

(8204 - 2124) Labile Carbon in bauxite mined-soils under rehabilitation process with *Eucalyptus spp.* and *Anadenanthera peregrina*

Matheus Andrade Ferreira[1]; Luiz Fernando Negris Gardioli[1]; Ricardo Cardoso Fialho[1]; Rafael da Silva Teixera[1]; Caroline Moreira Análio[1]; Ivo Ribeiro da Silva[1]
Universidade Federal de Viçosa[1]

In Brazil, the rehabilitation of mining areas is a legal obligation of the companies responsible for mineral exploration. The planting of forest species such as *Eucalyptus* spp. and N-fixing species such as *Anadenanthera macrocarpa* might be a satisfactory alternative to promote the rehabilitation of soil, especially carbon stocks, essential to the system's sustainability. The labile organic carbon (LOC), due its high sensibility to changes in soil, is considered an important parameter for evaluating rehabilitation techniques. In this study, our objective was to evaluate the LOC in bauxite mined-soil under rehabilitation process with forest species. The study was carried out near to the city of São Sebastião da Vargem Alegre, Minas Gerais state. After the mining process and properly soil layers reconstruction, the experiment was set up using a complete randomized block design, with five replicates and three treatments: Eucalyptus (*Eucalyptus spp*.), Angico Vermelho (*Anadenanthera peregrina*) and no plants (control). Soil samples were collected (0-20cm) six months after the end of mining activities and six years (0-10 cm) after treatments implantation for LOC determination. An undisturbed native forest fragment (Atlantic Forest), adjacent to the mining area, was also sampled as a reference of natural environment. The results vary from 0,423 mg g^{-1} to 3,808 mg g^{-1} of LOC in the area without plant or

native forest fragment, respectively. The Angico Vermelho and Eucalyptus plantations increased the soil LOC content in approximately 300% and 271% in comparison to the post mining area. The increase in the soil LOC indicates that the cultivation of these forest species, mainly Angico Vermelho, are able to promote the reestablishment of soil functionality in bauxite mined-soil. However, a longer period of time is necessary to reach desirable values as those found for Atlantic Forest.

(8363 - 812) Late application of potassium fertilizer to soybean: effects on yield and nitrogen concentration in grain

Monica M. Barbazan[1]; Lucia S. Rocha[1]
University of the Republic, Uruguay[1]

Soybean [Glycine max (L.) Merr.] , one of the main crops in the world, requires a large amount of potassium (K) to complete its cycle. However, there is limited information of the effects on yield and seed composition when potassium fertilizer is applied in advanced stages of the soybean growth. This information is important, especially for Uruguay, where agriculture depends strictly on imported fertilizers and where K has recently been found as one of the main factors limiting the crop production. The objective of this study was to evaluate the effects of K fertilizer on the yield and concentration of nitrogen (N) of soybean seeds, when K is applied to the soil in two stages of the growing season . Field experiments were conducted in four different sites, using a randomized complete block design. Treatments were three rates (0, 50, and 100 kg of K ha-1) applied at 2-3 leaves or at R1-R2 stages. Granulated K fertilizer (potassium chloride) was applied to soil, on four commertial soybean crops under no-tillage system. Initial soil K tests (STK) (NH4Ac method) were 0.15, 0.22, 0.37, and 0.60 cmolc kg-1. Trifoliolate leaf- and petiole-K concentrations and STK at R1-R2, and yield and N concentration (Kjeldahl method) in seed were determined. The results showed significant yield increase in the two sites with lower STK, but no statistic differences were observed between rates or timing of K application. Trifoliolate leaf- and petiole-K concentrations at R1-R2 showed a better relationship with the yield than STK at that stage. In seeds, the concentrations of N ranged from 4.8 to 6.1% of N. This N concentration decreased in one of the sites compared with the control (without K application), in other site increased, whereas in the other two sites were stable. Our results suggest the possibility of correcting K deficiency of soybean by K fertilization at early reproductive stages. Further research is needed to make K fertilizer recommendations.

(1721 - 235) Leaf litter decomposition in silvopastoral systems in Colombian Caribbean

Martínez-Atencia, Judith[1]; Osorio-Vega, Nelson[2]; Loaiza-Usuga, Juan[2]; Cajas-Girón, Yasmin[3]
CORPOICA[1]; Universidad Nacional de Colombia[2]; Consultor[3]

The degradation of soils and grasslands in the livestock systems of the Colombian Caribbean region decreases plant and animal productivity. The silvopastoral systems can favor the recycling of carbon and nutrients from the addition of litter and its subsequent decomposition. However, there is little knowledge about the actual contribution of nutrients by plant species within multi-stratum silvopastoral systems and the speed with which they are released into the soil. The objective of this work was to determine the rate of decomposition and the release of nutrients from fallen litter of five plant species in thirteen years old silvopastoral arrangements and a grass-only meadow in the Middle Valley of the Sinú River, Colombia. The results show that (i) the decomposition of leaf litter and the release of nutrients (C, N, P, K, Ca and Mg) depended on the plant species that originated the litter and independent of the silvopastoral arrangement; (ii) these arrangements presented a real return of nutrients greater than that of the pastures; (iii) the litter decomposition was significantly related to the N / P ratio and the P and Mg concentration of the litter and not to the C / N ratio.

(8364 - 544) Lignin and lignin / nitrogen ratio associated with arboreal-shrub components in an agroforestry system without semiarid.

Rafaela Batista Magalhães[1]; Lucas de Sousa Oliveira[1]; Rafael de Souza Miranda[1]; Mirian Cristina Gomes Costa[1]
Federal University of Ceará[1]

Agroforestry systems (AFSs) constitute a more sustainable alternative of land use. The tree components present in AFSs are environmentally important for the adequate functioning of the systems. The amount of lignin directly influences the rate of decomposition of plant material from the tree components. The objective was to analyze the soil and roots of the tree species of SAF in relation to the lignin content and to the lignin: nitrogen ratio. The study was carried out in an agrosilvipastoril system in the semi-arid region. The experimental design was completely randomized, with split plots and four replicates. Four tree-shrub components randomly located in the area were evaluated in the plots: A – 'Catingueira' (*Poincianella pyramidalis*); B – 'Pau Branco' (*Auxemma oncocalyx*); C – 'Sabiá' (*Mimosa caesalpiniaefolia*); and D – 'Gliricídia' (*Gliricidia sepium*). Two sampling sites were evaluated in the subplots: A - inside crown projection area; B - outside crown projection area. For lignin contents in the roots, *Auxemma oncocalyx* showed higher value inside the crown projection area. Only *Poincianella pyramidalis* and *Auxemma oncocalyx* resulted in higher mean values inside the crown projection area, in the comparison between sampling sites. Regarding lignin:N ratio, *Auxemma oncocalyx* resulted in the highest mean value among the species and inside the crown projection area. Among the studied species, *Gliricidia sepium* and *Mimosa caesalpiniaefolia* showed the lowest values of lignin:N ratio. For lignin contents in the soil, *Auxemma oncocalyx* and *Poincianella pyramidalis* led to higher mean values inside the crown projection area. It is concluded that due to the lower lignin:N ratio, which will result in faster decomposition, *Gliricidia sepium* is promising to supply nutrients in the AFSs in shorter time among the studied species. The *Poincianella pyramidalis* and *Auxemma Oncocalyx* have higher lignin:N ratios, resulting in long-term improvements associated with an organic soil matter that takes longer to decompose.

(4132 - 2707) Long term impacts of integrated crop-livestock system with different grazing intensities and stocking methods on soil chemical attributes

Lucas Aquino Alves[1]; Tales Tiecher[1]; Luiz Gustavo Denardin[1]; Mateus Goulart[1]; Amanda Posselt Martins[1]; Ibanor Anghinoni[1]; Paulo César de Faccio Carvalho[1]
Federal University of Rio Grande do Sul[1]

The insertion of the animal component into the crop production (integrated crop-livestock systems – ICLS) can alter the nutrient dynamics and, consequently, the soil fertility status of the soil over time. This change occurs differently according to the arrangement adopted, depending on both, the intensity and frequency of animal grazing and crop rotation. The objective of this study was to evaluate

the long-term (13-yr) impact of sheep grazing in different intensities and grazing methods in the winter, on soil chemical attributes, in a monoculture and crop rotation in summer season of an ICLS. The study was performed in an experiment established in 2003, in a subtropical Acrisol in southern Brazil, arranged in a randomized block design with split plots. The treatments are two grazing intensities (moderate - 2.5 times the potential of consumption of animals and low - 5.0 times the potential of consumption of the animals), two methods of grazing (continuous and rotational) subdivided into two crop systems (monoculture of soybean/soybean and soybean/corn rotation). The evaluated chemical attributes were: water pH; exchangeable Al, Ca and Mg; available P and K; potential acidity (H+Al); base saturation (V); Al saturation (m); cation exchange capacity CEC (*t*), and organic carbon (C), at 0-5, 5-10, 10-20, 20-30, and 30-40 cm soil layers. Rotation with maize/soybean resulted in acidification of soil over time, with a pH of about 0.3 units (pH = 3.9) lower than in the monoculture (pH = 4.2) for the 0-40 cm soil layer. On the other hand, CEC was approximately 20% higher in crop rotation (3.9 $cmol_c\ dm^{-3}$) than in the monoculture (3.3 $cmol_c\ dm^{-3}$) in the 0-5 cm soil layer. In the same soil layer, CEC was 15% higher at low grazing intensity (3.9 $cmol_c\ dm^{-3}$) compared to moderate grazing intensity (3.4 $cmol_c\ dm^{-3}$). The C content in the monoculture was higher (1.4%) than in rotation system (1.1%) up to 10 cm depth. Moreover, low grazing intensity resulted also in an increase of C content up to 10 cm soil depth. The other evaluated soil chemical attributes were not affected by the treatments. The soybean monoculture system combined with low grazing intensity increases the levels of C in the most soil superficial layer. Monoculture coupled to low grazing intensity is more effective in maintaining soil fertility, and the grazing method does not seem to affect soil fertility over time.

A long-term application of organic amendments, in Mediterranean dryland agricultural systems with low organic matter (OM) soil content, could improve physical fertility and cause porosity changes (total, size and shape). Shape pore parameters: Circularity (*C)*, Aspect ratio (*AR)* and Solidity (*S*) reveal the irregularity, tortuosity and roughness of pores that affect water retention capacity, a relevant parameter in dryland systems. This study was aimed to evaluate the effects of organic amendments on soil pore shape parameters after a long-term (19 years) application period. The experiment was established in the 1997-98 cropping season in Lleida, Spain. Winter cereals are the main crops. Five fertilization treatments were distributed in three randomized blocks. Organics were applied annually, just before sowing: pig slurry (30 t $ha^{-1}\ yr^{-1}$; ≈ 50 kg OM t^{-1}; 30PS), low and high rate composted sludge (10 t $ha^{-1}\ yr^{-1}$ and 20 t $ha^{-1}\ yr^{-1}$, ≈ 290 kg OM t^{-1}). They were compared with an unfertilized control (CO) and with a chemical fertilization (MI). In April 2015, undisturbed soil samples (0–0.05 m depth) were taken and later they were dried, impregnated in polyester resin to obtain a thin section (0.05 m wide, 0.13 m long). From each thin section two images were taken under crossed polarisers to obtain digital binary images. From them, shape pore parameters: *C* (4π pore area/pore perimeter^2), *AR* (major axis/minor axis), and *S* (area of the pore/convex area of the pore) were quantified and analysed in four intervals of pores (apparent diameter: 30–60 µm*,* 60–100 µm*,* 100–200 µm*,* 200–400 µm and >400 µm). In all treatments, the *C* and *S* tended to decrease as pore size increased and an opposite trend occurred in the *AR*. The results indicate that shapes are modified by treatments at pore ranges of 60–100 µm (*AR*), 200–400 µm (*S*) and >400 µm (*C*) The *AR* values were lower in 20CS (1.668) and CO (1.662) than in 10CS (1.785) and 30PS (1.786) treatments. Treatments with added OM tended to decrease *S* (PS: 0.736; 20CS: 0.734; 10CS: 0.702) compared with no OM addition (CO: 0,766 and MI: *S*: 0,742). Similar differences were detected in *C* between organic treatments (PS: 0.304; 20CS: 0.300; 10CS: 0.261) and the rest (CO: 0.337 and MI: 0.325). These changes in pore shapes could be considered a positive effect of organic amendments in Mediterranean dryland agricultural systems.

(2437 - 1701) Microbial community changes in red latosol under swine liquid manure treatment

Deisi Navroski[1]; Graziela Moraes de Cesare Barbosa[2]; Maria Aparecida de Matos[2]; Adonis Moreira[3]; Arnaldo Colozzi Filho[2]
Londrina State University[1]; Agronomic Institute of Paraná State[2]; Brazilian Agricultural Research Corporation[3]

Brazil is the fourth largest producer of pork meat worldwide and as result, a great amount of swine liquid manure (SLM) has been commonly used as organic fertilizer in farming areas. This study focused on evaluating microbial community changes in a soil under SLM treatment. The experiment was performed in 1988 at an experimental station of IAPAR, on a soil classified as eutrophic Red Latosol (Oxisol) under no-till grain crops (NT). Soil samples were collected in October 2016, in a depth range of 0 to 10 cm, after ten days SLM application. Soil samples from a native primary forest (PF) nearby the experimental area were also gathered. Soil total DNA was extracted using a commercial kit, following the manufacturer's instructions. PCR amplifications of 16S rDNA gene fragment from *Archaea* and Bacteria and of the fungal 18S rDNA gene were made using universal and domain-specific oligonucleotide primers. Amplification products were denaturated by gel electrophoresis (DGGE) with 8% polyacrylamide gel (fungi and Archaea) and 6% (bacteria). PCR-DGGE profiles were analyzed by BioNumerics software package, and the dendrogram built using the UPGMA algorithm and Jaccard coefficient, with tolerance of 1%. The similarity among all treatments, including FP, was 38.1% for fungi, 38.6% for Archaea, and 63.2% for bacteria. A 70% similarity cutoff was used to define clusters; the Archaea community profile revealed a similarity of 84% among doses, and only 38% in relation to PF. Bacterial community was assessed by the same criterion, forming three clusters, one comprising the doses of 15 and 30 $m^3\ ha^{-1}$ (78% similarity), while the others were composed by control (0 $m^3\ ha^{-1}$) and PF. The fungal profile showed the same behavior, and the doses of 15 and 30 $m^3\ ha^{-1}$ had a 95% similarity, while control and PF remained separated again. In all cases, bands were greater in intensity at the dose of 15 $m^3\ ha^{-1}$, followed by that of 30 $m^3\ ha^{-1}$, but to a lesser degree at control; therefore, microbial diversity seems to be greater when SLM is used. The high similarity between the doses of 15 and 30 $m^3\ ha^{-1}$, as well as their

greater intensity of bands show that SLM addition to the soil surface may provide carbon and other organic compounds, which can be beneficial to autochthonous and zymogenous microorganisms therein. Our findings showed that the soil microbial community was altered after SLM addition, besides the fact that the most diverse microbial profile also reached a new break-even point.

(7891 - 2301) Multifunctional agroecosystems contributing for nutrients cycling in irrigated environments of the Brazilian semi-arid

Alessandra Monteiro Salviano[1]; Lincoln Monteiro Bagagi[2]; Andreia Amariz[2]; Maria do Socorro Conceiçao de Freitas[3]; Vanderlise Giongo[1]
Embrapa[1]; UPE[2]; IFSertão[3]

The Brazilian semi-arid region is characterized by monoculture that eventually degrade the soil. Due to this reality, there is a need to recover degraded areas and to preserve those that still are productive. Different practices are used for soil management and conservation, the most important being the green manure, which consist of the use of plant mixture that cover the soil. Therefore, the present work aims to evaluate the micronutrient cycling capacity by the use of green manure in mango production systems in the Brazilian semi-arid to mitigate the excessive use of fertilizer in agroecosystems. The study was carried out in long-term experiment installed in Petrolina, Pernambuco, local climate classified as BSwh' and Ultisol dystrophic plinthic, loamy/clayey plain relief. The experiment was conducted in a randomized block design with four replications and treatments arranged in subdivided plots. The plots consisted of two soil management systems (tillage and no-tillage), and the subplots consisted of 3 types of green manures: plant mixture 1 (PM1); plant mixture 2 (PM2) and spontaneous vegetation (SV). The litter bag technique was used for the evaluation of the release of nutrients. Altogether, there were used 312 litter bags, with monthly collections of 13 samples, during 12 months. The micronutrients accumulation on the phytomass of the green manures wasn't influenced by the soil management, but changed the cycling capacity of Mn on green manure. The soil's stirring speeds up the decomposition of the vegetable residue, providing a faster release of most micronutrients. In the tillage systems, the Fe was the micronutrient that took longer to release in all of the green manures, but the release of the remaining micronutrients changed from study to study, due to the type of fertilizer. The Mn, followed by the Zn, were the micronutrients that released first in every green manure, and the release of the remaining nutrients changed due to the type of fertilizer. In general, the Cu was the slowest element to release, the liberation speed being PM1>PM2>SV. To this nutrient, the release speed in on its maximum on tillage. The practice of cultivating plant mixtures in between the orchard's rows, as well as the maintenance of the spontaneous vegetation is a very promising technology to the cycling of soil's micronutrients and to improve or maintain the soil's quality, providing sustainability to the irrigated mango crop on the Brazilian semi-arid.

Nitrogen mobility, ammonia volatilization, and estimated leaching loss from long-term manure incorporation in red soil J. Huang [1,2], Y. Duan[1], M. Xu[1], B. Wang[1,2], N. Sun[1] and S. Gao[3] [1]Institute of Agricultural Resources and Regional Planning, CAAS; [2] Red Soil Experimental Station of CAAS in Qiyang, Qiyang 426182, China; [3]USDA Agricultural Research Service, San Joaquin Valley Agricultural Sciences Center, 9611 South Riverbend Avenue, Parlier, CA 93648-9757, USA.

Nitrogen (N) loss from fertilization in agricultural fields has an unavoidable negative impact on the environment and a better understanding of the major pathways can assist in developing best management practices. But there has been a challenge in quantifying the leaching loss in agronomic cropping systems. The aim of this study was to evaluate the fate of N fertilizers applied to acidic red soil (Ferralic Cambisol) after 19 years of different mineral (synthetic) and manure fertilization treatments under a cropping system with wheat-maize rotations. Five field treatments were examined: control (CK), mineral fertilizer combinations of NK, NP or NPK, and the NPK with manure (NPKM, 70% N from manure). Using the soil total N changes in 0−100 cm depth, plant uptake, ammonia (NH_3) volatilization, and nitrous oxide (N_2O) emission data measured in the field, a mass balance approach was used and potential N leaching loss was estimated. In contrast to the NPKM, all mineral fertilizer treatments (NK, NP and NPK) showed nitrate (NO_3^-) concentration increased with greater soil depth indicating higher leaching potential. However, total NH_3 volatilization loss was much higher from the NPKM (19.7%) than other mineral fertilizer treatments (≤4.2%). The N_2O emissions were generally low (0.2-0.9%, highest from the NPKM). Total gaseous loss accounted for 1.7, 3.3, 5.1, and 21.9% for NK, NP, NPK, and NPKM treatments, respectively. Estimated N leaching loss from the NPKM was only 5% of those from mineral fertilizer treatments. All data demonstrated that manure incorporation improved soil productivity, increased yield, and reduced potential leaching, but with significantly higher NH_3 volatilization, which could be reduced by improving application method. This research confirms that manure incorporation is an essential strategy in N fertilization management in dryland red soil cropping system. (8724 - 625) Nutrient absorption by *capsicum annuum* l cv. topito and cubanel in santa marta, colombia

Nelson Virgilio Piraneque Gambasica[1]; Sonia Esperanza Aguirre Forero[1]; Ceiny Jimena Jimenez Turizo[1]
Universidad del Magdalena[1]

Pepper is considered a promising crop for the Colombian Caribbean region economy, due to its growing national and international

demand, high yield and low production costs, thus becoming one of the most cultivated vegetables in the Magdalena department of Colombia. At the Center for Agricultural Development and Forestry of the University of Magdalena, macronutrients and micronutrients absorption by the cultivars Topito and Cubanel (Capsicum annum L.) was determined. For this, based on Bertsch (2003) methodology, and wet mineralization method for plants described by ICA (1993), random samplings were performed every 15 days by taking 3 to 10 plants (according to phenological stage) with suitable physiological and morphological characteristics, growth parameters (stem diameter, number of leaves, plant height, biomass and dry mass) were evaluated to establish the growth and biomass accumulation curves by the cultivars. The nutrients absorption was determined according to IGAC (2006) methodology. Results allowed to establish that the nutrient most absorbed by the two cultivars was nitrogen and that the macronutrients absorption, although different in each cultivar, followed the sequence N> K> Ca> Mg> S> P> Na. Micronutrients had different sequences, where Topito was Fe> Mn> Zn> B> Cu and in Cubanel Fe > Mn> Zn> Cu> B. Topito exceeded 29% in biomass accumulation and 51% in dry matter accumulation to Cubanel. Arguments of judgment are contributed in this work, in order to incorporate them to existent knowledge on pepper crop management in the studied zone. It is also shown the relevancy of integrating adequate nutrients supply as an active component in the productive system in modern agriculture or management by specific site.

(6659 - 1989) Nutrient accumulation and shoot dry matter production by cover crop species

Guiverson Ferreira Bueno[1]; Rodolfo Bedeu[1]; Jayme Ferreira Neto[2]; Laerte Gustavo Pivetta[3]; Luis Fernando Correira de Mello[1]; Camila de Aquino Tomaz[1]; Juliana Pereira Bravo[1]
Faculdade La Salle[1]; Universidade Católica Dom Bosco[2]; Instituto Federal do Mato Grosso[3]

In the choice of cover crops for no-tillage system it is very important to consider the amount of shoot dry matter produced in order to protect soil surface against erosion processes and the ability to accumulate nutrients extracted from the soil avoiding, for example, nutrient leaching. In this context, grasses and legumes such as pearl millet (*Pennisetum glaucum L.*), sun hemp (*Crotalaria spectabilis*), sudangrass (*Sorghum bicolor*) and finger millet (*Eleusine coracana L.*) can be attractive alternatives for no-tillage system. This study aimed to evaluate the nutrient accumulation and shoot dry matter production from pearl millet, sun hemp, sudangrass and finger millet evaluated in the flowering of each specie. This experiment was set up in March 2017 in Lucas do Rio Verde, Mato Grosso, Brazil. A randomized block design consisted of the four cover crop species, sown in March and collected for shoot dry matter and nutrient accumulation evaluation around the end of April and beginning of May by the flowering occasion. Sudangrass produces greater amounts of shoot dry matter followed by finger millet, pearl millet and sun hemp but the cover crop specie that accumulates more N, P, K, Ca, Mg, S, was finger millet.

Keywords: Nutrient extraction, *Pennisetum glaucum, Crotalaria spectabilis, Sorghum bicolor, Eleusine coracana L*.

(6619 - 1735) Organic and inorganic phosphorus in yellow latosol under chronosequence of crops under no-tillage system in eastern Amazon

Edilson Carvalho Brasil[1]; Rubia Carla Ribeiro Dantas[2]; Leticia Cunha da Hungria[2]; Sidney Daniel Araújo da Costa[2]; Alessandra Danieli Miranda de Araújo[2]; Mario Lopes da Silva Júnior[2]
Embrapa Amazônia Oriental[1]; Universidade Federal Rural da Amazônia[2]

Phosphorus deficiency (P) is one of the main limiting factors of productivity in Brazilian soils. However, soil management under no-tillage (NT) system may alter soil P availability. The objective was to evaluate the organic and inorganic fractions of P in a Yellow Latosol (Oxisol), in chronosequence of crops under no-tillage system in the Eastern Amazon. The study was conducted in the Paragominas city, southeast Pará, in a chronosequence of crops under NT, using a completely randomized experimental design in subdivided plots. The plots were constituted by the management systems and the subplots corresponded to the depths (0-10, 10-20, 20-30 and 30-40 cm). The management systems were: NT with nine (NT9), eleven (NT11), thirteen (NT13), fourteen (NT14) and fifteen (NT15) years of adoption, plus one area under conventional tillage (CT) and another with native forest (NF). The soil samples were submitted to the chemical fractionation of P and the obtained fractions were classified in inorganic P - Pi (sum of Pi_{RTA}, Pi_{BIC}, $Pi_{Hid0,1}$, Pi_{HCl} and $Pi_{Hid0,5}$) and organic P - Po (sum of Po_{BIC}, $Po_{Hid0.1}$ and $Po_{Hid0.5}$). In general, the organic fractions were predominant in the NT, while the inorganic fractions were the predominant ones in the area under CT, suggesting that in the soil managed under NT the P accumulates, preferably, in organic forms. In the layers 0-10 and 10-20 cm, all the areas under NT presented values of Pi highest to the CT, while in the layers 10-20 and 20-30 cm no difference was observed between the treatments. Considering the 0-10 cm layer, there was significant increases in the content of Po, in function of the time of NT adoption, with mean values of 256, 297, 319, 324 and 333 mg kg^{-1}, respectively, for treatments NT9, NT11 , NT13, NT14 and NT15. The Pi fraction presented similar behavior, but with absolute values in a smaller magnitude, with mean values of 133, 142, 180, 242 and 253 mg kg^{-1}, respectively, for the same systems. In the result of the higher organic matter input, soil non-tillage system and higher nutrient cycling, the NT promotes greater availability of the Po fraction when compared to CT.

(1753 - 1418) Parameters of Soil fertility as function of soil tillage systems and liming in Sugarcane

Murilo de Campos[1]; Gabriela Siqueira de Ferraz[1]; Jorge Martineli Martello[1]; Vinicius Barreto[1]; Daniele Scudeletti[1]; Ciro Pozzi Garcia[1]; Carlos Alexandre Costa Crusciol[1]; Juliano Carlos Calonego[1]; Tiara Moraes Guimarães[1]
São Paulo State University, College of Agricultural Sciences, Botucatu-SP[1]

The intense mechanization from planting to harvest in sugarcane production submits the soil to a strong compaction, reducing the root growth and yield. For these reasons, new soil tillage systems are being studied, aimed longevity and the maximum economic return. It is also necessary to evaluate the interaction with soil chemical attributes, as well as the use of limestone, since the recommendations of limestone in sugarcane were developed for the conventional soil tillage and harvest after burning. The aim of this study was to evaluate soil chemical attributes in function of the soil tillage systems and limestone doses. An experiment was carried out in a Oxisol, in Pirajú-SP, with a randomized complete block design, in a subdivided plot scheme, with four replications. The plots consisted of two soil tillage systems: 1. Conventional Soil Tillage (CST) with limestone applied in surface total area; 2. Modified Deep Soil Tillage (MDST) - Preparation

with rod up to 0.80 m and rotating hoe, with limestone only in the tillage range, applying ¼ of the limestone dose in depth. In the subplots, were used four different doses of limestone (0, 1, 2 and 3 times the recommended dose). Soil samples were collected in tillage range soon after the plant harvest at deeps of 0-0.2, 0.2-0.4, 0.4-0.6, 0.6-0.8 and 0.8-1.00 m. The evaluated parameters were: Sum of Bases (SB); Effective Cations Exchenge Capacity (CEC_e); Percentage Aluminum Saturation (AS) and Percentage Bases Saturation (BS). In all evaluated profiles, there was significant interaction ($p < 0.01$) between soil tillage systems and limestone doses at the parameters SB, BS and CEC_e. For these three variables, MDST was higher than CST at the highest limestone doses (2 and 3 times the recommended dose). When the recommended dose was used, the CST had higher values, evidencing the need of higher limestone doses in MDST, possibly due to the greater volume of explored soil. The variables Al^{+3} and AS showed significant interaction ($p < 0.01$) between soil preparation and limestone doses. The values of Al^{+3} and AS at all depths, were statistically lower in the CST with the recommended limestone dose. However, with 3 times the recommended dose, the MDST showed lower values of Al^{+3} and m%, mainly in subsurface. As these evaluations are related to the first year of cultivation, the values obtained show that the MDST can be a promising technique for sugarcane longevity, acting mainly in the deeper layers of soil.

(5633 - 1278) Percolate displacement and soil phosphorus content from the application of bovine livestock wastewater

Morais Carneiro dos Reis[1]; Ludimila Lucas da Silva[1]; Willian Geraldo da Silva[1]; Raysner Cesar Gral[1]; André Santana Andrade[1]
Centro Universitário de Patos de Minas[1]

The application of wastewater (WW) in soils has been a viable alternative for its final destination, both in industries and in farming systems. The utilization of WW in the fertirrigation of agricultural crops has been shown as an option in the reduction of environmental pollution, besides promoting better soil characteristics. Although application of WW in soils be viable, there is a shortage in technical criteria for proper application and environmental monitoring. Among the important parameters for monitoring and soil phosphorus content, biochemical oxygen demand (BOD) and percolate pH. Thus, the objective of this work was to quantify these parameters considering columns of soil submitted to different rates of application of WW. The work was conducted at Farm Terra Molhada, municipality of Lagoa Formosa, MG. The experiment was carried out in a randomized complete block design (RCB), with eight treatments and three replications, totaling 24 plots distributed in a 2x4 factorial scheme, represented by columns with two soil depths (0.30 m and 0.60 m) and four increasing ARB rates (0, 7.69, 15.38 and 23.07 kg / ha / week of N) calculated by the N content of dairy cattle WW applied. Five weekly applications were performed. The P extractor was the Mehlich-1. The analysis of variance was performed for all the characteristics evaluated by the Ftest ($P<0,10$). The averages were compared by the Tukey's test ($P <0,10$). Statistical analysis was performed by SISVAR software. Was observed an increase in the BOD rate of 41.58 mg L^{-1} for percolated effluents in the soil columns of 0,30 m. It was verified that there was no statistical difference between the treatments and as different depths analyzed. As for the P content of the soil, the result can be justified by the reduced experimental time, which was insufficient for the occurrence of significant mineralization of organic P present in WW. , not altering, consequently, their contents in the soil. As for ph, the result can be justified by the low volume of WW application, and by the high oxidation capacity and soil buffer power, which was able to oxidize the organic load of the WW and to absorb alterations in the pH of the percolated water. It is concluded that the amount of RA applied to the soil, even in the highest studied dose, in the studied period, does not pose environmental risks.

(5059 - 2226) Phosphorus efficiency and grain yield response of oat cultivars to soil-phosphorus levels.

Pedro Alexandre Varella Escosteguy[1]; Jonas Manica[1]
University of Passo Fundo[1]

This study was carried out to assess the nutritional efficiency of phosphorus (P) and the grain yield response of oat cultivars to soil-P levels. The treatments were evaluated in an 8 x 3 factorial scheme (Cultivars x P levels), with four replicates, in a randomized experimental design. Cultivars of *avena sativa* were grown in a greenhouse under low, medium and high soil-P level. To assess the nutritional efficiency indices and the oat response to soil-P levels, dry mass and P concentration of the aerial (stem, leaves, grains) and root part of the plant were evaluated, at physiological maturation. The cultivars with higher nutritional efficiency were distinguished by the higher efficiency of P use for grain yield which was due to the accumulation of this nutrient in the aerial part, mainly in the grains. Cultivars Barbarasul, Ouro and Taura are nutritional efficient for P, while FAEM 007, URS 21, Farroupilha, and Afrodite are inefficient. FAPA Slava is on the edge of efficient and inefficient group of cultivars. Most of the cultivars (Barbarasul, Ouro, FAEM 007, URS 21, and Farroupilha) are responsive to soil-P level, where Afrodite, FAPA Slava and Taura are not responsive to the increase of P in soil.

Keywords: *Avena Sativa*; grain yield, efficiency of use, efficiency of utilization, efficiency of acquisition.

(5972 - 884) Phosphorus fractions of Southern Chilean soils according to their genetic evolution

Dante Pinochet[1]; Gerardo Otzen[2]; Susana Valle[1]
Instituto de Ingeniería Agraria y Suelos. Facultad de Ciencias Agrarias. Universidad Austral de Chile. Centro de Investigación en Suelos Volcánicos (CISVo)[1]; Instituto de Ingeniería Agraria y Suelos. Facultad de Ciencias Agrarias. Universidad Austral de Chile.[2]

Total phosphorus (P) is composed by different reservoirs, which represents different mineral and organic components and their lability. By using sequential extraction methodology, these pools can be assessed and related to changes in P availability occurred during soil development and maturity. In Chile there are few studies comparing P fractions in function of soil maturity and no studies are known about the accumulation and distribution of P fractions in the soil profile. This study evaluates the hypothesis that the accumulation of P in soil varies with the genetic development of their horizons and soils with greater genetic evolution show different pattern the P accumulation in the P soil fractions. Three soil series profiles with different degree of evolution from the South Regions of Chile were evaluated: Valdivia soil, derived from volcanic ashes (duric Hapludand) from the Holocene period, the Fresia soil from volcanic materials (typic Haplohumult) from Pleistocene and Hueicoya soil (Haplohumult) a soil from before the three last glaciations on the region. The soils were sampled in all the horizons until C horizon and by sequential extraction method de Total P was fractionated in 8 different fractions. The total P is reduced with the soil evolution degree. Valdivia soil (the youngest soil evaluated) has 2 times more P than Fresia soil and 8.5 times more P Hueicoya soil, the oldest in evolution development. In all the soils the greatest accumulation of P was determined in the superficial Ap horizon and they have similar

proportions of their total P in the subsuperficial horizons. The inorganic P dominates over organic P in all the soil horizons being over 55% in all the soils. The soil series varied their relative P accumulation according to their permanent features related to P retention capacity. Independent of their total P the the Hueicoya soil (with low retention capacity) presented the greatest proportion of its P in the labile P fractions (Resin and bicarbonate) compared to the other soils which accumulated their P in their moderately labile fractions (NaOH and HCl 1M).

Keywords: P sequential fractions; total P, inorganic P, organic P, genetic soil evolution

(1704 - 580) Phosphorus organic forms release in long term field experiment depending on maize fertilization and growing systems

Stanko Milić[1]; Jordana Ninkov[1]; Jovica Vasina[1]; Živanov Milorad[1]; Jelena Marinković[1]; Branka Žarković[2]

Institute of Field and Vegetable Crops, Laboratory for soil and agroecology, Novi Sad, Serbia[1]; Faculty of Agriculture-University of Belgrade, Department of Agrochemistry and Plant Physiology, Belgrade, Serbia[2]

Since phosphorus is a non-renewable resource and one of the main pillars of modern agriculture the majority of global studies are directed toward more efficient use of phosphorus fertilizers, its recycling, and the use of alternative sources. Soil samples for the study were taken from long-term trial of the Institute of Field and Vegetable Crops at the experimental station at Rimski Šančevi. The trial was set up in 1965 as two-factorial, and replicated four times, according to the plan of divided plots (split-plot design with randomized variants). This study is based on monitoring the effect of crop rotation and fertilizers (manure, harvest residues and mineral fertilizers) on the presence of phosphorus and its organic fractions in different layers of rhizosphere by long-term use of particular maize growing and fertilization systems. The following factors were analysed: 1. Fertilizing systems: single-crop system (Ø, NPK, NPK+maize remains, NPK+manure) and two-crop rotation – maize/barley (manure, NPK+manure); 2. Soil depth: 0-20 cm; 20-40 cm; 40-60 cm. Chemical parameters, which was monitored on 324 number of soil samples, during the this investigating period was: basic chemical characteristics of soil, content of total phosphorus, content of total organic phosphorus, fractionation of organic phosphorus, activity of acid and alkaline phosphatase and yield. Organic matter content ranges from 1.88% to 2.98%. The highest values are characteristic for the treatments where manure was included together with mineral fertilizer. The highest content of total and organic phosphorus was found in the treatments with manure application, increase ranging from 27% to 70% depending of the variant. Characterisation of different types of organic phosphorus (labile, moderately labile, nonlabile) showed clear demarcation among studied treatments. Significant differences in all studied fractions and depths divided two basic groups, with and without use of organic fertilizers, wherein the highest values were actually found in the treatments with manure application. This was also proved by achieved statistical significances of LSD test between analysed components. In the year of the study, as well as for the long-term period, the lowest yields were achieved in the control variant of maize cultivation in single-crop system. Treatment two-crop rotation NPK+manure has statistically significantly highest yield comparing to all investigated variants.

(5303 - 2335) Potential reduction of fertilizer application in paddy soils: Nutrient reserve approach from soil mineralogical composition in Indonesia

Markus Anda[1]; Dedi Nursyamsi[1]

Indonesian Agency for Agricultural Research and Development[1]

Paddy soils occupied about 155 million ha of the world land surfaces and about 144 countries grow rice as the crucial source of food. The strategic approach to promote high yield, efficient use of fertilizer, environmentally sound and sustainable rice production in rice cultivation area worldwide is crucially required. The objectives of the study were (i) to evaluate easily weatherable minerals as natural nutrient reserves in various paddy soils developed from different parent materials in Indonesia, and (ii) to relate nutrient reserve-minerals with availability of soil K-nutrient as management strategy to omit or reduce K fertilizer rate without loss of rice yield. In this study, the soils were selected to represent paddy soils derived from volcanic, alluvial, and sediment materials at four main islands of Indonesia. Soils were sampled from each layer of soil profiles to determine easily weatherable and resistant minerals using a polarization microscope and to analyze various available nutrients. Results showed that soils deriving from acid volcanic material (rhyolite, Sumatera island) and intermediate sediment parent material (marl tuff, claystone and karst, Sulawesi island) contain high sanidine (25-42%) and biotite minerals, corresponding to high status of available K in whole soil profile layers. In addition, soils derived from brownish dark tuffaceous pumice and andesitic materials in Sumbawa Island also contain high status of available K due to K trapping in pumice structure during volcanic eruption. All those soil available K-derived parent materials (not from fertilizer) were more than enough to meet rice requirement, hence K-fertilizer could be omitted. For soils derived from alluvium materials (consisting of mainly quartz minerals, 74-80% in Java island), the available soil K was very low (< 0.1 $cmol_c\ kg^{-1}$). This indicates rice crop could experience severe K nutrient deficiency, hence high rate of KCl fertilizer should be applied as a management strategy to satisfy rice requirement. Implication of the study is the ignorance of naturally available K derived from K-bearing minerals in current management practices of paddy soils worldwide has led to wasting fertilizer and environmental pollution in soils containing high K-bearing minerals. Hence, the strategy should be made to apply fertilizer in paddy soils on mineral based composition to effectively reduce chemical fertilizer, cost and pollution and to sustain rice yield production.

Keywords: Paddy soils; fertilizer efficiency; soil minerals; rice yield

Brazil[4]; Universidade de Pernambuco, Campus Zona Rural, Petrolina, PE. Petrolina, Brazil[5]; Universidade de Pernambuco, Campus Petrolina, Petrolina, Brazil[6]

Vitiviniculture is an activity of great social and economic importance in the Lower Middle São Francisco region. The soils cultivated with grapevine in this region are poor in organic matter content, presenting in general low natural fertility. Thus, nitrogen and potassium fertilization generally have a great impact on the production and

chemical characteristics of grape and wine. This work was carried out with the objective of evaluating the effect of nitrogen and potassium fertilization on wine grape cultivation. The experiment was installed in the Bebedouro Experimental Field - Embrapa Semi-arid, in Petrolina, state of Pernambuco, Brazil. Grapevines of the Syrah cultivar were grafted onto the 1103 Paulsen rootstock. The planting was carried out in the 3x1 m spacing in the espalier system. Irrigation was performed by drip irrigation, with emitters spaced 0.5 m in the plant line and with 4 L h^{-1} flow. The treatments consisted of five levels of nitrogen (0, 15, 30, 60 and 120 kg ha^{-1}) and five levels of potassium (0, 15, 30, 60 and 120 kg ha^{-1}). These treatments were combined in a fractionated 5^2 factorial scheme, making a total of 13 combinations. The experiment was arranged in a randomized block with four replicates. The experimental unit consisted of 17 plants. Nitrogen was supplied as potassium nitrate and urea and potassium was supplied as nitrate, chloride and potassium sulfate, applied via fertigation. The production and quality characteristics of the grapes were evaluated during three harvests. Production increased linearly with increasing nitrogen rates; potassium fertilization did not change production. Volume of must, pH and total acidity increased as a function of nitrogen fertilization. The evaluation of the phenolic compounds revealed a higher concentration of polyphenols with increasing nitrogen levels and an increase in the concentration of anthocyanins and flavonoids in the higher levels of potassium. Nitrogen fertilization promoted even higher concentrations of citric and tartaric organic acids, but reduced the concentration of malic acid in the must.

Keywords: *Vitis vinifera*; mineral nutrition; fertilizer

(3409 - 489) Productivity and Dry Response of Eucalyptus and Its Relations with Soil Attributes in Brazil

Vinícius Evangelista Silva[1]; Salatier Buzetti[1]; Jean-Paul Laclau[2]; Rafael Montanari[1]; Alan Rodrigo Panosso[1]; Sharlles Christian Moreira Dias[3]
UNESP - Ilha Solteira[1]; CIRAD (France)[2]; Eldorado Brasil Celulose S/A[3]

It is observed that there is a great scientific effort to isolate and quantify the factors of the forest production, as well as the response to drought of the eucalyptus, but sometimes it becomes difficult and complex to separate them, due to the spatial and temporal confusions intrinsic to forest productivity and the response to drought. Thus, the objective of the present study was to evaluate the impacts of soil physical and chemical characteristics on productivity and response to drought of eucalyptus in climatically similar sites. For this, 33 experiments were installed in Brazil and Uruguay to obtain strong edaphoclimatic contrasts, and thus, to measure productivity and the response to drought and to describe its relations with soil attributes. Dry response was assessed with a 30% ratio rain exclusion system (70% of the rain left on the forests).The attributes of the soil Sand, Silt, Clay, organic material (O.M), cations exchange capacity (CEC), have a "maximum value" behavior in relation to eucalyptus productivity. The optimal values of Sand, Clay, Silt, CEC, O.M to maximize the wood productivity were 54.68%, 18.94%, 7.02%, 31.49 $mmoml_C$ / dm^3, 27.17 g / cm^3. Productivity correlated strongly in the sub-humid climate with the sand; and to a lesser extent with clay and silt; for the drought response, strongly correlated with the T variable. For the sites located in the Wet aridity class, productivity correlated strongly with O.M and clay, and positively with sand. For the dry response, the correlations were observed for Sub-Humid climate for the CEC and Sand variables, and for the Humid climate, no correlation was observed between the soil attributes and the dry response. It is observed that for the sub-humid climate it will be necessary to reduce 1.58% of the sand texture to increase 1m^3 / ha of productivity (R^2 = 0.47); already for Drought Response an increase ratio of 1.47 mmolc / dm^3 of Cations Exchange Capacity (CEC) was observed for a 1% increase in dry response. (R^2 = 0.67). In Brazil, similarly to Australia, most species of eucalyptus react well when planted to deep soils and medium texture. Soils in classes situated in the wet drought class behave as true hydroponics, and sub-humid regions are extremely more dependent on higher natural fertility soils to ensure reasonable levels of productivity. In addition, much of the soil attributes that are beneficial to plantations in Súb-Humid areas are not for soils located in humid regions.

Keywords: climate, edafoclimatic groups, tolerance to forest aridity.

(7002 - 1714) Productivity and quality of watermelon fruits according to Potassium fertilization in Amazon

Wesley Santana Ferreira[1]; Fabio Regis de Souza[1]; Francisco de Assis de Menezes[1]; Reginaldo Almeida de Andrade[1]; Anderson Cristian Bergamin[1]; Cauandrey Deyverson Fagundes[1]; Rodrigo Maciel Nunes[1]; Júnior Antônio Rodrigues Mello[1]
Fundação Universidade Federal de Rondônia[1]

Watermelon is a fruit that present different cultivars, can be distinctive with each other by the size, fruit format, color of the pulp and peel. The management of planting, cultural tracts like irrigation, control of pests and diseases, fertilization, conduction of the tillage until harvest point are factors that can influence in productivity, as theydirectlyinfluence, and when are realized on the correct way, resulting in good earnings of the culture. The objective of this work was evaluate the agronomic performance of watermelon culture submitted a potassium fertilization doses. The experiment was installed at experimental farm of Foundation Federal University of Rondônia (UNIR), municipally of Rolim de Moura. Geographic coordinates 11°43' 18" S e 61°46' 00" W, located at RO 479, km 15-North, municipally of Rolim de Moura RO, in the understood period between 20/04 and 10/07/2016. The delineation was in randomized blocks with five treatments and four repetitions. The treatments consisted in potassium doses: 0; 50; 100; 150 e 200 kg of K2O ha-1 applied on potassium chloride (60% of K2O). Application of the treatments occurred in fragmented form to 15, 30, 45 and 60 Days After Emergency (DAE), applied 25% of the tasted doses. The cultivar used was Crimson Select Plus. The variables analyzed were: average weight of the fruits, longitudinal and transverse diameter of the fruits, number of fruit by plants, content of soluble solids total (SST), thickness of peel and area total of productivity. Potassium doses not affected the average weight, in longitudinal and transverse diameter of the fruit. Was significant for number of fruit by plants presented a good result when was applied (200 kh.ha-1 de K2O). Thickness of peel reduces linearly according to the rise of the potassium doses. The rise of the doses has significant effects for the content of soluble solids total (SST), and area total of productivity, where the bests results were when applied (157,04 kg ha-1 of K2O) and (147,02 kg ha-1 de K2O) respectively.

(4637 - 1643) Productivity of summer crops due to organic or mineral fertilizers in ILP.

Paulo Hentz[1]; Juliano Corulli Correa[2]; Élita Terezinha de Azevedo Weschenfelder[1]; Carla Luíza Silvestrini[1]; José Juscelino de Oliveira[1]; Lucas Balena[1]
IFC Campus Concórdia, SC[1]; Embrapa - Suínos e Aves[2]

The practice fertilization with organic fertilizers promotes a productivity gain equal to or greater than mineral fertilizer when carried out for long years. The objective of this work was to evaluate

the fertilization response with doses of poultry litter, swine manure and mineral fertilizers in corn yield in the ILP system. The experiment was set up in a randomized block design in factorial 5x3 + 1, with four replications. Fertilizer treatments were composed of three organic fertilizers, poultry litter, swine manure, and mineral compound and two minerals, Mineral 1 - M1 and Mineral 2 - M2 with nutritional concentration equivalence to organic pairs, in interaction with three doses which corresponded to 75, 100 and 150% of the recommended fertilization applied to the crop of interest in question and the control (absence of fertilization). The recommendation of fertilization with increasing doses of organic or mineral fertilizers in the ILP system allowed raising corn productivity in the years 2015 and 2017 and soybeans in 2016. The history with more than five years of use of these good fertilizer use practices allows recommending 100% when using compound, M1 and poultry litter and 150% for swine manure and M2 in soybean crop and, again, 150% for all fertilizers in maize to obtain high productive levels in the ILP system.

Keywords: Poultry litter, swine manure, soybean

(8997 - 378) Quantifying phosphorus loss in surface runoff from different crop-pasture rotations in Uruguay.

Barreto, Patricia[1]; Mario Perez Bidegain[1]; Oswaldo Ernst[2]; Carlos Perdomo[1]
University of the Republic of Uruguay, Agronomy Faculty, Soils and Waters Department[1]; University of the Republic of Uruguay, Agronomy Faculty, Plant Production Department[2]

Phosphorus (P) runoff losses from agricultural soils contribute to surface water eutrophication. In Uruguay there are ample reports of high levels of P concentration in surface water, however, few studies have quantified P losses in our agricultural production systems. In this study, P losses were measured under natural rainfall with runoff microplots (1.5x1.5m) installed in 2012 in the northwest region of Uruguay. The soil was classified (USDA) as a fine, mixed, active, thermic Typic Argiudoll with a 4% slope. The experiment was arranged in a randomized complete block design with three replications, and the treatments were some combinations of tillage methods (CT= conventional tillage and NT= no till) and rotations (CC= continuous cropping and PR= pasture rotations), namely NTPR, NTCC, and CTPR. Additionally, PR combinations were split by two P rates (0 and 200 $kgP_2O_5.ha^{-1}$). The croppasture rotation used in the experiment consisted of three years of agriculture (two crops per year) and three years of a planted legume-grass meadow under livestock grazing. A natural pasture (NP) nearby was used as a control. From 2012 to 2014 total P (TP) and soluble P (SP) concentrations were determined in runoff water. The concentration of particulate P (PP) was estimated as the difference between TP and SP, and P loads as the product of runoff volume by P concentrations. Annual TP loads ($kgP.ha^1.yr^{-1}$) in the treatments receiving no P fertilizer were lower in CTPR and NTCC (0.8 and 1.5, respectively) than in NTPR (1.8), while the TP load in NP was 0.6 $kgP.ha^{-1}.yr^{-1}$. In the PR fertilized plots, TP losses in CT and NT were 2.3 and 5.2 $kgP.ha^{-1}.yr^{-1}$ respectively, but the interaction between tillage method and P rate was not significant. The annual PS loads ($kgP.ha^{-1}.yr^{-1}$) were also higher under NT, both in the unfertilized (0.9 vs 1.3) and in the fertilized plots (2.0 vs 4.5) for CT and NT, respectively. Therefore, the trends found in TP were also reflected and even augmented in SP. The flow-weighted mean TP concentrations followed the order NTPR_200P > CTPR_200P > NTCC_0P > CTPR_0P > NTPR_0P > NP. These results suggest that under Uruguayan conditions NT increases soil P runoff losses in relation to CT, especially in soluble form after fertilizer application.

(7395 - 2668) Reduction of the active acidity of the soil due to the application of limestone doses based on different methods of recommendation

Rafael Felippe Ratke[1]; Tiago André Kulzer[2]; Julian June of Jesus Lacerda[2]; Sammy Sidney Rocha Matias[2]; Denise Batista de Moraes[2]; Tamara Araújo Schenfert[2]
Universidade Federal do Mato Grosso do Sul[1]; [2]

Agriculture in Brazil is practiced largely on acid soils. To correct the soil acidity, limestone is used. The limestone dose recommendation is performed by methods and calculation based on the physical and chemical attributes of the soil, as well as the nutritional needs of the crops. There are different methods and calculation of liming in Brazil. The methods of liming in Brazil are method based on aluminum, calcium and magnesium exchangeable, SMP buffer method, base saturation method and Al^{3+} neutralization method and the increase of $Ca^{2+} + Mg^{2+}$ contents. However, the method is efficient and provides an improvement in soil chemistry for plant cultivation. Therefore, the objective of this research was to evaluate the increase of soil pH after the application of limestone doses based on liming methods and calculation. The soil used was collected at a depth of 0.20 to 0.40 m from a dystrophic Red Latosol. The chemical analysis of this soil showed initial pH (H_2O) of 4.3. The experiment was carried out in a completely randomized design in a 12 x 2 factorial scheme, being (12 methods and 2 classes of soils) with 4 replications. An additional treatment (without limestone) was also carried out. The limestone doses were based on the following methods: SMP buffer (4 pH levels: 5.5, 6.0, 6.5 and 7.0), base saturation (4 levels of base saturation: 30%, 50 %, 70% and 90%) and the method of neutralizing Al^{3+} and increasing $Ca^{2+} + Mg^{2+}$ levels. The soil was placed in 500 mL containers. The limestone doses used were: 0; 0.66; 0.72; 0.78; 0.82; 0.84; 0.92; 0.95; 1.16; 1.45; 2.08 and 2.71 g pot^{-1}. The soil was kept moist at 80% of the capacity of the vessel conferred with constant weighing on a precision scale. Soil samples were collected at each reaction time (90 days after application of limestone) in each plot. The soil samples were analyzed chemically for pH (H_2O). The obtained data were statistically analyzed by applying the F test in the analysis of variance through software R. Significant results were submitted to polynomial regression analysis. The pH of the soil increases in proportion to the dose of limestone applied. The method of base saturation showed a greater amplitude of soil pH reaching 6.7. The limestone doses estimated by the SMP method did not decrease the soil acidity as predicted, and the pH was below 5.2 when expected was that the pH of 7.0 at the dose of 0.84 g $plot^{-1}$ limestone.

(1912 - 1568) Reduction of the effects of water deficit on soybean and corn grain yield by the chemical improvement of the rooting layer

Marcieli Piccin[1]; Douglas Dalla Nora[1]; Telmo Jorge Carneiro Amado[1]; Antonio Cesar Batista Mazuco[1]; Tiago de Gregori Teixeira[1]; Fábio Henrique Gebert[1]
Universidade Federal de Santa Maria[1]

The Oxisols represent 31% of Brazilian soils and their main limiting factor is directly related to their acidity. The grain yield of soybean and corn crops grown in Oxisols with acid subsoil is strongly affected by the availability of water, and the acidity coupled with the chemical and physical impediment, have reduced the deepening of the root system of these crops, intensifying the deleterious effects of the deficit water on the grain yield. The present study aimed to evaluate the effect of the associated use of gypsum and lime as a chemical tool to improve

the conditions of the soil rooting layer and, consequently, to mitigate the damage that the water deficit can cause on the soybean and maize grain yield under no-tillage system (NTS). The experiment was carried out in the 2014/15 (soybean) and 2015/16 (maize) crops in a Dystrophic Oxisol with clay texture (Embrapa, 2006) in São Miguel das Missões in Rio Grande do Sul (Brazil), the region's climate is classified as subtropical (Cfa), according to Köppen-Geiger (1948). The treatments contained different doses of gypsum and associated lime, T0 (control); T1 (0.0 Mg ha^{-1} gypsum + 2.0 Mg ha^{-1} lime); T2 (3.0 Mg ha^{-1} gypsum + 2.0 Mg ha^{-1} lime) and; T3 (5.0 Mg ha^{-1} gypsum + 2.0 Mg ha^{-1} lime). The experimental arrangement was of subdivided plots with three replicates. The treatments received rain restriction chambers in subplots during the most critical period of the crop, which excluded 100% of the rainfall. For soybean, there were 30 days of exclusion and 20 days for maize. The soil samples collected was stratified from 0.00 m to 0.60 m. The associated application of gypsum and lime was able to increase the productivity of soybean and corn crops regardless of precipitation being excluded. However, when submitted to water deficit, accumulated productivity increased with the application of inputs (gypsum and lime) was 46% higher in both seasons. The chemical improvement of the soil rooting layer was able to attenuate the productivity losses that the water deficit would cause in soybean and corn crops.

(1434 - 2366) Revised soil survey by changing landuse in Korea

byung keun HYUN[1]; Yeon Kyu Sonn[1]; Sang Ho Jeon[1]; Soon Gan Yun[1]; Hyun Jun Cho[1]; Sug Jae Jung[1]; Jung Won Choil[1]
NAS[1]

Agricultural lands have decreased continuously, which was caused by urbanization, land consolidation, and road construction etc. Especially, Chungju city near Daejeon city has the severe land use change. Therefore, we studied changes of land use, soil properties, and soil information in order to provide the basic soil information and soil management practices in this city. The area of crop cultivated land in Korea (2016) reduced by 35,424 ha compared to ones from the previous year (2014). The paddy field decreased by 12,455 ha, upland field by 22,969 ha also. One of the reasons for the reduction of the paddy field was converting paddy field to upland (22,780 ha) > others (3,646) > public facilities (2,740) > building(2,642) > idle land (1,439). But, reasons for increase of upland field were switching paddy to upland (22,780 ha) > others(5,330) > land developed (1,415). The main reason of converting paddy field to upland was changing from rice to more profitable speciality crops or orchard. The cropland area of Chungju city reduced by 1,087 ha (2014/1999). The ratio of cropland area in this city reduced by 47.9% dramatically compared 2014 to 1999. The paddy fields located in alluvial plains in Chungju city were changed into upland or green house. In particular, paddy fields have been changed to not only upland, orchard, greenhouse cultivation but also to fallow in Chungju city. To analyze result of soil survey of Chungju city, 3686 soil codes (soil phases) were used and the area was 3834.2ha. The number of soil series increased from 65 to 74, and that of soil phase increased from 126 to 160. The largest increased area was Sachon(coarse loamy fluvaquentic endoaquepts) soil series. 536.3ha of Sachon soil series was incorporated from the existing Yecheon, Sanju, Wolgog, and Seongsan soil series.

Keywords: Soil survey, Landuse, Paddy field, Chungju city

(2136 - 2911) Second-crop corn responses to different residual potassium fertilizer management

Michel Esper Neto[1]; Carolina Fedrigo Coneglian[1]; Eunápio José Oliveira Costa[1]; Antonio Feijó de Góes Neto[1]; Éder Júnior de Oliveira Zampar[1]; Evandro Antônio Minato[1]; Marcos Renan Besen[1]; Bruno Maia Abdo Rahmen Cassim[1]; Fabrício Linares Mazzi[1]; Tadeu Takeyoshi Inoue[1]; Marcelo Augusto Batista[1]
UEM[1]

Potassium is an essential macronutrient and is the most abundant cation in plants tissue. The corn crop can reach uptake rates of 2.6 kg ha^{-1} day^{-1} according to development stage, however, only 7 kg ton^{-1} are extracted by corn kernel produced. In Brazil, successive soybean and corn crops in no-tillage system are common. Some researchers show that loams and clayey soils will hardly occur potassium leaching. The objective of this work was evaluated corn components production after different fertilization management carried out in previous crop (soybean). The experiment was carried out in Unidade de Difussão de Tecnologia (UDT) of the COCAMAR Agroindustrial in Floresta, Paraná, Brazil. The soil was classified as Red Latosol (Oxisol) with clayey texture. The potassium level in soil was 0.2 $cmol_c$ dm^{-3}, that was considered medium. The commercial corn hybrid (*Zea mays* L.) AG 9010 was cultivated. The experiment carried out as a factorial (5x2x2) at randomized block design with four replicates. The first factor were K_2O doses (0, 40, 80, 120 and 160 kg ha^{-1}). The second factor was potassium application (broadcast) time: before (15 days) or after (15 days) soybean sowing. The third factor was sowing fertilization (banded): 0 or 30 kg ha^{-1} of K_2O. All potassium fertilizer was applied in soybean crop. Corn was evaluated in two crop seasons (2016 and 2017). Each plot consisted of 10 corn lines of 8 m length spaced 0.45 m. The variables analyzed were number of rows in corn ear (NR), number of kernel per row (NK), mass of one thousand kernel (MTK) and yield (YD). The data were submitted to statistics basic assumptions (Shapiro-Wilk and Bartlett) and after to joint analysis of variance and regression (p<0.05). There were differences for all variables for the year. In 2016, frost decreased corn YD, NK MTK and NR. In 2016 NK and NR were significantly lower than 2017. Despite this, increasing linear models were adjusted according to the potassium doses for YD:YD = 3704 + 3.3x (R^2 = 0.84) and YD = 7473 5.6x (R^2 = 0.88) for 2016 and 2017, respectively, showing that residual fertilization was important and may be a management alternative to reduce costs and increases corn yield. MTK and YD also increased due K sowing fertilization. Normally, the potassium critical level in soil is considered to be around 0.16 $cmol_c$ dm^{-3}, although the initial soil content was higher than this, corn increases yield with potassium fertilization increasing.

(5654 - 1546) Shoot dry mass production of the sunflower crop under irrigation levels and potassium fertilization

Raphael Pereira França de Paula[1]; Luana Glaup Araujo Dourado[1]; Marcio Koetz[1]; Edna Maria Bonfim-Silva[1]; Tonny José Araújo da silva[1]
Federal University of Mato Grosso - UFMT[1]

Sunflower (*Helianthus annuus* L.) is among the four crops with the largest production of edible oil in the world, and is among the plant species with the highest potential for renewable energy production in Brazil. Sunflower cultivation presents characteristics of adaptability to several regions, reaching high yields. Soil fertilization and cultivation in areas with good water availability are important strategies to achieve good production. Thus, the objective of this study was evaluating the shoot dry mass production of the of the sunflower crop in response to soil water replacement levels and potassium levels in Cerrado Oxisol. The experiment was carried out in a greenhouse at the

Federal University of Mato Grosso, Campus of Rondonópolis - MT. The statistical design used was in randomized blocks, in a 5x4 factorial scheme, with 20 treatments and four replications, making 80 experimental plots. The treatments consisted of five potassium doses (0, 40, 80, 160 and 240 mg dm^{-3} of K_2O) and four levels of soil water replacement (75, 100, 125 and 150% of field capacity). Irrigation management was carried out by the reading of tension in the tensiometers installed in the experimental units with 100% replacement of the recommended water depth, and calculated to raise the values of the tension to those of the field capacity (6KPa) when the established tension was achieved. The water depth was applied according to the percentages for each treatment. The results were submitted at 5% probability regression analysis, using the statistical program SISVAR. The unfoldment of potassium doses within irrigation levels had a significant effect. The potassium doses of 240, 187.75, 204.52 and 197.73 mg dm^{-3} combined with the levels of 75, 100, 125 and 150% of the field capacity provided the highest shoot dry mass, with 55.09, 65.17, 76.69 and 95.69 g $vessel^{-1}$, respectively. A linear increase of the shoot dry mass (71.48, 82.89, 91.80 and 92.01 g^{-1}) was observed in the irrigation levels within the potassium doses of 40, 80, 160 and 240 mg dm^{-3}) with increasing irrigation levels.

(4632 - 3060) Short-term dynamics of exchangeable and nonexchangeable K pools in tropical soils under eucalypt

Naiara Fernanda de Souza[1]; Filipe Bruno de Oliveira[1]; Sérgio Henrique Carneiro[1]; Ianna Bizerra Barros[1]; Samuel Vasconcelos Valadares[1]; Ivo Ribeiro da Silva[1]
Universidade Federal de Viçosa[1]

The releasing of K from nonexchangeable pools (NEK) help to explain the variable responses of plants to K fertilization. Some long-term studies have reported an important role of NEK for eucalypt nutrition. The aim of this study was assessing the extraction of NEK and EK during the initial development of eucalyptus plants in tropical soils. The experiment was carried out in a greenhouse. The treatments were five soils with different textures and mineralogy. The experiment was carried out in randomized blocks with four replicates. The experimental units were pots containing 2 dm^3 of soil. Soil samples were collected (0.2 dm^3 of soil) at the beginning of the experiment in each experimental unit and 114 days after planting when the plants were cut at the soil level. The extraction of EK was performed with Ammonium Acetate (1 mol L^{-1} pH 7). A hot Nitric Acid (2 mol L^{-1}) solution was used to extract NEK forms. A 1:10 soil/solution ratio was used for both extractions. The total K content in plant shoots was also measured. The K content in soil and plant extracts were analyzed using a flame photometer. Variations of NEK (Δ - NEK) and EK (Δ - EK) pools were obtained by subtracting it´s values measured in the initial soil samples from those measured in the final soil samples. A two-way ANOVA followed by a Tukey test (P <0.05) was used to compare the different soils regarding Δ – NEK and Δ - EK. Pearson correlation tests were used to assess the relationships between dependent variables. Higher values of Δ – EK were observed for the soil with higher initial EK. An opposite behavior was observed for the Δ – NEK (i.e.: soils with lower initial EK presented higher Δ – NEK). We found good correlations of Δ – EK with plant K (r=0.65 P<0.05). High correlations were observed between the initial EK and plant K (r=0.84 P<0.05). We found no correlations between Δ – NEK or initial NEK with plant K. No correlations were also observed for final EK or NEK with plant K. Our results support the evidence that the release of NEK in soils under eucalypt are linked to the availability of this nutrient (i.e.: plants activate mechanisms to release NEK when EK is low). Despite the extraction of NEK during the early development of eucalypt, the EK pools are better predictors of plant K during this stage. Soil K tests that extract EK will be more suitable to predict short term K availability for eucalypt (e.g.: soil K to guarantee a better initial growth of the plants).

(1079 - 930) Shrub encroachment effects on key soil properties and restoring potential of Patagonian rangelands

Braian Vogel[1]; Ludmila La Manna[2]
Centro de Estudios Ambientales Integrados (CEAI) - Universidad Nacional de la Patagonia San Juan Bosco (UNPSJB)[1]; Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) - Universidad Nacional de la Patagonia San Juan Bosco (UNPSJB)[2]

In Argentinian Patagonia, rangelands have been under intense grazing pressure since late XIX century. Vegetation growing on volcanic soils in the forest-steppe ecotone, has seen dramatic physiognomic changes. Its fragmentation increased, perennial grasses reduced their cover and shrubs incremented it. We choose 4 study sites of this ecotone in NW of Patagonia, to evaluate soil changes associated to shrub encroachment. For every site 4 transects were established in both grass and shrub dominated areas, to characterize the vegetation. Dominant shrub was *Mulinum spinosum*, and dominant perennial grasses were *Festuca pallescens, Poa ligularis* and *Pappostipa speciosa* var. *speciosa.* At each transect, we took soil samples (0-5 cm) in bare soil patches and beneath vegetation canopies for laboratory analysis. Resulting data were analyzed using ANOVA with blocks. Significant differences *(p <0.05)* were found between samples. Soils under canopies were higher in organic matter (OM) and porosity (PS) and lower in coarse fragments (CF) (i.e., 2 - 75 mm), compared to bare soil patches. Non erodible fraction (NEF) (i.e., 0.84 - 2 mm) was lower in shrub areas, whether the soil was covered or not. Electric conductivity (EC) was higher under shrubs, compared to the other conditions. Bare soil patches in shrub areas had lower values in OM and PS, and higher in CF and sodium fluoride pH (NaF pH, non-crystalline aluminosilicates indicator). Higher CF could indicate more intense historic erosion processes, with losses of first soil centimeters and rocks concentration. This loss could expose layers containing finer textures, hence, with lower NEF values. Some of this subsurface layers contained imogolite, a non-crystalline silicate originated from volcanic ashes. Higher NaF pH in bare soil patches of shrub areas could indicate active erosion processes exposing this layers. When this minerals are exposed to desiccation, progressive crystallization occurs. Hence, where erosion is lower in magnitude, crystalline clays predominates resulting in lower NaF pH. Basic soil fertility properties like OM and PS have similar values, both under grasses and shrubs. Higher EC values (always at normal level) found under the hemispheric canopy of *M. spinosum* could show greater bases incorporation. Our results shows that present soil conditions are not limiting a potential recolonization by perennial grasses. It seems possible to recover some of the carrying capacity of this Patagonian rangelands.

(9993 - 535) Soil carbon variability across different agricultural land use types in Oye-Ekiti, Nigeria

Shittu O. Olubunmi[1]; Ayodele O. Julius[1]; Ilori A. O. Akinmayowa[1]; Nkemjika, J. Nkeonyediriya[1]
Department of Soil Resources and Environmental Management, Ekiti State University, Ado-Ekiti, Ekiti State, Nigeria.[1]

Decline in soil organic carbon and nutrients, with deterioration of soil structure characterized the conversion of native forest land to agricultural lands. Effects of four agricultural land use types; arable land, fallow land, forest plantation and ranchland with soil depth on

soil organic carbon fractions was evaluated in Oye-Ekiti, Nigeria. Core samples were collected at 0-5, 5-10, 10-20 and 20-30 cm depths for organic carbon fractions determination and one bulked sample at depth 0-30 cm at each site using a soil auger for routine analysis. The predominantly loamy sand soils in Oye-Ekiti were slightly acidic (pH 6.21, ranchland) to neutral (pH 7.0, forest plantation) in reactions with medium available P levels and generally sufficient total N with balanced cation contents. On average across depths, contents of particulate organic carbon (POC), total organic carbon (TOC), soil microbial biomass carbon (SMBC) and water soluble organic carbon (WSOC) showed that converting native land to forest plantation had better capacity for sustaining the various forms of soil organic carbon. Forest plantation recorded highest values of 10.36, 1.26, 5.80 and 2.11 g kg^{-1} for TOC, SMBC, POC and WSOC except for TOC in ranchland (16.78 g kg^{-1}), while arable land had the least values except for WSOC in ranchland (1.55 g kg^{-1}). Across the land use types, the surface soils had the highest mean concentrations of the various soil organic carbon fractions attributable to the slow rate of decomposition, mineralization and natural mixing of organic materials with the soil particles in relation to litter fall and decreases with depth except for POC that had the higher means at the subsurface depths and the SOC fractions had medium to high variations across the depths. Fallow contribution to TOC, SMBC and POC was minimal compared to forest plantation and ranchland except for WSOC where it had non-significantly higher contents than others except forest plantation, with arable land having the least content of all SOC forms. Soil organic carbon fractions showed low to medium non-significant relationships with the soil properties except POC with percentage base saturation ($r = 0.675^*$; $p < 0.05$) and WSOC with SMBC ($r = 0.600^*$; $p < 0.05$). Management practices in line with conservation agriculture that will immediately restored the poorly managed agricultural lands contributing to low SOC forms, for sustainable agricultural production and environmental protection should be encouraged.

(3537 - 2207) Soil Chemical Attributes on the Function of Different Kinds of Limestone and Reaction Time

Catharina Bertollini Vassão[1]; Bruna de Lima Fávaro[1]; Graziela de Biaggi Cantaccei[1]; Ana Maria Conte[1]; Osvaldo Sato[1]
UENP[1]

Soil is a fundamental part of the development of life on earth from which we extract the food necessary for human food, animal and the constitution of essential elements for the planet's biodiversity. In order to verify 4 reaction times in the soil and 3 correctives found commercially to improve the soil chemistry, an experiment was installed in a protected environment in the Experimental Farm. Dr. Eduardo Meneghel Rando from the State University of Northern Paraná, Luiz Meneghel-Bandeirantes Campus in soil classified as LATOSOLO RED. The experimental design was a randomized complete block design using 4 incubation times (0, 30, 60 and 90 days) and 3 types of limestone (limestone powder, liquid and granulate), by the base saturation methodology, for limestone powder, for commercial granular limestone the commercial recommendation is the use of a 20% dose of limestone with 80% PRNT, liquid limestone according to the manufacturer's recommendation is a dose of 10L ha -1, and the basis for the liming calculation was to achieve a base saturation of 70%. These recommendations resulted in the following doses: for 9 Mg ha-1 limestone, 1.5 Mg ha-1 granules and 10 L ha-1 liquid limestone, and one control without liming. The soil was sampled and analyzed according to the incubation time for each type of limestone. The soil chemical parameters were analyzed by the soil and plant laboratory of the UENP for organic matter, pH, phosphorus, calcium, magnesium , potassium, aluminum, potential acidity -H + Al, cation exchange capacity (CEC), aluminum and base saturation. For the statistical analyzes, the SASM-Agri program was used and the means of the significant interactions were evaluated by the ESTAT program. The Tukey test was used in a 1% and 5% to treatments and interactions that were significant. According to the results, there was a significant interaction between the different reaction times of the applied correctives, in which the organic matter content of the soil showed a decrease from the first 30 days after the application of the products during the experimental period. It was also observed that the limestone and liquid limestone presented similar behavior at 30 days after application, while the granular limestone obtained a statistical increase at 90 days after application. The results of the study allowed the conclusion that from the 30 days the limestone powder resulted in the chemical improvement of the soil used in the experimental condition.

(9986 - 1466) Soil chemical attributes, nutrition and yield of corn and soybean as a function of the application of magnesium silicate

Luiz Gustavo Moretti[1]; Carlos Alexandre Costa Crusciol[1]; Ricardo Rossi[2]; Pietro Hunger Micheri[1]; Cleiton José Alves[1]
São Paulo State University (Unesp), School of Agriculture, Botucatu, São Paulo, Brazil[1]; C MAG Fertilizantes, Jaboticabal, São Paulo, Brazil[2]

The magnesium fertilization is frequetly neglected and its lack affects plant growth. Many essential functions in plants require adequate sources, their role being most visible in root formation, chlorophyll and photosynthesis. The magnesium silicate comes from the igneous rock milling, being essentially a peridotite. It is consists mostly of olivine $(MgFe)_2SiO_4$. It is contains approximately 40% magnesium oxide (MgO) and 34% silica (SiO_2). The experiment was conducted in a greenhouse in School of Agriculture of UNESP, in Botucatu city - São Paulo State - Brazil, from November 2016 to March 2017. The experimental design used was completely randomized blocks, with 5 doses of Mg, and 4 replicates. The tests were performed in two soils granulometry, sandy texture and in clay texture. The application of the silicate powder was done 20 days before sowing [Glycine max (L.) Merr.] and corn [Zea mays (L.)] in 25 L pots of corrected soil (70% base saturation). The treatments were constituted by the absolute control (0 kg ha_{-1}), and 4 doses of the magnesium silicate stipulated to maintain the 1/1 ratio; 2/1; 3/1 and 4/1 between Ca/Mg, respectively 1866; 822; 476 and 300 kg ha^{-1} in sandy soil, and 3084; 1084; 416 and 84 kg ha^{-1}, respectively, in clayey soil. All treatments and phytosanitary management was performed according to the necessity and recommendation for each crop. Was analyzed the chemical attributes of the soil after harvesting, with the following variables being the levels, sum and bases saturation (Ca, Mg and K), phosphorus (P), sulfur (S), silicon (Si), potential acidity, cation exchange capacity, pH, content and saturation by aluminum (Al). For both cultures were analyzed the macro and micronutrient contents, production components and yield. The data were submitted to the Shapiro-Wilk normality test and then to analysis of variance - ANOVA by the F test ($p \leq 0.05$). Polynomial regression was performed for the doses of the powdered silicate. The source of magnesium and silicon promove the elevation of magnesium contents in the soil and improvements in the same chemical attributes, in sandy and clayey soil, for the potential acidity, sum and saturation bases, besides providing silicon to the soils. Was found increase magnesium and silicon in the leaf contents in the soybean and corn crops in sandy and clayey soil. It is also provides increased dry matter mass on the plants, and increased of grain to the yields for the crops tested in both soils.

(1658 - 1123) Soil factors affecting sugarcane productivity in Kitadaito and Kume Islands, Okinawa, Japan.

Naoko Miyamaru[1]; Koichi Yoshida[2]; Takeshi Kawanaka[3]; Koki Toyota[4]
Okinawa Prefectural Agricultural Research Center[1]; Okinawa Agricultural Technology & Development Co. Ltd[2]; Okinawa Environmental Analysis Center Co. Ltd[3]; Tokyo University of Agriculture and Technology[4]

The Okinawa Islands are located in the south area of Japan and belong to subtropical climate. The main crop in the Okinawa Islands is sugarcane (*Shaccharum officinarum* L.) and the sugarcane cultivation greatly contributes to the regional economies, especially in small islands such as Kitadaito Island and Kume Island. The average sugarcane yield in Kitadaito Island for the past 30 years was 44 Mg ha^{-1}, 31% lower than that (64 Mg ha^{-1}) in Okinawa prefecture. On the other hand, the yield in Kume Island has decreased for the past 30 years, from 80 Mg ha^{-1} in 1985 to 48 Mg ha^{-1} in 2015. Many reasons are considered for the low sugarcane productivity in both islands and the effects of soil factors have not been sufficiently studied. The objective of this study was to clarify the soil factors affecting the sugarcane yield in each Island. Soil physical and chemical properties were investigated in 50 fields of spring planting in Kitadaito Island in 2013. The sugarcane yield was positively correlated with the soil available nitrogen, available phosphate, humus, EC and plow layer depth. Statistical analysis of classification and regression trees (CART) showed that the sugarcane yield was low in fields with low available nitrogen (less than 16.5 mg kg^{-1}) and with shallow plow layer depth (less than 29 cm). The soil available nitrogen had a significant positive correlation with soil humus. Two-times of subsoiling in fields before planting and during growing period resulted in the significant increase of the plow layer depth, compared to fields with single or no subsoiling. In 2014, the same experiment was conducted in 40 fields of spring planting in Kume Island. Typhoon hit the Island twice in October and its damage was seen at random. However, the sugarcane yield was positively correlated with the soil plow layer depth. The average plow layer depth was 24.8 cm in fields without subsoiling, which was significantly shallower than 34.7 cm in fields with subsoiling. The main soil type of both Islands is Red-Yellow soils, and their soil texture is LiC to HC. A plow pan is liable to be formed in such heavy textured soils. Our study showed that subsoiling is a primarily important soil management to increase the sugarcane productivity in fields with heavy textured soils.

(1177 - 1733) Soil Fertility Survey in St. Vincent and the Grenadines

Renrick Williams[1]; Michael Delpesche[1]; Basil Nash[1]; Lucia Ballantyne[1]; Chun-Chun Huang[2]; Chu-Chung Chen[3]; Chien-Hui Syu[3]
Ministry of Agriculture(Plant Protection and Quarantine unit)[1]; International Cooperation and Development Fund[2]; Taiwan Agriculture Research Institute[3]

Saint Vincent and the Grenadines is a small volcanic country, 389 km^2, located between the Caribbean Sea and the Atlantic Ocean. This tropical country is known for its mountainous terrain. Agriculture, tourism and construction are the main economic activities. The main export crops are banana, plantain and root crops such as eddoes, dasheen, sweet potatoes and arrowroot which are exported mainly to the regional markets. Approximately 26% of the land is used for agriculture which employs 26% of the labor force. Soil testing capabilities were limited due to the absence of a soil fertility lab and the high cost of sending samples abroad. A soil laboratory was established in 2015 to provide soil analytical services to farmers and other stakeholders. During the period from May 2016 to November 2017, three hundred and forty soil samples were collected from farmlands at a depth of 15cm and analyzed for pH, organic matter (OM), electrical conductivity (EC), texture, available nitrogen (NO_3^-, NH_4^+), phosphorus (P), potassium (K) and calcium (Ca). Seventy-one (71%) of samples ranged between 5.5 to 6.5 pH was considered ideal for most crops. The OM content in 51% of the samples was higher than 4%. High OM would help to keep nutrition from leaching and help to retain moisture. However, the stable organic matter would retard mineralization or nitrogen release that reflects on results for EC and nitrogen. EC values were low with 90% below 100 μScm^{-1}.This can be related to the soil texture or indication of low nutrient holding capacity. Sixty-five (65 %) of soil samples were sandy loam which indicates well drained and low water and nutrient holding ability. Sixty percent (60%) of samples had a Nitrogen content less than 25 $mgkg^{-1}$. Fifty-nine percent (59%) of the available P content was less than 17 $mgkg^{-1}$ which are considered insufficient for most of the crops, however, some noticeably high values (9%), higher than 34$mgkg^{-1}$, were observed in the northeastern area of the island. Potassium content in 75% of samples was higher than 125 $mgkg^{-1}$ which are considered sufficient for most crops. Sixty-five percent (65%) of the calcium content showed medium range values from 800 to 3000 $mgkg^{-1}$.

(1943 - 2037) Soil organic matter and productivity of boreal clay soils

Helena Soinne[1]; Riikka Keskinen[2]; Mari Räty[2]; Sanna Kanerva[1]; Visa Nuutinen[2]; Eila Turtola[2]; Tapio Salo[2]
University of Helsinki[1]; Natural Resources Institute Finland[2]

Soil organic matter plays a key role in soil functions by maintaining biological activity, increasing water holding capacity and enhancing the stabile structure formation. Further, increasing the soil organic carbon content is promoted as a mean to reduce the concentration of atmospheric carbon dioxide and to slow down the climate change. In this study we aimed to find out whether increasing the soil organic carbon content has measurable beneficial effects on clay soil (clay% >30) productivity in boreal conditions. Soil samples were collected in the autumn 2016 and each field was divided into two plots: unfertilized plot and plot receiving N fertilization. From each plot, yield and soil samples were collected from four sampling points. Soil samples were analyzed for texture, organic carbon (C%), bulk density. Four fields were further sampled for an incubation experiment to study the net nitrogen mineralization and respiration and for water extractable dissolved organic carbon (DOC) and water extractable nitrogen (N). According to preliminary results, there was no clear relation between surface soil C% and yield. The bulk density was lower in soils with higher C% and the lowest yields were collected from plots with high bulk density. Net nitrogen mineralization and respiration correlated negatively with water extractable DOC/N -ratio. Preliminary results suggest that for unfertilized clay soils, low clay/C -ratio predicts higher yields. Further, the water extractable DOC/N -ratio appeared to correlate negatively with the yield.

(4595 - 265) Soil quality indicators in crop sequences with a high proportion of soybean: effects of cover crops inclusion and fertilization.

Fontana, Marianela[1]; Novelli, Leonardo[1]; Sterren, María[1]; Uhrich, Walter[1]; Barbagelata, Pedro[1]; Benintende, Silvia[1]
FCA - UNER[1]

The aim of this study was to evaluate the effect on soil properties, of cover crops and fertilization in sequences with a high proportion of soybean. The research was conducted on a long-term field trial in an Aquic Argiudoll. We studied: soybean monoculture (S), soybean monoculture fertilized with P and S (Sf), cover crop/soybean (CC/S), cover crop/ soybean fertilized with P and S (CC/Sf), cover crop fertilized with N/soybean fertilized with P and S (CCN/Sf), and cover crop/soybean in a crop rotation with maize (CCN/Sf rot). Samples were taken from 0-5 cm and 0-15 cm. Evaluated variables were: Microbial Biomass C and N (MBC and MBN) and N from anaerobic incubation (Nan), soil organic matter (SOC), total N (TN) and particulate organic matter (POM) C and N. The cumulative mass approach was used to estimate variables stocks based on measured bulk density and concentration of variables. ANOVA for DBCA was performed and treatments were compared using an LSD test. We applied a discriminant analysis to evaluate the separation among groups of treatments. In both layers SOC differed among treatments showing the highest values in the CCN/Sf. In the 0-5 layer, from highest to lowest, the treatments order was CCN/Sf, CCN/Sfrot, CC/Sf, CC/S, S and Sf. Total N (TN), also differed among treatments and ordered treatments similar to SOC in the 0-5 cm layer. Particulate organic matter C (POM-C) and N (POM-N) differed among treatments. For POM-C and POM-N, crop sequences were separated similarly in 0-5 cm. Treatments CCN/Sfrot and CCN/Sf had the highest values, showing statistical differences with CC/S, S and Sf. Microbial biomass C and N did not show differences among crop sequences. The lowest value of Nan in the 0-5 cm layer was found in S. We performed a discriminant analysis in the two soil depths separately. In 0-5 cm, apparent error rate of classification was 25.0 %. Treatments without cover crops (S and Sf) were clustered in the right side of the plot, and there were no samples that belonged to these two treatments classified in the groups of the treatments that include CC (CCN/Sf, CCN/Sf rot, CC/Sf and CC/S). In the other side, only 2 samples (of a total of 24) that belonged to CCN/Sf rot and CC/S were classified in the Sf treatment. The cross-classification table emphasizes that the inclusion of cover crops, especially with fertilization treatment, had a significant effect on soil variables reflecting improvement of soil quality of this management practice.

(6218 - 988) Sol Organic matter in a Integrated Crop-Livestock Integrated System in different grazing intensities in a subtropical Oxisol

Gabriel Furtado Garcia[1]; Deborah Pinheiro Dick[1]; Ibanor Anghinoni[1]; Paulo César de Faccio Carvalho[1]
Universidade Federal do Rio Grande do Sul[1]

Soil management systems usually provide an adequate environment for the development and availability of nutrients for the roots and for the microorganisms along the profile, which is essential for soil organic matter (SOM) maintenance and for a sustainable production system. The objective of this work was to investigate the influence of grazing intensity on the SOM composition and carbon (C) stocks in a Brazilian subtropical soil profile under Integrated Crop Livestock System (ICLS) after 15 years. The experiment was conducted in a oxisol, in randomized blocks with three replications, employing different grazing intensities, evaluated from the pasture height left after grazing: 10 cm (P10), 20 cm (P20) and 40 cm (P40) cm). Soil samples were collected in different layers within 100 cm soil depth from grazing treatments and from in a forest area (reference), as well as litter. C and nitrogen (N) contents were determined by dry combustion and the isotopic signature $d^{13}C$ was analyzed by dry combustion in a mass spectrometer coupled to an elemental analyzer. Soil density was calculated by the volumetric ring method and the carbon stock by apparent density in each soil layer in the soil profile. The highest accumulated C stock up to 100 cm was observed under P40 treatment and the lowest was verified in the forest area. In contrast, the highest stock in the 0-5 cm layer was observed in the forest in comparison to grazing treatments. Probably, this result is related to the greater accumulation of C from the forest, due to its slower cycling in comparison to the residue from the grazed area. Soil density down to 0-10 cm layer was higher in P10 and P20 treatments compared to the P40 and forest, but in deeper layers higher densities were observed in P40. This effect may be related to a lower root production due to the increase in forage availability for the animals. In relation to C and N contents, a decrease with depth occurred, as expected. Contribution of the new plant material introduced by ICLS to the SOM composition was identified only at the 0-5 cm layer, as indicated by $d^{13}C$ values. Our results showed that in a heavy clayey Oxisol under ICLS, SOM cycling occurred only at 0-5 cm depth regardless the grazing intensity. Soil C stocks tended to increase with the decrease of grazing intensity.

(9198 - 756) Spatial distribution of soil chemical properties as affected by dairy effluent application system

Omar Casanova[1]; Amabelia del Pino[2]; Virginia Takata[3]; Andrei Assanelli[3]; Ana Bianco[4]; Soledad Gutiérrez[5]
Facultad de Agronomía, Universidad de la República, Garzón 780 Montevideo, Uruguay[1]; Facultad de Agronomía, Universidad de la República, Garzón 780, Montevideo, Uruguay[2]; Facultad de Agronomía, Garzón 780, Montevideo, Uruguay[3]; Instituto Nacional de la Leche, 19 de Abril 3482, Montevideo, Uruguay[4]; Facultad de Ingeniería, Universidad de la República, Herrera y Reissig 565, Montevideo, Uruguay[5]

soil application of dairy effluents has been widely used in Uruguay, recently has gained importance, due to environmental concerns. The risk of water pollution by nutrients and organic matter (OM) led to the prohibition of effluent discharge to water courses and the recommendation to reuse and recycle. At the moment coexist in the country many systems of manure and effluent management, which are intended to adapt to the characteristics of the different farms. Our aims were: 1) To characterize the effects of different effluent management/irrigation systems on soil properties (pH, OM content, available P and exchangeable cations). 2) To assess the spatial distribution of soil properties. 3) To use the generated information to make guidelines for effluent application. Five farms were selected to encompass different management systems: 1) Irrigation with fresh effluents through tubes and spreader, 2) gravity flow of effluents from an anaerobic pond through a fixed irrigation line, 3) and 4) Distribution of anaerobic pond slurry with tanker. 5) Spreading with liquid effluent from a solid screw press separator. The paddocks that had been under grain and fodder crops received effluents for at least 4 years. The soil was sampled alongside 5 divergent transects, separated by 30º angles. The starting point of transects was the closest to the effluent generation, and composite soil samples were taken every 20 m (25 samples per paddock). All the paddocks showed effects of effluent application in one or more of the evaluated soil properties. Regarding available P, except for one case, average values were above critical levels for crops and pastures, making it unnecessary to add P fertilizer

to effluents. A high spatial variability was observed in all parameters, with the lowest variation in pH (Variation coefficient (VC): 4 to 8 %), and the highest for available P (VC: 26 to 47 %). The study of the spatial distribution of different soil properties showed significant effects of distance, indicating a higher accumulation of nutrients, especially P, in the vicinity of the effluent generation or storage facilities. It was concluded that the sampling methodology allows to successfully assess the high spatial variability generated by effluent application. Moreover it is possible to separate areas affected by elevated nutrient levels, specially P, in which it will be advisable to discontinue effluent applications, from those which admit further additions.

(6825 - 1427) Spatial heterogeneity of tillage increases the resilience of the PLFA profile, but not the size, of the microbial community

Iain Dummett[1]; Professor Jane Rickson[1]; Dr Lynda Deeks[1]
Cranfield University[1]

Reducing tillage intensity results in an increased reliance on the functioning of soil biological communities to generate the soil conditions necessary to support crop yields. There is, therefore, a need to identify soil management practices which can limit the harm to, and maximise the resilience of, soil microbial communities whilst maintaing crop yields. Plant and animal ecology provides examples of undisturbed areas of habitat increasing the rate of recovery of proximate areas of disturbed habitat following ecological disturbance events such as forest fires. This concept was tested in the context of soil microbial ecology and tillage. Undisturbed soil samples measuring 40 cm x 20 cm were taken to a depth of 10 cm and subjected to a) no tillage, b) simulated tillage (achieved by passing soil through a 5mm sieve) and c) simulated strip tillage where half the soil was not tilled and the other half was subjected to the simulated tillage treatment. Samples were stored in a polytunnel, and microbial biomass carbon and PLFA profiles were measured over a 99-day period. Compared to the soil of the samples which were all subject to simulated tillage, the undisturbed soil of the simulated strip tillage treatment showed increased resilience of the structure, but not the size, of the microbial community. Thus this study suggests that the spatial heterogeneity of tillage can increse the resilience of the structure of soil microbial communities.

(4042 - 1512) Spatial variability of fertility and productivity in a fertigated açaí area in State of Pará

Graziele Rabelo Rodrigues[1]; Felipe Oliveira Ribeiro[1]; Jeane Oliveira da Silva[1]; Antonio Anizio Leal Macedo Neto[1]; Gilson Sergio Bastos de Matos[1]; Lincoln Stephano Lima Costa[1]
Universidade Federal Rural da Amazônia[1]

The açaí tree (Euterpe oleracea Mart.) Is a palm tree very demanding in K and Ca for the production of bunches and fruits. The objective of this study was to evaluate the spatial variability of productivity and the exchangeable contents of K, Ca and Mg in the soil in a fertigated açaí area. The study was conducted on a farm in the city of Tomé-Açu, PA, with a sample area of 5.75 ha and density of 400 tussocks/ha planted in a yellow latosol. In the seventh year of planting, a sampling grid, with 80 georeferenced points, was made, at each point a group of five plants was considered as a reference for soil collection and productivity. Spatial variability was performed using the geostatistical tool. The K and Ca contents showed a coefficient of variation above 20%, considered high, indicating low precision sampling, as for productivity and Mg the CV was 30%, a value classified as very high, which also indicates a low precision. Mg had 56.2% of samples in medium status, followed by K with 93.7% and Ca with 95% in good soil status. The good availability of exchangeable bases in the soil, which naturally has low fertility, may be related to the adequate management of the fertigated fertilization in this area. Productivity was on average 5 t / ha, considered low for a 7-year crop, which has an average of 8 t / ha. The semivariogram models found were spherical for Ca, exponential for K and Mg and Gaussian for productivity. There was spatial dependence for the three nutrients and for the productivity variable. The values of spatial dependence varied between 0.5 and 0.9, being classified as medium for K and high for productivity and for other nutrients. The range was 138.9m for K, 60m for Mg, 48.4m for Ca and 44m for productivity. Most of calcium and potassium samples showed high fertility, whereas magnesium had most of its samples with medium fertility. It was possible to determine the spatial variability of nutrients through geostatistics, there was spatial dependence for all variables and potassium was the nutrient that presented the greatest range.

(4364 - 1382) Spatial variability of teak leaf nutrition on a farm in the State of Pará

Jeane Oliveira da Silva[1]; Graziele Rabelo Rodrigues[1]; Antonio Anizio Leal Macedo Neto[1]; Gilson Sergio Bastos de Matos[1]; Rodolfo Daniel Vieira de Assunção[1]
Universidade Federal Rural da Amazônia[1]

Teak is a tree species with wood of great commercial importance. One of the determining factors in the production of wood is related to the good nutrition of the plant, which combined with precision agriculture can increase the productivity of the species. The objective was to perform the nutritional diagnosis and to evaluate the spatial variability of the N, P and K foliar contents in a commercial teak cultivation. The study was carried out on a farm in the City of Capitão Poço, State of Pará, Brazil, on a 52 ha area. A total of 155 georeferenced points were collected to determine the spatial variability of leaf nutrients, each point was composed of three trees to form a composite sample. About the 155 foliar samples, 51% presented deficient status for phosphorus, 82% for nitrogen, and 100% for potassium. A large number of deficient samples, especially in K, may be associated with reduced fertilization of this nutrient in the area. In addition, K is one of the most demanded nutrients by forest species and is directly related to the reduction of trunk size. In relation to the DBH, this presented an average of 0.24 cm, a value considered low for the farm's own reference parameters and also for the literature. The models of semivariograms found were exponential for nitrogen, Gaussian for phosphorus and spherical for potassium and DBH. There was spatial dependence for the three nutrients and for the DBH, which presented values ranging from 0.35 to 0.79, and all four variables presented moderate spatial dependence. Regarding the four variables studied, three presented a coefficient of variation below 20% (N, K and DBH), which shows that their sampling was of high precision, the phosphorus presented a coefficient of 29%, presenting a medium precision. The range values were 120 m for nitrogen, 180 m for phosphorus, 200 m for potassium and 125 m for DBH. It was possible to generate maps of spatial variability for the three nutrients. In all of them, potassium showed the highest frequency of deficiency. Potassium was the variable that presented the greatest range and the variations in N, P and K and DBH levels are well explained by spatial variability.

(9647 - 1780) Spatial-temporal variability of available phosphorus in integrated crop-livestock systems in lowlands

Mateus Westerhofer Goulart[1]; Luiz Gustavo de Oliveira Denardin[1]; Filipe Selau Carlos[1]; Paulo César de Fáccio Carvalho[1]; Ibanor

Anghinoni[1]

Universidade Federal do Rio Grande do Sul[1]

The irrigated rice is one of the systems that more cause modifications in the natural cycles. Besides that, with the introduction of different managements and the presence of animals, characterizing an integrated crop-livestock system (ICLS), providing greater complexity to the system, the study of spatial-temporal variability become fundamental for understand better the soil fertility and provide the use of betters practices of managements for the farming. Thus, the objective of this study was evaluate the spatial-temporal variability of available phosphorus (P) in a lowland soil (Albaqualf) from 2013 to 2015, submitted to different arrangements of ICLS in comparison to the traditional system (TS) of irrigated rice cultivation, with ploughing and heavy disking. The study was conducted in a long-term ICLS trial at the Corticeiras Farm, located in Cristal County, Rio Grande do Sul State, Brazil. The treatments consisted of five production systems: (S1): rice monocropping with fallow in winter; (S2): rice/annual ryegrass (AR); (S3): rice/AR/soybean/AR; (S4): AR + white clover (WC)/sudan grass/AR + WC/soybean/AR + WC/corn/AR + WC/rice and (S5): AR + WC + birdsfoot trefoil/ succession field (native pasture species). The results indicated non-constant coefficient of variation (CV) differences among treatments over time, with increase in S2 and S3 only, of 4% and 36%, respectively. However, in S1, S4 and S5 there was decrease in CV of 15%, 59% and 32%, respectively. In relation to the temporal variation, all the treatments presented increases in available P content, but in different proportions. While the TS showed an increase of only 74%, all other ICLS showed increases of 162, 349, 142 and 200% in T2, T3, T4 and T5, respectively. Based on the results, it was concluded that the adoption of conservation management practices in lowlands, such as no-tillage, combined with ICLS promote increases in soil available P in comparison to the TS. In addition, the adoption of ICLS from insertion of the animal don't significantly increase the spatial variability of P content in the soil.

(4760 - 737) Study on multi-scale simulation and scale effect of organic carbon in regional soil using a combination of variogram, spatial autocorrelation and multi-fractal methods

Zhang Shiwen[1]; Huang Yuanfang[2]

Anhui University of Science and Technology[1]; China Agricultural University[2]

Under the background of global environmental change, carbon storage estimation has become one of the hottest topics in soil carbon sequestration, and soil carbon pool is the largest carbon pool of terrestrial ecosystems. The spatial variability of soil organic carbon (soil organic carbon, SOC) is one of the reasons for the uncertainty in the estimation of carbon reserves. The spatial distribution characteristics on multidimensional scale, is of great significance for revealing soil nutrients, pollutant transport, precision management of farmland and achieving sustainable development of agriculture. Combined with the current research progress and shortcomings on spatial distribution characteristics and scale effects of soil properties, using a combination of variogram theory, spatial autocorrelation theory, multi-fractal theory and other methods from the aspects of the spatial variability of soil properties and the structure, the paper gradually revealed the spatial distribution characteristics of SOC (soil organic carbon) and its scale effects under 4 kinds of scales. The results show that: Ratio of nugget to sill of SOC under 15, 25, 35 and 45 km scales were 61.78%, 42.65%, 49.98% and 39.34%, respectively, which showed a moderate spatial correlation. The spatial correlation from high to low was 45, 25, 35 and 15 km in turn. Except the 15km scale, the spatial variability caused by random factors including representative measurement error and the micro-scale process, was less than the structure variance, namely the ratio of nugget to sill was less than 50%, the structural factors were dominant, and spatial variability from the random part showed a decreasing trend with the scale increasing.The variation function couldn't be described with discrete characteristics (i.e. spatial negative correlation), which was also impossible to make a significant test for variable range. As the separation distance increased, the Moran index decreased from full positive to negative, then the positive and negative values alternately occurred, and eventually the values turned out to be negative totally.Nearer positive correlation distance represents the spatial correlation distance, which is the first cross point of positive and negative conversion under different scales, and were 1 607, 7 520, 8 649 and 9 053 m for 15, 25, 35, and 45 km scale.

(8623 - 1743) Sugarcane growth and yield as a function of deep soil tillage and liming rates in a clay soil

Gabriela Ferraz de Siqueira[1]; Jorge Martinelli Martello[1]; Daniele Scudeletti[1]; Murilo de Campos[1]; Ariani Garcia[1]; Ciro Pozzi Garcia[1]; Juliano Carlos Calonego[1]; Carlos Alexandre Costa Crusciol[1]

School of Agricultural Sciences, Sao Paulo State University[1]

The intense mechanization in the sugarcane production system, in which the soil is revolved each 5 years an average, lead to strong compression and consequently reducing productivity and longevity due to the impediment of root growth. Besides that, the liming recommendation on sugarcane for Sao Paulo State is been considered underestimated what could be limiting the sugarcane yield causing productivities under the potential for the crop. The soil tillage system associated with a correct lime rate may be the mainly factors for high yields, therefore, the aim of this study was to evaluate the effect of deep soil tillage compared with conventional tillage and liming rates in the sugarcane growth and yield. The experiment was installed in 2015 in an oxisoil soil at Macatuba, SP, Brazil. The experimental design was a randomized block with split-plot design with four replications, where the plots consisted of three systems of soil tillage: conventional soil preparation (CSP); deep soil tillage (DST) with lime application in surface total area; and modified deep soil tillage (MDST) with lime application in the surface planting strip, with ¼ of the dose in deph; and the subplots consisted of liming rates: 0, 1, 2 and 3 times the recommended dose (RD) for sugarcane production in São Paulo State, based on soil samples of 0.0-0.20 and 0.20-0.40 m). For the deep tillage treatments all the machines were equipped with GPS equipment in order to control the traffic and it was possible to define a plant growth zone and a traffic zone. The treatments DST and MDST provided higher stalk length compared with CSP in the dose 3 x RD. For all tillage systems the dose 2 x RD provided plants with higher stalk length. Regards the diameter, the dose 2 x RD also provided higher values for all tillage systems. In relation to the stalk and sugar yield the results for CSP and DST systems were fitted in quadratic functions, increasing from dose 0 until 2 x RD, but decreased in 3 x RD, but for MDST the results were fitted in linear function, increasing from dose 0 until 3 x RD.

(3019 - 462) Sugarcane roots growth as function of deep soil tillage and liming

Juliano Carlos Calonego[1]; Ciro Pozzi Garcia[1]; Carlos Alexandre Costa Crusciol[1]; Gabriela Ferraz de Siqueira[1]; Tiara Moraes Guimarães[1]; Erilene Romeiro[1]

São Paulo State University, College of Agricultural Sciences[1]

Soil compaction has been a recurrent problem for sugarcane yield increases due to several factors, including the impediment to root growth. Another factor that influences the root growth of sugarcane is the supply of calcium and the soil acid alleviation. The aim of this experiment was to evaluate the root growth of sugarcane as a function of the soil tillage system and the presence or not of liming with machinery traffic controlled. The experiment was installed in 2015 in a sandy soil at Borebi, SP, Brazil, with pH 4.5 and base saturation of 42% in the 0-0.2 m layer. The experimental design was a randomized complete block with four replications, where the plots consisted of three systems of soil tillage: conventional soil preparation (CSP) – standard / control; deep soil tillage (DST); and modified deep soil tillage (MDST). The subplots were established by the presence and absence of limestone. The CSP system was characterized by the tillage with disk harrow, chiseling and disk harrow again, with application of limestone in total area before the first operation of the soil tillage. In the DST was used deep tillage with rod up to 0.80 m and rotating hoe, with application of limestone in total area. The MDST was differentiated from DST by the application of limestone only in the tillage range. After three months of liming the sugarcane was planted with a double spacing (0.90 m x 1.50 m). All the machines were equipped with GPS equipment in order to control the traffic and it was possible to define a plant growth zone and a traffic zone. Sugarcane roots samples were collected soon after the plants harvest at depths of 0-0.20, 0.20-0.40, 0.40-0.60, 0.60-0.80 and 0.80-1.00 m in the middle of the plant growth zone and the traffic zone. The liming increased the roots dry matter at 0.80-1.00 m layer in the traffic zone with DST and MDST. In plant growth zone, the absence of liming increased the amount of roots in the 0-0.2 m layer with the CSP, and in the layer of 0.80-1.00 m in the DST and MDST treatments.

(8437 - 3025) Sugarcane straw decomposition as a function of quality and quantity of green tops and dry leaves associated with climate conditions

Lauren M. S. Menandro[1]; João L. N. Carvalho[2]; Heitor Cantarella[3]; Clovis D. Borges[2]; André C. Vitti[4]; Henrique C. J. Franco[2]

UNICAMP / CTBE-CNPEM[1]; CTBE-CNPEM[2]; IAC[3]; APTA[4]

Sugarcane straw decomposition can be influenced by several factors, including the quality and quantity of green tops (Gt) and dry leaves (DL) and climatic conditions. Our goal was to evaluate how the relation between these factors influence the decomposition. An experiment was conducted across two years (2014-2016) in sandy soil located in Agudos- SP, Brazil. The treatments were: Gt (4 Mg ha^{-1}), Gt+25%DL (6 Mg ha^{-1}), Gt+50%DL (8 Mg ha^{-1}), Gt+DL (12 Mg ha^{-1}) and DL (8 Mg ha^{-1}). In both years, litter bags were installed and collected about 90, 180, 270 and 360 days after they are installed. In the 1st year, the greater the increase of DL to Gt, the greater is the rate and constant (*k*) of decomposition and shorter is half-life time ($T_{1/2}$) (51, 55, 57 and 65%, 0.0019, 0.0022, 0.0023 and 0.0029 days-1, 352, 311, 293, 235 days, for Gt, Gt+25%DL, Gt+50%DL, Gt+DL, respectively). With the Redundancy Analysis (RDA), we verified that this occurred due to the relation between the amount of bulk straw and the water deficit (-175 mm vs -32 mm in the 2nd year) in the first three months of crop growth (ie., crop canopy not closed and major influence of treatments). With water restriction, the presence of larger amounts of straw may have favored the decomposing organisms, increasing decomposition. In the 2nd year, the highest rainfall (510 mm) and temperature (23.1 ºC) in the first three months (1st year - 226 mm and 21.4 ºC) were responsible for reversing the process, with rates and *k* lower and higher $T_{1/2}$ in treatments with lower DL (87, 85, 83 and 74%, 0.0055, 0.0049, 0.0044, 0.0035 $days^{-1}$, 126, 141, 157 and 196 days, for respective treatments). Without climatic restrictions, treatments with a higher proportion of Gt were more easily decomposed. This is because the quality of Gt and DL also determines the decomposition, which was evidenced by DL treatment. Regardless of year, DL had lower rates and k and higher $T_{1/2}$ (38%, 0.0013 $days^{-1}$ and 533 days, 66%, 0.0029 $days^{-1}$, and 237 days, for 1st and 2nd year, respectively). This is associated to the higher lignin, cellulose and hemicellulose contents and higher C/N ratio in DL than in Gt. We conclude that the relation between quality, quantity and climatic conditions interferes in the decomposition and Gt are more easily decomposed than DL. The differences between these are plausible for recommendations of straw management, in which, for example, Gt are more indicated to nutrients recycling while DL is better for soil cover.

(1745 - 3044) The impact of quality and proportions of composting organic materials on the solubilisation of Kodjari phosphate rock in semi-arid West Africa

Elisee Ouedraogo[1]; Ousmane Badogo[2]; Leo Stroosnijder[3]

World bank/CEAS-Burkina[1]; Ministry of Agriculture[2]; Wageningen University[3]

A study was conducted at Gomtoaga (Burkina Faso) in the Albert Schweitzer Center for Ecology Research Center to assess the possible effect of Kodjari phosphate rock (PR), composting organic resource quality and proportions on compost carbon dynamics, N and P recovery and the solubilisation of Kodjari PR. The design was a split plot with three replicates. PR and no-PR were the main treatments. The sub-treatments consisted of 75 % *Andropogon spp.* straw + 25 % cattle dung (T1), 25 % *Andropogon spp.* straw + 75 % cattle dung (T2) and 50 % *Andropogon spp.* straw + 50 % cattle dung (T3). PR affected significantly N recovery only in T1 with 41 % in PR treatments vs. 53 % in no-PR treatments. Total P recovery is affected significantly by PR in all treatments, the highest recovery being observed with 47 % in T3 followed by T1 (33 %) and T2 (24 %). PR enhanced compost carbon loss when increasing the *Andropogon spp.* straw proportion up to 75 % (T1). The highest and significant difference in available P (33 mg kg^{-1}) was also observed in T1. It was concluded that the enhanced decomposition of composting organic materials and PR solubilisation is more efficient under P-limiting conditions. Although further composting time may be necessary, T1 responded well to PR on decomposition, N recovery and PR solubilisation. Farmers can save at least two months composting time and labour with added benefit in compost quality. Thus, improving composting techniques in West Africa requires integration of PR into the composting system, adoption of adequate proportions of organic materials during the composting process and suitable composting pits which prevent leaching and good composting management to control water supply.

(1101 - 492) The soil potassium contents and form transformation under long-term fertilization in red soil

Huimin ZHANG[1]; Tianfu HAN[1]; Kailou LIU[2]

Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences[1]; Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences/Jiangxi Institute of Red Soil, Jinxian, Jiangxi[2]

The soil potassium contents and form transformation under long-term fertilization in red soil

Huimin ZHANG[1], Tianfu HAN[1], Kailou LIU[1,2]

[1] Institute of Agricultural Resources and Regional Planning, Chinese Academy of Agricultural Sciences, Beijing 100081, China; [2] Jiangxi Institute of Red Soil, Jinxian, Jiangxi 331717, China.

Potassium (K) and lime application are necessary for attaining high crop yield in the red soil region. However, little is known about the soil K form transformation in organo-mineral complexes (OMCs) and rhizosphere soil (RS) after application of K fertilizer and lime. A long-term (since 1990) field experiment of wheat-maize rotations and a pot experiment of different soil pH were conducted to investigate soil potassium (K) contents and form transformation in OMCs and rhizosphere soil (RS) under lime and K application. Treatments selected were unfertilized (CK), nitrogen and phosphorus fertilizers (NP), NPK, NPK plus half of straw (NPKS), NPK plus pig manure (NPKM). After the soil sampled, lime treatments (NP, NP plus lime (NPCa), NPK, NPKCa, NPKS, and NPKSCa) were carried out.RS and bulk soil (BS) samples were collected at four stages of maize in 2014. The results showed that more K released from mica and/or 1.4 nm transition mineral in treatments without K (CK and NP) as compared to NPK, NPKS and NPKM. The exchangeable K (EK) and non-exchangeable K (NEK) contents of soil OMCs were increased only in K treatments.The accumulation of NEK of soil OMCs (released in 300 hours) followed as: (<2 μm) > (2~10 μm) > (10~50 μm and >100 μm) > 50~100 μm and of treatments followed as: NPKM > NPK > CK > NP. As compared to NPK and NPKS, the EK, NEK and KS (K saturation) of RS significantly increased in NPKCa and NPKSCa, respectively. Similarly, the K surplus and deficit rate in RS was higher in lime treatments due to lower EX- (Ca^{2+}+Mg^{2+}) in RS than BS. The highest K availability was at pH 5.5-6.5. So, NPKM was best treatment to increase the K supply in red soils. Further research on K depletion and balance is required. (3899 - 1083) Total and dissolved organic carbon in deep soil profiles following pasture conversion, New South Wales, Australia.

Rubeca Fancy[1]; Brian R Wilson[2]; Heiko Daniel[3]; Yui Osanai[3]

University of New England, Armidale NSW 2351, Australia (rfancy@myune.edu.au)[1]; University of New England, Armidale NSW 2351, Australia; NSW Office of Environment and Heritage, Armidale NSW 2351, Australia[2]; University of New England, Armidale NSW 2351, Australia[3]

Globally, research attention is currently focused on the storage and cycling of organic carbon (OC) in soils, due to its importance in the global carbon cycle. Land-use change has significant impact on soil OC storage worldwide. In Australia and internationally, land-use change from cropland to pasture is a practice that is known to increase the amount of OC in the carbon depleted cultivated soils. Although the effect of land-use change on OC cycling in soils has been widely investigated, studies have typically focused on carbon dynamics in topsoils (0-30 cm). We investigated the quantity and depth distribution of total organic carbon (TOC) and the significance of dissolved organic carbon (DOC) to 1.0 m in the soil profile where land-use change occurred from C_3 (crop) to C_4 (pasture) vegetation. Here we discuss the depth distribution of TOC and DOC down the soil profile and the relative importance of DOC to soil OC transport and change in the soil profile. Using $\delta^{13}C$ of TOC and DOC we examine the source and quantity of "new" carbon in the soil system and the significance of C_4 vegetation for additional carbon storage in these Australian soils.

Keywords: Soil organic carbon; land-use change; Australian soils.

(6926 - 2425) Total organic carbon as an indicator of the impact of soil management in mountain agriculture in the region of Nova Friburgo, RJ

João Victor Almeida Arantes[1]; Pedro Araújo Garcia[1]; Isabela Beatriz Pereira da Cruz[1]; Luiz Alberto da Silva Rodrigues Pinto[1]; Nivaldo Schultz[1]

UFRRJ - Federal Rural University of Rio de Janeiro[1]

Vegetable farming with soil revolving towards the slope of the ground is common in the mountainous region in Rio de Janeiro, causing the chemical, physical and biological soil degradation because it promotes water erosion. The analysis of the total organic carbon (TOC) in soil can be an indicator of the impact of soil use in this system. The purpose of this work was to evaluate the TOC contents of a Cambisol under different management systems. Four areas were selected on a hillside with slope varying between 20% and 40%. The areas are under the following management systems: 1. Conventional system with alternation of different vegetables for more than 30 years, with at least one action of soil revolving per year - CS; 2. Well managed pasture for 28 years – WMP; 3. Vegetable farming in a conservation system (cultivated in a conventional system for more than 30 years, but since 2012 the soil has been revolved, prepared for the vegetable farming and seeded with black oats (Avena strigosa) to form the soil cover in winter , for the vegetable farming in winter / summer) – CMS; and 4. Forest regeneration process for more than 30 years – RF. Within each area were selected four subareas of 9 m2 (3x3m), in which 8 single samples were collected to form a composite sample per layer. The layers were 0.0-0.10, 0.10-0.20 and 0.20-0.40 m depth. In these samples, the soil TOC contents were determined. Data were compared statistically through analysis of variance and the means compared by t-test (LSD) at 10% significance. At the depth of 0.0-0.10 m the TOC was 21.17, 28.85, 70.85 and 74.63 g kg-1 for CS, CMS, WMP and RF, respectively, differing from each other, except for WMP and RF that did not differ from each other. In the layer of 0.10-0.20m the TOC was 23.62, 26.74, 42.36 and 57.29 g kg-1 to CS, CMS, WMP and RF, respectively, with no difference between CS and CMS, but these were inferior to WMP and RF, being RF superior to WMP. In the 0.20-0.40 m layer the TOC contents were 15.05, 21.13, 31.96 and 38.12 g kg -1 for CS, CMS, WMP and RF, respectively, with no difference between CS and CMS, as well as between WMP and RF, but the latter two were superior to CS and CMS. Based on the TOC of the soil under forest, the results show that the conventional management system has significantly reduced the TOC content of the soil and that the conservation system is enabling the recovery of TOC over time.

(6912 - 1396) Use of biofertilizer associated to nitrogen-fixing bacteria on yield and yield components of soybean crop

Jaqueline Gaio Spricigo[1]; Alvaro Fernando Portes[2]; Mateus Bedin[2]; Gabriela Naibo[1]; Carlos Alberto Casali[3]; Everton Skoronski[4]; Mauricio Vicente Alves[1]

University of West of Santa Catarina[1]; Federal Technological University of Paraná[2]; Professor, Federal Technological University of Paraná[3]; Professor, State University of Santa Catarina[4]

In order to increase the efficiency of biological nitrogen fixation in soybeans with a prospect in enhancing yield levels, an alternative is the use of biofertilizers, where it offers the maximum amount of viable cells for colonization of the plant's rhizosphere. This study aimed to evaluate the symbiotic efficiency between the inoculant (*Rhizobium*) and a liquid biofertilizer, on the components of soybean yield and yield. The experiment was carried out at Renascença - PR, in the 2015/2016 crop with no-tillage system sowing. The soil was classified as Red Latosol/Oxisoil. The experimental design was a randomized block design with four treatments and four replications, with the following treatments: Control, Seed inoculation, Seed furrow directed inoculation and Microgeo® furrow directed inoculation. The nodule number per plant (NN), root dry matter (RDM), shoot dry matter (SDM), number of pods per plant (PP), weight of a thousand grains (WTG), yield and foliar nutrients were evaluated in this study. The data were submitted to analysis of the variance and when significant to the means were evaluated by the Tukey test through Assistat program. The use of biofertilizer and inoculant in different forms in the crop did not obtain significant results, in both the yield and yield components; for NN, RDM and SDM the highest values were 40.3; 9.04 and 58.86 respectively in treatment with furrow inoculation via biofertilizer. Foliar nutrients did not differ between treatments, and nitrogen contents were above the range considered ideal, between 45.1 and 55.0 g kg^{-1}. However for the phosphorus, the contents remained within the sufficiency range of 2.6 to 5.0 g kg^{-1}. Regarding the potassium, the values were less than desirable, being indicated between 17.1 and 25.0 g kg^{-1}. No differences were found between the treatments, possibly due to all soybean cultivations, inoculation, as well as good physical, chemical and biological conditions of the soil, together with the crop rotation with winter cover crops and the use of the product in the first agricultural year.

Keywords: Inoculant; biological fertilization; furrow inoculation

(4883 - 3052) Use of steel slag as a liming material on soil pH and microbial population in an acidic soil of the central Andes of Peru

Raquel Zea[1]; Sady Garcia[1]; Dixie Chuquimia[1]; Silvia Aguero-Aguilar[1]; Rosa Meneses Florian[1]
Universidad Nacional Agraria La Molina[1]

Steel slag is a solid waste from steel production. The disposal of slags is becoming a serious problem in Peru. The application of steel slag can be of interest as an amendment for acidic soils, although limited information is available concerning the effect of soil microbial population. A pot experiment was conducted to determine the effect of using steel slag (46% calcium carbonate equivalent) as a liming material on chemical and biological properties of an acidic (pH = 5.05, 1.0 $cmol_c$ kg^{-1} exchangeable acidity), loamy soil from Sincos (Central Andes of Peru). Steel slag was applied at doses to neutralize 25%, 50%, 100% and 200% of exchangeable acidity), and a non-amended treatment was included as a control. Soil was placed in 4 kg plastic pots and incubated at field capacity during 220 days. Barley var. Centenario was planted 30 days after amendment and received two doses on N fertilization (100 and 200 mg kg^{-1}). A complete randomized design with 2x5 factorial arrangement and five replicates, was used. Soil pH, soil respiration rate (alkali absorption), and total bacterial, actinobacterial and fungal populations (CFU g^{-1}) were evaluated after incubation. Soil pH increased gradually with the dose of amendment. Doses of 100% and 200% of exchangeable acidity were significantly different than control. The application of steel slag did not affect neither soil respiration rate nor fungal population. The dose of 200% of exchangeable acidity increased the population of actinobacteria compared to the control. The nitrogen doses did not affect soil pH, nor microbial populations, but 200 mg kg^{-1} significantly decreases soil respiration. The application of steel slag as a liming material showed to be adequate to acidic soils with low impact of microbial populations, although upscale to field level is needed to conclusive results.

Keywords: steel slag, acidic soils, liming, soil microbial population.

(5202 - 1740) Variability spatial-temporal of potassium in different lowlands production systems

Luciano Pinzon Brauwers[1]; Luiz Gustavo Denardin[1]; Ibanor Anghinoni[1]; Paulo César de Faccio Carvalho[1]
UFRGS[1]

The adoption of no-tillage in integrated agricultural production systems affects directly the variability of the availability of nutrients in the soil profile. From this, has the premise that, compared to a conventional system of irrigated rice cultivation, with soil tickler and monoculture, the introduction of the animal in the system leads to greater heterogeneity in potassium available in space and time. The present study was conducted in a long-term experiment, started in 2013, situated in the municipality of Cristal - RS. 176 georeferenced soil samples were collected in may of 2013 and october of 2015, with further analysis of potassium available, in five production systems, contemplating different arrangements with different agricultural crops and animal frequency in the system. The results indicate an increase in potassium available in the soil in all production systems, however in different scales. The system only with the rice cultivation without the animal in the system presented the lowest potassium available in 2015 (116 mg dm^3), while the system that had more frequently of the animal, with permanent presence of grazing animal, presented the highest content of potassium (150 mg dm^3). With the exception of conventional system, that had increased in the coefficient of variation of 28% to 32%, all other integrated systems showed decrease in the coefficient of variation, with variation from 44% to 27%, indicating greater uniformity in the distribution of this nutrient in the soil. From this, we conclude that the adoption of integrated livestock-crop production systems in lowlands promote greater increase in the potassium content available, in the soil in the course of time, as well as, a lower spatial heterogeneity of these levels, in relation to the traditional system of cultivation of irrigated rice in lowland environments of the Brazilian subtropics.

(9718 - 712) Water use efficiency on sunflower crop under irrigation levels and potassium doses in Oxisol

Luana Glaup Araujo Dourado[1]; Márcio Koetz[1]; Edna Maria Bonfim-Silva[1]; Tonny José Araújo da Silva[1]; Tulio Martinez Santos[1]
UFMT[1]

Sunflower (*Helianthus annuus* L.) represents approximately 15% of all vegetable oil produced worldwide and occupies a prominent position placing the species currently as the fifth oilseed in production of feedstock. Sunflower has been increasingly cultivated for its various characteristics, such as short cycle, high quality and quantity of produced oil, resistance to drought, cold and heat, possessing a high degree of adaptability, in this way arises the need to seek modern technologies to meet their requirements and thus adapt or satisfy them according to what each region can offer. Thus, the objective was

to evaluate the water use efficiency in sunflower cv. SYN 042 in response to soil water replenishment levels and potassium doses in Cerrado Oxisol. The experiment was carried out in a greenhouse at Federal University of Mato Grosso, Campus of Rondonópolis - MT. The experimental design was randomized blocks, in a 5x4 factorial scheme, with twenty treatments and four replications. The treatments consisted of five potassium doses (0, 40, 80, 160 and 240 mg dm^{-3} of K_2O) and four levels of soil water replacement (75, 100, 125 and 150% of humidity equivalent to field capacity). To measure the levels of water tension in the soil were installed in the vessels, tensiometers of puncture, one per block, totaling 4 tensiometers. The irrigations were calculated to raise the values of the tension to those of the humidity equivalent to field capacity (6 kPa) for all treatments at the 100% level of soil water replacement, when the established tension of 10 kPa was reached. The water depths applied in each experimental unit were defined according to the percentages for each treatment. The results were submitted to the regression analysis at 5% of probability, using the statistical program SISVAR. The unfoldment of potassium doses within irrigation levels had a significant effect. The potassium doses 196.29, 187.5, 237.5 and 210.53 mg dm^{-3} combined with the levels of 75, 100, 125 and 150% of the humidity equivalent to field capacity, provided the maximum efficiency in water use, 1.67, 1.46, 1.29 and 1.08 g L^{-1}, respectively. In the unfoldment of the irrigation levels in the potassium doses of 40, 80, 160 and 240 mg dm^{-3}, as the levels of irrigation in the soil increased, there was a decrease of the water use efficiency, with greater efficiency in the lower applied water depth (75% of the humidity equivalent to field capacity).

(2268 - 1624) Whey as a sourge of nutrients for farage grasses

Anderson Romão dos Santos[1]; José Ricardo Mantovani[2]; Ana Beatriz Carvalho Terra[2]; Gabrielle Oliveira Serafini Lima[1]

University José do Rosário Vellano - UNIFENAS[1]; University José do Rosário Vellano -UNIFENAS[2]

Whey is a residue from the manufacture of cheeses, generated in abundance in dairy products. As this residue has high levels of K and N, an alternative would be its use in agriculture. This study aimed to evaluate the effect of whey on the production of forage grasses: *Panicum maximum* cv. Mombasa; *Brachiaria brizantha* cv. Marandu; *Brachiaria ruziziensis*. The experiment was carried out in pots, in the greenhouse. A randomized block design was used in a 5 x 3 factorial scheme with four replications. The treatments consisted of the combination of 5 doses of whey: 0; 400; 800; 1200; 1600 mL pot^{-1}, equivalent based on the soil volume of each pot at 0; 114; 228; 342 and 456 m^3 ha^{-1}, and 3 forage grasses: Mombasa, Marandu, and *Brachiaria ruziziensis*, respectively, belonging to the most demanding; intermediate and low in nutrients groups. Portions of 7 dm^3 of the superficial layer (0 to 0.2 m) of clayey soil received dolomitic limestone and 250 mg dm^{-3} of P as superphosphate were transferred to pots, moistened with distilled water at about 70% of the retention capacity, and remained in incubation for 30 days. At the end of the incubation, the three grasses were sowed, and the doses of whey were applied to the soil surface, according to the treatments. The whey used had 1.1 and 1.4 g L^{-1} of N and K. After emergence, thinning was carried out to maintain 4 plants per pot. The experiment was conducted by 3 cuts, and after the first and second cuts the doses of whey were reapplied. The application of whey increased, in each cut, the height of the plants, the number of tillers and the dry matter production of the aerial part of the grasses. When comparing the extreme treatments (control and receiving the highest dose of whey), there were increases of 2.1; 2.0 and 2.7 times the accumulated dry matter production (sum of the three cuts) of forages Mombasa; Marandu and *Brachiaria ruziziensis*, respectively. The application of whey increases the production of the forages Mombasa; Marandu and *Brachiaria ruziziensis*.

C3.3.11 - Biochar for soil fertility management

(4123 - 1207) Accumulation of macronutrients and dry mass in winter cover crops after application of forest biomass ash

Gabriela Naibo[1]; Jonas Guerra[1]; Rodrigo Roani[1]; Jaqueline Gaio Spricigo[1]; Augusto Henrique Debiasi Orsatto[1]; Cristiano Nunes Nesi[2]; Mauricio Vicente Alves[2]

University of West of Santa Catarina[1]; Professors, University of West of Santa Catarina[2]

The use of leguminous species as winter cover crops increases the availability of nitrogen in the agricultural lands facilitating its absorption by culture in succession. The main objective of this study was to evaluate the accumulation of macronutrients and dry matter in oat and vetch as winter cover crops under different levels of forest applied biomass ash. The experiment was conducted at the Unoesc - Xanxerê / SC experimental plant on a Dystrophic Red Latosol/Oxisoil. The experimental design was randomized in blocks with four replicates. No-tillage was used in the sowing, with a consortium between vetch (*Vicia cracca*) (40 kg ha^{-1}) and oats (*Avena sativa*) (50 kg ha^{-1}) and fertilization according to soil analysis and crop requirements. The ash dose was indicated according to the potassium content in the ash and the required of the culture. There was a single dose of 30 kg ha^{-1} of nitrogen in all treatments. At the end of the vegetative cycle of oats and vetches, all plots were sampled by cutting 0.25 m^2 in the flowering stage of the crops, in order to quantify the green biomass production. Samples were weighed, dried at 65° C and then mill-milled using a 1 mm mesh sieve. The nutrient analyzes, N, P, K, Ca and Mg in whole plant were performed according to methodology described by Tedesco (1995). Regarding the dry mass, ash + oat/vetch and oat + vetch treatments did not differ statistically between them, being 1459.27 kg ha^{-1} and 1227.9 kg ha^{-1}. However, they differed significantly from fallow and ash treatments, which was 237.05 kg ha^{-1} and 189.85 kg ha^{-1} respectively. The N, in the ash + oat/vetch and oat + vetch treatments did not differ statistically from the others, with 31.27 kg ha^{-1} and 26.22 kg ha^{-1} respectively. The phosphorus in the ash + oat/vetch and oat + vetch treatments did not differ statistically from the others, having 1.34 kg ha^{-1} and 1.02 kg ha^{-1} respectively. The potassium in the ash + oat/vetch and oat + vetch treatments did not differ statistically from the others, being 55.35 kg ha^{-1} and 50.95 kg ha^{-1} respectively. However, for magnesium and calcium, the ash + oat/vetch and oat + vetch treatments did not differ statistically from the others, being 2.95 kg ha^{-1} and 2.57 kg ha^{-1} respectively for calcium, and 0.65 kg ha^{-1} and 0.60 kg ha^{-1}, respectively for magnesium. It was observed that after ash application, both accumulation of macronutrients and dry mass of cover crops was improved.

(7186 - 1105) Adsorption isotherms for different kind of designer biochar.

Yuki Moriyama[1]; Shinjiro Sato[1]

Soka University[1]

Nitosol which covers 12.5% of Ethiopian land has originally very low soil fertility, and requires fertilization for sound agricultural practices. Biochar is a carbon-rich product obtained when biomass is pyrolyzed with little or no available air. It has been demonstrated that biochars when applied to soils could improve soil physicochemical and biological properties including soil fertility and nutrient-use efficiency. Also, it is known that biochars with high (>600), low (300–400), and middle (450–600) pyrolysis temperatures are generally prone to adsorb well NO_3^-, NH_4^+, and PO_4^{3-}, respectively. Recently, designer biochars, produced to possess enhanced specific physicochemical properties to meet specific soil environments, are attracting attention. It has been shown that biochars pretreated by lanthanum ($LaCl_3 \cdot 7H_2O$) enhanced adsorption capacity for NH_4^+, NO_3^- and PO_4^{3-} significantly. Also, pre-treatment by clay mineral (montmorillonite) significantly increased adsorption capacity of biochars for NH_4^+ and PO_4^{3-}. This study examined the adsorption capacities of different designer biochars treated by lanthanum and clay for NH_4^+, NO_3^- and PO_4^{3-}. Two different feedstocks (wheat straw and corn stover) were used for biochars and pyrolyzed at 300, 400 and 500°C. Each feedstock was pre-treated by lanthanum (LT) or montmorillonite (MM). Fresh biochars without any pre-treatments were also produced at each temperature. The adsorption capacity was evaluated for each biochar for NH_4^+, NO_3^- and PO_4^{3-}. For NH_4^+ adsorption, fresh wheat biochar (300°C) and fresh corn biochar (400°C) showed the best performance. MM-treated biochars showed better performance than LT-treated biochars. Fresh biochars did not show any NO_3^- adsorption. For most of temperatures, LT-treated biochars showed better performance than MM-treated biochars for NO_3^- adsorption. Most of biochars did not show any PO_4^{3-} adsorption, but only wheat LT-treated biochars showed some adsorption. There were almost no differences between feedstocks for NH_4^+ and NO_3^- adsorption, therefore only wheat straw will be used for developing adsorption isotherms. Pyrolysis temperatures will be 300 and 450°C for NH_4^+, 600 and 750°C for NO_3^- and 450 and 600°C for PO_4^{3-} to develop isotherms. In this experiment, it is expected that lower temperature biochars and higher biochars will do the best performance for NH_4^+ and NO_3^- adsorption, respectively. For PO_4^{3-}, it is expected that only LT-treated biochars will do good performance.

(3553 - 923) Biochar and biochar-treated poultry litter compost can reduce greenhouse gas emissions and leaching of inorganic nitrogen from soils

Eunice Agyarko-Mintah[1]; Annette Cowie[2]; Bhupinder Pal Singh[3]; Lukas Van Zwieten[2]; Flavio Fornasier[4]; Steven Harden[2]
University of new England, Australia[1]; Department of Primary Industries, Australia[2]; Department of Primary Industries, Australia[3]; CREA - Centro di Ricerca Viticoltura ed Enologia, Italy[4]

Release of inorganic N from mineralization of labile N-rich organic amendments is a significant source of N lost via gaseous emissions. We hypothesise that co-composting with biochar, a stable C-rich amendment with recognised sorption capacity, would regulate N release to minimise N loss from soils receiving compost. A nine-week incubation experiment was conducted to assess the influence of biochar and biochar-amended compost on emissions of N_2O and leaching of N from two contrasting soils, Ferrosol and Tenosol (Australian soil classification), over three wetting and drying (W-D) cycles. Treatments included co-composted greenwaste biochar and poultry litter (GWBC), co-composted poultry litter biochar and poultry litter (PLBC), poultry litter biochar (PLB), poultry litter compost (PLC) and control (nil organic amendment), applied to the soils at 2 % (dry w/w). Two extra sets of the same soils/ amendments were used to assess changes in leaching of N and soil chemical and biological properties. Results on N dynamics were expressed relative to the initial amount of total hydrolysable (HN) in soil + amendments. About 50 – 90 % of N_2O emitted from the Ferrosol was released in the 1st cycle and cumulative N_2O emissions per g of HN were 60 – 80 % lower across the PLBC, PLB, GWBC and PLC treatments *cf* control (19.1 mg N_2O g^{-1} HN). In the Tenosol, cumulative N_2O emissions per g of HN were ~ 40 % lower in the PLB treatment, and ~ 100 % higher in the PLC and ~ 30 % higher in the GWBC and PLBC treatments, *cf* control (1.4 mg N_2O g^{-1} HN). The cumulative NO_3^--N leached per g of HN in the PLB, GWBC and PLBC over the entire period was significantly lower, by 30 –50 % in the Ferrosol, and 60 – 86 % in the Tenosol, relative to the respective controls. The sorption ability of biochar may be enhanced as biochar ages during composting and/or during interaction in the soil. We further postulated that biochar and biochar-treated co-compost promoted biochar-organo-mineral interactions, particularly in the Ferrosol, stabilising organic N to decrease N_2O emissions and N leaching. Organic additions increased biological activity (dsDNA and enzyme content) *cf* control only when compost was supplied, and only in Tenosol at the first sampling, while these measures decreased in the 2nd and 3rd sampling due to W-D cycles. We therefore conclude that biochar and biochar co-composted could be beneficial in mitigating climate change challenges and improve N use efficiency when apply to soils.

(2754 - 1933) Biochar application shaped the distribution of native soil organic carbon accumulation in soil aggregates in a long-term wheat-maize cropping system

zhangzhengcheng[1]; Liguitong[1]
Department of soil and water sciences, University of China Agricultural University[1]

Biochar application shaped the distribution of native soil organic carbon accumulation in soil aggregates in a long-term wheat-maize cropping system Zhang zhengcheng,liguitong Department of soil and water sciences, University of China Agricultural University An understanding of the influence of biochar on soil organic carbon (SOC) formed from different carbon (C) sources, other than biochar, at field scale is required to accurately assess and predict the C sequestration potential of biochar. For this study, we set up a field experiment in 2009, including four treatments (i.e. B0, B30, B60, and B90, where the biochar application rates were 0, 30, 60, and 90 t ha−1, respectively). We then assessed the impact of biochar after eight years (i.e. in 2017) on native SOC in different sizes of aggregate derived from C3 (wheat) and C4 (maize) crop residues, as well as the changes of different aggregates. Previous study has revealed that (xinliangdong find Biochar application constrained native soil organic carbon accumulation from wheat residue inputs in a long-term wheat-maize cropping system).0–20-cm soil samples were taken to measure the size distribution of soil water-stable aggregates by wet sieving, The present study is aiming to investiga-te the underline mechanisms. In

each fraction (different sizes) of aggregates, native SOC derived from C3 (wheat) and C4 (maize) crop residues will be evaluated through stable isotope (13C) analysis. After eight years, we will test the contents of TOC and TN as well as organic carbon in different size of aggregates,then we will dig into the effect of Biochar application for soil organic carbon accumulation in different sizes of aggregate from wheat residue inputs in a long-term wheat-maize. The findings from the present study will advance our understanding of were meaning biochar's influences on crop residue degradation and organic matter stability.

(6598 - 1877) Biochar impacts on earthworm and bacterial communities in two long-term field experiments in Finland

Jure Zrim[1]; Visa Nuutinen[2]; Asko Simojoki[3]; Petri Penttinen[4]; Bruno Glaser[5]; Priit Tammeorg[3]

University of Helsinki, P.O. Box 27 FIN-00014 (jure.zrim@helsinki.fi)[1]; Natural Resources Institute Finland (Luke)[2]; University of Helsinki, Finland[3]; Zhejiang A & F University, Lin'an, China[4]; Soil Biogeochemistry, Institute of Agronomy and Nutritional Sciences, Martin Luther University 2 Halle-Wittenberg, Halle/Saale, Germany[5]

Biochar is a carbon rich solid obtained via pyrolysis from biomass such as wood and crop residuals. Due to its beneficial physiochemical properties, biochar is considered as an efficient tool to sequester carbon, enhance soil fertility and potentially increase crop yields. Biochar amendment can have significant impacts on soil organic carbon levels and physicochemical conditions. Consequently soil micro- and macro-biota may be affected and it is therefore important to understand how key biological components in the soil such as earthworm and microbial communities response to biochar application in the long-term. The study was conducted in South Finland in a fertile Stagnosol and a nutrient deficient Umbrisol, four and five years after biochar amendment, respectively. Biochars were produced from spruce (*Picea abies* (L.) H. Karst.) and pine (*Pinus sylvestris* L.) and applied at the rates of 10 t ha^{-1} and 30 t ha^{-1}. Earthworms and soil samples for microbial analyses were collected in September 2015. Casts from the sampled earthworms were also collected to investigate the consumption of biochar and the potential of earthworm bioturbation to affect biochar distribution. In addition, greenhouse gas emissions from soil were measured at the same spots from which the earthworm samples were taken. In both soils, the species composition of earthworm community was typical for Finnish arable soils with the dominance of endogeic, *Aporrectodea caliginosa* Sav., followed by epigeic *Lumbricus rubellus* Hoff. The total earthworm density and biomass were higher in Stagnosol field compared with Umbrisol field, but the proportions of different species were similar at both sites. Biochar and fertilizer treatments or their interaction had no statistically significant effects on the earthworm abundance, community composition or greenhouse gas emissions in either field. The preliminary results also show that earthworms had ingested biochar as earthworm casts from biochar treated-plots contained significantly more black carbon than those in the control plots, demonstrating that earthworm bioturbation is a potentially important factor in the translocation of applied biochar in the soil profile. Microbial community structure data will be presented in the final presentation. Softwood biochar amendment seems to be a safe method for carbon sequestration in Southern Finland conditions.

(7719 - 1469) Biochar improves productivity of degraded pasturelands in Brazil: environmental and socio-economic analysis

Agnieszka Latawiec[1]; Aline Rodrigues[1]; Ana Castro[2]; Andre Junqueira[2]; Catarina Jakovac[2]; Ednaldo Araujo[3]; Etelvino Novotny[3]; Gerard Cornelissen[4]; Luiz Fernando de Moraes[3]; Sarah Hale[4]

PUC-Rio[1]; International Institute for Sustainability[2]; Embrapa[3]; NGI[4]

Land covered with forage grasses for animal grazing occupies 26% of global ice-free land and livestock provides employment and sustenance to nearly one third of the world's population. Pasturelands have significant contribution (40%) to gross domestic product of the world's agriculture. Yet, pasture degradation due to inadequate handling and soil-fertility loss renders pasture productivity below its potential and leads to adverse economic and environmental impacts. Degraded, low-productivity pasturelands are predominant throughout the tropics. In Brazil, a country that holds the world's largest commercial cattle herd, pasture-fed cattle ranching occupies 158 million hectares corresponding to 75% of agricultural land in Brazil with more than 70% of pastures being degraded and of low stocking rates (mostly below 1 animal unit per hectare). Pasturelands' productivity is often compromised by low soil pH, carbon content and reduced water holding capacity, and could therefore benefit from biochar. Studies that look into the potential of biochar to improve forage grass productivity in Brazil are scarce. Here we provide the first analysis of biochar amendment effect on Brazilian pasturelands with the aim of increasing yield for the two common forage grasses in Brazil (*Brachiaria* and *Panicum*). We performed both pot trials in controlled conditions for six vegetative cycles as well as field study for two vegetative cycles. Biochar (in combination with organic fertilizer and/or with inoculum) significantly improved biomass volume for both grasses, which can be explained by significant improvement of macronutrient content in soil (P, K, Mg) and pH regulation. We also observed increased K and P in the aboveground biomass but lower than control contents of Mg, Ca, Mn and Zn. There were no significant differences in belowground biomass between the treatments. We also performed cost-benefit analysis of biochar in Brazilian pasturelands and we valuated ecosystem services (carbon and nutrient retention) that follow biochar addition. To our knowledge this is the first study that investigates in a comprehensive way the use of biochar on pastures in Brazil, and one of the very few worldwide. Given widespread degradation of pasturelands in Brazil the results of this study may have significant implications, especially for smallholder farmers.

(5200 - 2119) Biochar preparation for returning nutrients to soil

Stella Cristiani Gonçalves Matoso[1]; Paulo Guilherme Salvador Wadt[2]; Valdomiro Severino de Souza Júnior[3]; Xosé Lois Otero Pérez[4]

Instituto Federal De Rondônia[1]; Embrapa Rondônia[2]; Universidade Federal Rural de Pernambuco[3]; Universidade de Santiago de Compostela[4]

Mineral enriched biochars have demonstrated high stability and high nutrient content available to plants, especially under low pyrolysis temperatures. These characteristics are similar to the properties of the organomineral complex of Amazonian Dark Earths. The objective of this study was to evaluate the effects of adding two specific soil types (sandy and clayey) to rice or coffee husk in order to generate organomineral biochars via pyrolysis. The pyrolysis (350 °C for 2 h) of biomasses (organic biochars) and solid mixtures (enriched biochar) of biomasses + soils (0,6:0,4 biomass-to-soil ratio), was carried out, resulting in six biochars. Thermal analyzes (TG/DSC) and chemical analyzes were performed. The elemental composition was obtained

in elemental analyzer (N and S) and by acid digestion using HNO_3, H_2O_2 and HCl (P, K, Ca, Mg, Na, Fe, Zn, Mn and Cu). The available contents were extracted with solution of Mehlich 3 (P, K, Ca, Mg, Fe, Zn, Mn and Cu) and ammonium acetate at pH 7.0 (Na). The nutrients concentration was determined by colorimetry, flame photometry and atomic absorption spectroscopy. The coffee husk gave rise to biochars more resistant to thermal degradation than the rice husk. This effect was potentiated in the enriched biochars. The F1 axis (69.26%) of the principal component analysis separated the biochars according to the biomass. The three biochars derived from coffee husk were similar, presenting higher content of N, S (total), P, K, Ca, Mg, Na and Cu (total and available) and lower content of Zn and Mn (total and available), when compared to the three rice husk-derived biochars. In the F2 axis (21.99%) it was observed that the higher Fe content (total and available) and total Mg separated the enriched biochars from the organic biochars. The elemental composition (mg kg^{-1}) of biochar derived from coffee husk resulted in: N = 19.5; S = 0.9; P= 1,644.6; K = 42,200.0; Ca = 13,740.0; Mg = 900.0; Na = 84.0; Fe = 1,290.0; Zn = 16.0; Mn = 159.0 and Cu = 39.0. With available levels of (mg kg^{-1}): P = 102.1; K = 33,893.8; Ca = 4,288.2; Mg = 420.0; Na = 0.01; Fe = 101.0; Zn = 5.5; Mn = 87.4 and Cu = 1.7. Therefore, the biochar derived from coffee husk is a good alternative to return nutrients to soil. The enrichment with clay soil, despite decreasing the total and available contents of most nutrients, increases the Mg, Fe and Mn contents and the thermal stability of the biochar. Thus, enhanced potential as slow-release fertilizer is obtained.

(2064 - 741) Characterization of biochars produced from different animal manures and crop straws

Qamar Sarfaraz[1]; Gerson Laerson Drescher[1]; Fabiane Figueiredo Severo[1]; Leandro Souza da Silva[1]
Federal University of Santa Maria, 1000 Roraima Ave, Santa Maria - RS, 97105-900, Brazil[1]

Huge amounts of crop residues and animal wastes are produced each year in Southern Brazil as the region has plenty of rice, soybean, and corn production and huge number of animals (cattle and swine) are produced. Recently a new technique is introduced to compensate the animal manures and plant residues, making biochars and applying to soils to enhance soil fertility as well as crop yield. However, biochars produced from different materials may present different characteristics. This study was proposed with an objective to characterize the biochars produced from different animal manures and crop straws. Manures (swine, poultry, cattle) and crop straws (rice, soybean, corn) were collected from experimental areas of Centre of Rural Sciences (CCR) of the Federal University of Santa Maria. Biochars were prepared at low temperature (450^{O}C) under slow pyrolysis conditions (10^{O}C increase in temperature per minute) for 1 hour in a muffle furnace, as previously reported that biochars produced at low temperatures are more suitable for agricultural use as they contain greater quantities of functional groups and higher exchange capacity. All results were analyzed for ANOVA and LSD was used at 5% to indicate significant variations for different elements. The biochar production rate is low in the study ranging from 26 to 57% because oxygen was not completely limited during pyrolysis of biomass. All biochars are alkaline in nature with maximum pH 10.41 found in rice straw biochar. The alkalinity of biochar is influenced, might be due to disappearance of acidic functional groups such as −COOH at high temperature. These results are reasonable, biochars produced from straw feedstock containing more carbon and less nitrogen than manure biochars except soybean straw. Carbon contents in all biochars are higher except cattle manure biochar 16%. The lost C and N were presumably transferred to bio-oil or un-condensable exhaust. It is well known that pyrolysis conditions dramatically influence the yield and properties of biochar. Nitrogen, phosphorus, potassium, calcium and magnesium contents are high for each biochar. Cation exchange capacity (CEC) of all biochars is higher ranging from 117 to 170 cmolckg-1. Hence, it can be concluded that biochars produced at low temperatures are rich in total C, can sequester C in soil, alkaline in nature, might be beneficial for acidic soils and are rich in nutrient concentrations, may be used to enhance crop yield by improving soil fertility.

(5243 - 2827) Crop yield and greenhouse gas emissions from sugarcane systems in Brazil: effects from biochar amendment with organic fertilizers

Tatiana F. Rittl[1]; Sara de Jesus Duarte[1]; Marina Colzato[1]; Carlos Eduardo P. Cerri[1]
USP-ESALQ[1]

Brazil is the largest producer of sugarcane in world. Sugarcane ethanol produced in Brazil is considered economic and environmental sustainable, however, management practices such as the addition of waste products from ethanol production (filter cake and vinasse) to sugarcane fields in the form of organic fertilizer may increase the greenhouse gas (GHG) emissions due their richness in carbon (C) and nitrogen (N). Therefore, although the recycling of vinasse and filter cake in sugarcane fields are desirable due their agricultural benefits, better management practices need to be developed to minimize their negative effects on GHG emissions. Biochar, the product of biomass carbonization, has the potential to reduce GHG emissions from agricultural systems, and to promote crop yields in the tropic regions. However, although the perspectives of using biochar to reduce GHG emissions and increase crop yield are promising little has been done, especially in the tropical areas. Here, we simultaneously investigated the potential of biochar amendment with sugar cane residues to increase crop yield and reduce GHG emissions in a sugarcane plantation in Brazil. For that, we carried on a field experiment with nine treatments and one negative control (without any amendment). Treatments comprised of four rates of biochar (0; 6.25; 12.5 and 25 Mg ha^{-1}) with addition of sugarcane filter cake and with or without addition of vinasse. The main findings of this study show that biochar addition improved soil fertility and promoted crop yield, however its effects on GHG emissions were variable and dependent on the applied biochar rate and type of organic fertilizer.

(3680 - 1174) Does softwood biochar act as a long-term fertilizer in boreal conditions?

Subin Kalu[1]; Asko Simojoki[1]; Priit Tammeorg[1]
Department of Agricultural Sciences, Faculty of Agriculture and Forestry, University of Helsinki[1]

Biochar addition to soil has been recently identified as a potential way to enhance productivity and environmental sustainability of agriculture. Due to the high aromaticity that slows down the decomposition of biochar and makes it persist in soil for long periods of time, biochar is credited as the most promising C sequestration tool. In addition to the effects enhancing C sequestration and soil physical properties, it has been reported that biochar could also act as slow-release fertilizer especially for P and K. However, studies on the longer-term (i.e. more than five years) effects of biochar are scarce, and more so in colder climates where soils typically have high initial

SOM contents as compared with (sub-) tropical climates. Also, the possible interactions with fertilizer type (organic vs. mineral) with biochar need to be explored before the practice can be recommended in larger scale. This study provides information about the effects of biochar on the plant nutrient uptake in a boreal Umbrisol with loamy sand texture for 7 years (2011 – 2017). The field experiment was set up with a split-plot design with the biochar application rate (0, 5, 10, 20 and 30 tons DM ha^{-1}) as the main-plot factor and fertilizer treatment (unfertilized control, meat bone meal and inorganic fertilizer) as the sub-plot factor. Biochar was added only in the first year in 2011 while the plots were fertilized every year. Only the plots with no biochar (0 tons ha^{-1}) and highest biochar application rate (30 tons ha^{-1}) were considered for this presentation. The crop rotation under study was wheat-wheat-barley-grass-grass-oats-peas, annually plant samples were taken during full flowering growth stage. The plant samples taken for the determination of aboveground biomass (AGB) were later ground for analyzing macronutrients and micronutrients. C and N were analyzed using Variomax C N analyzer while other nutrients were analyzed using ICP-OES after dry ashing of plant samples at 500^{o}C and dissolving the ash in 0.2 M HCl. The plant nutrient uptake will be calculated by multiplying the AGB with the nutrient concentrations. The detailed results will be presented in the final presentation. In short, the effects of experimental treatments on measured properties will be tested with a mixed model function with biochar level, fertilizer type, and their interactions as fixed effects and replicate and its interaction as random effects.

(6093 - 2509) Effect of biochar and phosphorus application on soil pH and phosphorus availability in a clay and sandy loam soil

Rolivhuwa Mudau[1]; Jude J.O Odhiambo[1]
Department of Soil Science, University of Venda[1]

The application of biochar (BC) in agricultural soils has gained prominence in the last few years. However, BC, due to its highly alkaline nature has the effect of increasing the soil pH and thus affecting availability of nutrients such as phosphorus (P) especially in highly weathered acidic soils which also have a high potential for P fixation. The objective of this study therefore was to determine the effect of three levels of application (BC rate) of three biochars (BC type) derived from different feedstocks (eucalyptus, hay and poultry litter), and P application rates (P rate) on soil pH and available phosphorus in a clay and sandy loam soil. A 70-day pot experiment in a 3×3×2 factorial arrangement was conducted in a plastic tunnel. Three (3 Kg) of soil or soil +biochar mixture was weighed into plastic pots (25 cm diameter and 25 cm height) and allowed to equilibrate for 10 days. 100 kg N ha^{-1} was uniformly applied to all pots as Limestone Ammonium Nitrate (LAN). Two levels of P (0 and 70 Kg ha^{-1}) were applied as superphosphate. Three hybrid maize seeds (variety PAN 6479) were planted in each pot. Four days after emergence thinning was done to two plants per pot. Seventy (70) days after emergence, shoots were harvested and soil samples were taken and analysed for soil pH and available P. Data was analysed using the general linear model (GLM) procedure of IBM SPSS software version 25. Application of biochar regardless of the feedstock source increased soil pH and available P in both soils. Biochar application rate had a significant effect on soil pH of the sandy loam soil and available P in both clay and sandy loam soil. Phosphorus application rate did not have any effect on the soil pH and available P. A significant ($p<0.001$) BC type* BC rate and BC type* P rate interaction was observed for soil pH in sandy loam and available P in clay and sandy loam soils, while a significant BC rate* P rate interaction was only observed for available P in both soils ($p<0.001$ in clay soil and $p<0.05$ in sandy loam soil). A significant BC rate*BC type*Prate was observed for soil pH in sandy loam soil and available P in clay and sandy loam soils. In summary, biochar application increased soil pH and available P, and poultry manure derived biochar showed the greatest influence on soil pH and available P compared to the eucalyptus and hay derived biochars.

(8284 - 648) Effect of different biochar treatments on maize growth and foliar nutrient status: the good, the bad and the ugly

Eduardo Guimarães Couto[1]; Heiriane Martins Sousa[1]; José Fernando Scaramuzza[1]; Alicia B. Speratti[2]; Mark S. Johnson[2]
UFMT[1]; UBC[2]

Biochar is the product of the thermal decomposition of different organic materials when heated in the absence of oxygen (pyrolysis) at elevated temperatures. It has the potential to improve soil chemical attributes and consequently plant nutrition, characteristics required in low fertility soils such as Arenosols. The objective of this work was to evaluate the effect of twelve biochars on the growth and nutrition of *Zea mays* in Arenosol. A greenhouse experiment was carried out using twelve biochars derived from four feedstocks: cotton husks (CH), swine manure (SM), eucalyptus sawmill residue (ER), sugarcane filtercake (SF) pyrolyzed at 400, 500 and 600°C and applied at 5% w/w. The effect on maize biomass and foliar nutrient status was evaluated along with its contribution to soil chemical properties, pH and electrical conductivity (EC). After six weeks, corn plants treated with ER and, in particular, SF biochar, showed the highest plant growth compared to control soil and with SM and CH biochars. However, application of SM and CH biochars was detrimental to plant growth and development and, in some cases, plant death was observed. This toxic effect could be due to the high levels of sodium and carbonates present in these biochars, which increased EC of soils to harmful levels. Despite this negative effect, we concluded that our biochars, especially the ones obtained at 400°C, showed nutrient incorporation potential, allowing better plant growth and nutrition. Additionally, decreasing the application rate of SM and CH biochars to < 5% (w/w) could avoid high salinity and, at the same time, reduce costs and contribute to improved plant growth and nutrition in Cerrado Arenosols.

(7634 - 1144) Effect of the biochar and manure application on the soil carbon dioxide emission

Ginebra Aguilar, Milagros[1]; Muñoz Vargas, María Cristina[1]; Vergara San Martín, Marcela[1]; Zagal Venegas, Erick[1]
Universidad de Concepción[1]

Soil degradation is defined as the loss of productivity. The management of animal manure can be an alternative to modify soil fertility and induce changes in greenhouse gas emissions. Biochar application in agricultural soils is an ancestral practice. Biochar is chemically and biologically more stable than its original sources. At present, biochar is produced by the pyrolysis of natural organic materials under oxygen limited conditions. Biochar has gained international research attention, but few studies have investigated the potential of biochar from manure in mitigation of climate change in Chilean agriculture. The objective of this study was to compare

biochar and manure application effect on soil carbon dioxide emissions. Two Chilean soils (Ultic Palexeralfs (Alfisol) from Cauquenes, Maule region and Typic Rhodoxeralfs (Alfisol) from Collipulli Araucania Region) were incubated with two manure (cow and pig) and two biochar from cow and pig manure. Carbon dioxide emission was evaluated during 56 days. The emissions of carbon dioxide did not increase significantly with the application of biochar in any soil. While soil-manure treatment had seven times more emissions than the soil alone. No significant differences were found between soil-biochar-manure and soil-manure treatments. Carbon dioxide emissions were higher in the first ten days. Soil- biochar treatment emissions were stabilized at the end of the study and soil organic carbon increased. Conversion of animal manure to biochar and its application to the soil is a promising alternative to increase soil organic carbon without increasing carbon dioxide emissions.

(2133 - 2468) Effects of Biochar on Retention of Nutrients in a Tropical Sandy Loam Soil

Shih-Hao Jien[1]

Department of Soil and Water Conservation, National Pingtung University of Science and Technology, Pingtung, Taiwan[1]

Leaching of nutrients and organic carbon due to rainfall in tropics/subtropics not only lead to soil degradation but also adversely affects the aquatic environment. The incorporation of biochar to soil has been known to increase sustainability through carbon sequestration and soil quality improvement. However, its effects on nutrient leaching as well as soil and dissolved organic carbon (DOC) varies from different biochar and soil types and should be further clarified. A short-term column leaching experiment of 42 days was conducted to assess the effects of biochar application on nutrient retention. Two wood saw-dust biochars, produced through slow pyrolization at 300°C (WB300) and 600°C (WB600), were incorporated into a sandy loam soil with application rates of 2% (w/w), approximately 40 tons ha^{-1} respectively. Flushing of leachate was done at days 4, 7, 14, 21, 28, 35 and 42. The results indicated that the application of biochar improved soil health and retained organic carbon in the soil. The treatment of 4% 600°C was the most effective in impeding soil acidification, from pH 4.5 in the control to pH 6.0. As comparison with the control, the leachate volume was reduced by 20%, reflecting the increase in water holding capacity. In treatment of WB300, the soil organic carbon (SOC) was retained by 61%, and the DOC in the leachate was reduced by 50%. Besides, the WB300 remarkably reduced the leaching of NH_4^+-N by 31% which was better than WB600 (decreased by 11%). Regarding NO_3^--N, the treatments of WB300 and WB600 could prevent it from leaching by 14% and 16% respectively, compared with the control. The leaching of Ava. P was reduced remarkably by the WB600 at 68% indicating different surface charge properties between WB300 and WB600. Based on analyses of cation exchange capacity (CEC), anion exchange capacity (AEC) and zeta potential of WB300 and WB600, the biochar might prefer to adsorb anions than caitons due to very high AEC of biochar surface. The AEC obviously increased with pyrolized temperature of the biochar, which was agreed with our leaching results. The results of this study strongly indicate that the incorporation of wood biochar (Honduran mahogany (*swietenia macrophylla*)) can improve soil quality by increasing the capacity of soil to retain nutrients in sandy loam soil of the tropic/subtropical region.

(6179 - 1725) Evaluation of soil fertility before and after two crops of black oats under fly ash application

Wilson Galli[1]; Jonas Guerra[1]; Jaqueline Gaio Spricigo[1]; Cristiane Pain[1]; Whelyton Eduardo Candido[1]; Matheus Antônio Arcego Filipim[1]; Mauricio Vicente Alves[2]

University of West of Santa Catarina[1]; Professor, University of West of Santa Catarina[2]

Soil can be considered as a nutritional mediator to the plants, being highly dependent on the planting management. The combination of studies involving new alternative fertilizers such as the use of fly ash and the changes in the dynamic of soil fertility over an agricultural crop is necessary. The objective of this research was to evaluate the soil fertility before and after the oat-soybean-oat crops, after the planting under different doses of forest biomass ash. The experiment was conducted at the experimental plant of Unoesc-Xanxerê / SC, from May 2016 to October, 2017. The soil of the experimental area is classified as Distrophic Red Latosol/Oxisoil, and the climate classified as Cfb. The experimental design was completely randomized with 7 treatments and 5 replicates. Three applications of ash was carried out, on the soil surface without incorporation, prior to the sowing of oats /soybean /oats (May 2016, October 2016 and May 2017, respectively). The ash dose in each application was 25 t ha^{-1}, randomized in the 35 plots (0, 50, 100, 150 and 200 % of the ash dose recommended according to the potassium content in the ash and the need of the crop). It was also studied organomineral and chemical fertilizer (according to Manual of liming and fertilization for the Brazilian states of RS and SC). The sowing densities of the first year and second year of oats were 60 kg ha-1, with a fertilization of 90 kg N ha-1 and 120 kg K ha-1 in both crops. The sowing of soybean was in no-tillage, under density of 360 thousand plants ha^1, and with chemical fertilization of 100 kg P ha^{-1} and 90 kg K ha^{-1}, reaching with the expectation yield of 4000 kg ha^{-1} grains. Soil samples were collected in December 2016, after soybean cultivation, and in October 2017, after the second oat cultivation. Soil samples (P, K, Ca, Mg, Al, CEC pH7, acidity (pH), SMP index, CEC effective, and V) were collected from each plot at 0-10 cm depth, according to the methodology described in Tedesco. It was observed that some nutrients (such as K, Ca and base saturation) decreased with the use of oats due to the ash application along the crops, while other nutrients did not suffer relative alteration (Al, CEC pH7, SMP index). Effective CEC, P, Mg and pH were altered with the use of oats with any dose of ash, increasing their values throughout the seasons, contributing to the improvement of soil chemical quality.

(5280 - 845) Modelling of thermal properties of biochar amended soils

Boguslaw Usowicz[1]; Jerzy Lipiec[1]; Mateusz Lukowski[1]; Zbigniew Bis[2]; Wojciech Marczewski[3]; Jerzy Usowicz[4]; Agnieszka Latawiec[5]

Institute of Agrophysics, Polish Academy of Sciences, Lublin, Poland[1]; Department of Energy Engineering, Faculty of Environmental Engineering and Biotechnology, Czestochowa University of Technology, Poland[2]; Space Research Centre, Polish Academy of Sciences, Warsaw, Poland[3]; Torun Centre of Astronomy of the Nicolaus Copernicus University, Poland[4]; Institute of Agricultural Engineering and Informatics, Faculty of Production and Power Engineering, University of Agriculture in Krakow, Poland[5]

Recently, biochar is increasingly used as a soil amendment. This results in improved water retention, fertility and pH, and this is particularly desirable for sandy and acidic soils. Biochar in the soil also can change

the heat and water balance on the soil surface and the temperature and moisture distribution in the soil profile through changes in albedo and the thermal and hydraulic properties. However, the researchers have also found some unfavourable aspects of biochar effects on the physical and thermal properties of the soil and various processes therein. To evaluate the effect of biochar on the thermal properties of the soil we have used the statistical-physical model (Usowicz et al., 2016). We have evaluated the effects of wood-derived biochar (0, 10, 20, and 40 Mg ha^{-1}) incorporated to a depth of 0–15 cm on the thermal conductivity, heat capacity, thermal diffusivity and porosity in sandy soil under field conditions and in various soil-biochar mixtures in the laboratory. In addition, the measured thermal data and those from the literature are compared with the data obtained from the analytic model of Zhao et al. (2016) and the mentioned above statistical-physical model based on the data on the soil texture, bulk density, and content of water and biochar. It turned out that the addition of biochar into the soil causes a significant reduction in thermal conductivity and diffusivity. The studied soil without biochar shows the largest thermal conductivity and diffusivity that decreases in biochar amended plots and pure biochar. The reduction of both thermal properties is mostly due to decrease in particle density and bulk density. Dependence of the soil thermal conductivity and thermal diffusivity on water content is non-linear and the shape of the non-linearity largely depends on the biochar content and the bulk density of the soil. The slope factor of the thermal conductivity as a function of water content at a given density increases with the share of mineral fraction of the soil. Usowicz B., Lipiec J., Łukowski M., Marczewski W., Usowicz J., 2016. The effect of biochar application on thermal properties and albedo of loess soil under grassland and fallow. Soil and Tillage Research, Vol. 164, 45-51. Zhao, J., T. Ren, Q. Zhang, Z. Du, and Y. Wang. 2016. Effects of Biochar Amendment on Soil Thermal Properties in the North China Plain. Soil Sci. Soc. Am. J. 80:1157-1166.

(9387 - 1076) Nitrogen Dynamic and Crop Production in an Ethiopian Nitosol Applied by Biochars and Anaerobic Digestion Effluents

Takuya Nakajima[1]; Shinjiro Sato[1]
Soka University[1]

Low soil pH, nutrient deficiencies, and low levels of fertilizer application constrain crop production in Ethiopia. Anaerobic digestion effluents (ADEs) are remaining liquid residuals after organic biomass are anaerobically digested. The ADEs can be used as liquid fertilizer due to abundant plant nutrients such as nitrogen (N). Furthermore, biochars, pyrolysed from organic waste and used as soil amendment, have abilities to retain plant nutrients when applied to the soil and increase crop production. Therefore, in this study, incubation and field experiments were conducted to examine the effect of application of ADEs and biochars on N dynamics and crop production in Ethiopia. A soil used in this study was a Nitosol. Fresh biochar (FB), clay-treated biochar (CB), and H_2O_2-treated biochar (HB) were derived from corncob for incubation experiment, and separately FB and CB were produced from coffee husk for field experiment. ADEs were derived from cow manure (ADE-B) and food waste (ADE-D). After incubation soil NH_4^+-N, NO_3^--N, and pH were analyzed, and after field experiment soil NH_4^+-N, NO_3^--N, and pH as well as plant dry weight were analyzed. After incubation period, NH_4^+-N with FB and CB were increased, but that with HB was decreased. More NH_4^+-N might be adsorbed strongly by HB due to the highest cation exchange capacity. NH_4^+-N adsorbed on biochars may be released to soil slowly over time. The plant dry weights with ADE-B applied were significantly higher than those with no-N applied. Therefore, it appears that ADE-B can substitute for chemical fertilizer for crop production in Ethiopia.

(6945 - 1695) Nutrient content in the dry mass of *Avena strigosa Schreb* grown under fly ash doses.

Augusto Henrique Debiasi Orsatto[1]; Jonas Guerra[2]; Whelyton Eduardo Candido[2]; Matheus Antonio Arcego Filipin[2]; Mauricio Vicente Alves[3]
University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê/SC, Zip Code: 89820-000, Brazil (gut-cho@hotmail.com)[1]; University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê/SC, Zip Code: 89820-000, Brazil.[2]; Professor, University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê/SC, Zip Code: 89820-000, Brazil.[3]

Ashes of plant origin can present high levels of organic matter and carbon/nitrogen ratio above 30/1, which can interfere in the nitrogen cycle omitting its absorption and significantly reducing the content of this macronutrient, as well as other nutrients in the dry mass of plants. The objective of this study was to evaluate the nutrient content of nitrogen (N), phosphorus (P), potassium (K), calcium (Ca) and magnesium (Mg) in the dry mass of black oats (*Avena strigosa Schreb*) grown under different fly ash from boiler. The experiment was carried out at the experimental plant of Unoesc - Xanxerê / SC, from June to September, 2017. The soil in the experimental area is classified as Red Latosol Distrophic/Oxisoil, and the climate classified as Cfb. The experimental design was completely randomized with 7 treatments and 5 replicates. The ash was applied before black oats no-tillage at a dose of 25,000 kg ha^{-1}. The treatments carried out were: 0, 50, 100, 150 and 200 % of the recommended ash dose according to the K present in the ash and required by the culture. Besides it was included a treatment with chemical fertilization (CF), and a treatment with organomineral fertilization (OM), according to the Manual of Liming and Fertilization for RS and SC Brazilian states (2016). The plots measure $15m^2$. At the full flowering stage, $1m^2$ was collected each plot, dried in the greenhouse at 55 degrees for 72 hours and milled to 2 mm sieve. The method of tissue nutrient analysis was done according by Tedesco (1995). Data were submitted to analysis of variance using F test, with 95% confidence using the R Core Team program. For Ca, Mg, P and N macronutrients, the best results were obtained with CF (4.30 g/kg, 3.49 g/kg, 4.85 g/kg and 23.31 g/kg, respectively). For K a better performance was obtained with OM fertilization (52.16 g/kg). The highest levels of Ca and Mg were obtained from OM fertilization (3.20 g/kg and 3.14 g/kg). Regarding P and N, the worst results were with the dose of 100% ash (4.14 g/kg and 14.30 g/kg, respectively), whereas K had its lowest content with 50% ash dose (44, 08 g/kg). Although the values found varied, the results did not show a significant difference in N, P, K, Ca and Mg content in the dry mass of black oats when using different doses of ash on the surface before sowing.

(6859 - 1884) Nutrient content in the grain of *Avena strigosa Schreb* grown under fly ash doses

Juliano Marcarini Bordin[1]; Whelyton Eduardo Candido[1]; Jonas Guerra[1]; Cristiane Pain[1]; Cleberson Tiago de Souza[1]; Mauricio

Vicente Alves[2]

University of West of Santa Catarina[1]; Professor, University of West of Santa Catarina[2]

Black oats are used as a soil cover crop, grazing in the off season, and in the case of grains, in the formulation of concentrate feeds. The quality of ingested food is directly associated to the cationic balance of nutrients in the plant and soil and can be affected by excessive doses of chemical or organic fertilizers and the use of ash. This study aimed to evaluate nutrient (nitrogen, phosphorus, potassium, calcium, and magnesium) content in black oat grains grown under different doses of fly ash, from the burning of forest biomass. The experiment was carried out at the experimental plant of Unoesc Xanxerê /SC, from May to September, 2017. The soil in the experimental area is classified as Dystrophic Red Latosol/Oxisoil, and the climate is classified as Cfb. The experimental design was completely randomized with 7 treatments and 5 replicates. The ash was applied on the soil surface at 25 t ha^{-1}, before sowing in no-tillage oats, and after a soybean crop. The treatments were 0, 50, 100, 150, and 200 % of the recommended ash dose besides one treatment with mineral fertilization according to the Liming and Fertilization Manual for the RS and SC Brazilian states (2016). The plots measure $15m^2$. After physiological maturation, 1 square meter of oats were sampled from each plot and the grains were separated by a mobile thresh machine. The samples were dried in the greenhouse at 55 degrees Celsius for 72 hours, and milled with bark and sieved to 2 mm. Afterwards the nutrients N, P, K, Ca and Mg were analyzed according to Tedesco (1995). The data were submitted to analysis of variance and to the F test, with 95% confidence using the R Core Team program. The results obtained showed that N, P, K, Ca and Mg levels in the black oat grains did not differ statistically within the different doses of ash applied on the soil surface.

(2640 - 1090) Potential use of poultry litter derived hydrochar as soil amendment

Vlvian Mau[1]; Gilboa Arye[2]; Amit Gross[1]

Department of Environmental Hydrology and Microbiology, Zuckerberg Institute for Water Research, Ben Gurion University of the Negev[1]; French Associates Institute for Agriculture and Biotechnology of Drylands, Jacob Blaustein Institutes for Desert Research, Ben Gurion University of the Negev[2]

Hydrothermal carbonization (HTC) is a new technology that efficiently converts wet organic matter into a carbon-concentrated hydrochar, aqueous and gaseous phases. Differently from biochar, water is essential in the carbonization process which occurs at much lower temperatures than biochar with significantly smaller energy demand. HTC takes place under a typical temperature range of 180-250 °C, autogenous pressures, and reaction times varying from minutes to several hours. Like biochar, hydrochar is being considered as a potential soil amendment, however only a handful of reports have studied it. This study had the objective to characterize hydrochar produced from poultry litter in terms of its nutrient content, ion composition, hydrophobicity and surface free energy properties. Hydrochar was produced at temperatures of 180 °C, 220 °C and 250 °C, and reaction times of 5, 30 and 60 min. Nutrients and ions were analyzed by elemental analysis and inductively coupled plasma following standard methods. Hydrophobicity was assessed through the sessile drop and Wilhelmy plate methods. Surface free energy was calculated with contact angles formed between the samples and water, ethylene glycol, formamide and glycerol using the models OWRK and Wu. The resulting hydrochars had an acidic pH and contained significant nutrient concentrations that can potentially enhance plant growth. N and P concentrations were of 3%, while K concentration was much lower, around 0.1%. Considering other nutrient elements, 0.8% Mg was present, and Mn, Na, Fe, Zn were each present at 0.1%. It was also found that as treatment temperature increased hydrochar became increasingly more hydrophobic as evident by the contact angle that was less than 20° for the raw manure to 135° after carbonization at 250 °C. These changes were correlated with fiber composition. HTC lead to the degradation of hemicellulose at 180 °C, and cellulose at 250 °C. Hydrochar produced at 250 °C was composed mainly of lignin, and displayed high hydrophobicity over prolonged wetting period and repeated wetting cycles. As a result, the surface free energy decreased from 26 MJ/m^2 in the poultry litter to 8 MJ/m^2 after treatment at 250 °C for 60 min. Increasing hydrophobicity can enhance water holding capacity of soils and can positively affect irrigation efficiency, specifically in more porous soils such as sand. It is postulated that hydrochar can enhance soil fertility and properties thus improving soil productivity.

(1480 - 2110) Poultry Litter Biochar as an Alternative to Inorganic Phosphorus Fertilizer in a Year-Round Cropping System

Andressa M Freitas[1]; Vimala D Nair[1]; Lynn E Sollenberger[1]; Willie G Harris[1]

University of Florida[1]

Use of biochar as a fertilizer has gained prominence recently as an alternative to inorganic phosphorus (P), supplies of which are dwindling. Biochar prepared from different feedstocks behaves differently with respect to P retention and release. We evaluated P release from biochars from different feedstocks, including mixed hardwoods, poultry litter and biosolids, using solid state and solution procedures. Poultry litter biochar (PLB) had a very high P concentration, with P in the form of a sparingly soluble calcium phosphate mineral. Therefore, PLB is expected to provide P to plants on a long-term basis while simultaneously reducing nutrient leaching relative to the more soluble commercial fertilizer. In a separate field study, we evaluated the effects of P sources including PLB, inorganic P fertilizer providing the same amount of P as PLB, and a no P control. Treatments were arranged in six replicates of a randomized complete block design at two locations differing in soil type (Entisols vs. Spodosols). At each location, the annual cropping system consisted of sequential plantings of rye, corn, and sorghum. Crop yield and N and P in plant tissue were measured for each component of the cropping system, and soil P storage capacity (SPSC, a measure of the amount of P a soil can hold prior to releasing P) was determined after each crop was harvested. There was no negative impact of PLB application on P and N in the plant tissue after the first three cropping cycles. Preliminary results also suggest that SPSC was similar at a given site with PLB or inorganic fertilizer applications. Evaluation of treatments over a longer time scale is needed; the hypothesis is that PLB will result in greater soil P accumulation and lesser loss of P compared with inorganic P fertilizer.

(8429 - 1654) Sewage sludge biochar alters the microbiota involved in soil phosphorus cycling

Cícero Célio de Figueiredo[1]; Walda Monteiro Farias[2]; Thais Rodrigues

Coser[2]; Alessandra Monteiro de Paula[3]; Jhon Kenedy Moura Chagas[3]; Thamires Dutra Pinheiro[3]; Thais França Silva[3]
1University of Brasilia, Campus Universitário Darcy Ribeiro, ICC Centro, Faculdade de Agronomia e Medicina Veterinária, Brasilia, 70910970, Brazil (cicerocf@unb.br)[1]; 1University of Brasilia, Campus Universitário Darcy Ribeiro, ICC Centro, Faculdade de Agronomia e Medicina Veterinária, Brasilia, 70910970, Brazil[2]; University of Brasilia, Campus Universitário Darcy Ribeiro, ICC Centro, Faculdade de Agronomia e Medicina Veterinária, Brasilia, 70910970, Brazil[3]

Sewage sludge biochars (SSB) have shown great potential to improve soil quality and increase the availability of soil nutrients and crop productivity. However, there is still a lack of information on the effect of phosphorus (P) content from SSB on the soil microbiota, especially on arbuscular mycorrhizal fungi under field conditions. In the current study, the effects of the application SSB (produced under different pyrolysis temperatures) and their combination with mineral fertilization into an Oxisol cultivated with corn on soil P cycling microbial community were investigated. Six treatments were arranged in randomized blocks, with four replicates: 1) Control - without biochar; 2) Mineral fertilization with NPK; 3) Biochar 300 °C; 4) Biochar 500 ° C; 5) Biochar 300 ° C + NPK; 6) Biochar 500 ° C + NPK. 15 Mg ha^{-1} of SSB and mineral fertilizer (formula 4-14-8) were applied in two consecutives 2014/2015 and 2015/2016 seasons. The carbon contents of microbial biomass (MBC), percentage of mycorrhizal colonization and the levels of easily extractable glomalin (EEG) were evaluated. The application of SSB elevated MBC and the colonization of corn roots by arbuscular mycorrhizal fungi (AMF). As a consequence, SSB stimulated the synthesis and excretion of EEG. The high levels of P provided by the SSB applied together with NPK may limit mycorrhizal colonization, without, however, reducing the uptake of P by maize.

(8865 - 1932) Soil Water Retention and Plant Available Water in a Mexican Clayey Soil Applied with Designer Biochars Treated with Peroxide and Montmorillonite

Marcelo Takeda Ono[1]; Shinjiro Sato[1]
Soka University[1]

The world water consumption for agricultural purposes is estimated to account for approximately 70% of the world's fresh water volume. The demand for food has been increasing which leads to additional withdrawal of fresh water. Biochar is a carbon-rich material pyrolyzed by biomass with limited oxygen, and has been designed to possess specific properties enhancing important parameters such as water retention capacity. This study evaluated effects of soil application of biochars derived from "*Agave tequiliana*" treated with hydrogen peroxide and clay (montmorillonite) (including no treatment – fresh biochar) on soil water retention plant available water. Two pyrolysis temperatures of 400^{o}C and 800^{o}C were employed. Applications rates of biochar were 0 (control) and 3% (w/w). After biochar addition, the mixtures were incubated at 30^{o}C during 21 and 91 d and periodically wetted to keep the moisture at 40% of water filled pore space. Soil water retention curves using pressure plate apparatus were developed for the soil-biochar mixtures. Soils applied with clay- and fresh biochars at 400^{o}C increased water contents at saturation (pF 0) due to increased porosity, but showed sharp decreases from saturation to field capacity (FC) in soil water retention curve comparing to other biochar treatments. In general, 400^{o}C biochars presented greater plant available water contents than 800^{o}C biochars. Peroxide-biochars with both temperatures increased water contents at permanent wilting point (pF 4.2), which consequently decreased plant available water. Application of any types of biochars did not increase plant available water when incubated for 21 d compared to control. However, only clay- and fresh biochars at 400^{o}C improved soil water content at FC and plant available water when incubated for 91 d compared to control. Samples incubated for the longer period were more efficient to improve plant available water because soil-biochar mixtures became more compacted over time increasing cohesion forces among clay particles, biochars, and water molecules. Moreover, montmorillonite contributed to increase clay content in the mixture. The results of this study demonstrated that biochars should be used strategically to aim for improvement in soil water management.

(4972 - 472) Spatial correlation of chemical attributes of soil in black earth area of archaeologicals in the south of Amazon

Sabrina Isabela da Silva Fernandes[1]; Elilson Gomes de Brito Filho[1]; Milton César Costa Campos[1]; Fernando Gomes de Souza[1]; Juliana Malta de Assis[1]; Maria Clécia Gomes Sales[1]; Luana Celestino Calista[1]; Ludimila Souza de Oliveira[1]; Wildson Benedito Mendes Brito[1]; Estefani de Souza Oliveira[1]
Federal University of Amazonas[1]

The soils of Amazonas are considered as few fertile soils, presenting low values of cation exchange capacity and high levels of aluminum, a differential of these soils are Black Archaeological Land spots (TPAs), they are soils of a fertility well above the great majority of the typical soils of the Amazon region. In this sense, the aim of this study was to evaluate the spatial distribution of soil chemical attributes in an area of black archeological soil under cocoa cultivation in Apuí Municipality (AM). The study area is located in the municipality of Apuí, Amazonas, Brazil, located along the Transamazon Highway (BR-230), under the geographic coordinates of 7º12'05 "S and 59º39'37" W. a 42 x 88 m mesh, with regular spacing of 6 x 8 m, totaling 88 points, and then deformed soil samples were collected at depths of 0.0-0.05; 0.05-0.10; (PH, CO, Est C, (H + Al), P, K, Ca, H 2 O, Mg, SB, CTC and V%). Data were analyzed using descriptive and geostatistical statistics techniques. By the descriptive statistics the Ca2 + and Mg2 + contents were higher in the superficial layer of 0.0-0.05 and 0.05-0.10 m, where, in general, the TPAs exhibit high levels of nutrients, mainly Ca and P , from the remains of human bones and animals, in addition to the formation of complex organic matter-calcium of high stability. The basal saturation revealed high values in all the layers evaluated, the levels of available phosphorus were high in the anthropogenic horizons, with a tendency to increase in depth, varying from 93.7 to 124.34 mg dm-3, the CTC tended to decrease in depth, in relation to the normality test KS all attributes were significant at 5% probability. In relation to Geostatistics, the models that best fit were the exponential and the spherical, the coefficients of determination above 0.70, by the classification of Cambardella et al. (1994), the attributes remained in a strong and moderate degree of dependence, reaching between 12 and 60m. Thus, geostatistics provided adequate information to understand the spatial distribution of chemical attributes in the area of Cocoa and in depth (0.00-0.05m) all variables studied had strong spatial dependence, except for Est C and TOC that did not present dependence.

(2661 - 2400) The effect of biochar in Atlantic Forest Seedlings: environmental and socio-economic analysis

Aline Rodrigues[1]; Agnieszka Latawiec[2]; Etelvino Novotny[3]
International Institute for Sustainability/ Rio Conservation and Sustainability Science Centre[1]; International Institute for Sustainability/ Rio Conservation and Sustainability Science Centre/ Faculty of Production and Power Engineering, University of Agriculture in Kraków/ University of East Anglia, School of Environmental Science[2]; Embrapa Soil[3]

The Atlantic Forest used to cover vast areas of longitudinal stretch of the Eastern coast of Brazil but it suffered serious deforestation. Despite having lost approximately 90% of its vegetation it still provides habitat to thousands of endemic species and contributes to provision of crucial ecosystem services to Brazilian population. Over the last years, restoration has been promoted to recover habitat and ecosystem services in this fragile environment. One of the bottlenecks of restoration is seedlings production due to high costs and low survival of the seedlings in the field. This study assessed the effect of biochar on Atlantic Forest seedlings used in ecological restoration. Biochar is obtained from residue pyrolysis, which can be applied on soil to improve its chemical and physical properties. In this study biochar was produced from *Gliricidia sepium*. The seedlings species used in the experiment were: *Schinus terebinthifolius*, *Cariniana legalis*, *Senna multijuga* and *Trema micrantha* (30 replicates each). The treatments were: control, 20% of biochar, 40% of biochar and limestone. The species' germination, height and stem diameter were measured monthly. Focus groups with tree-nursery owners' and interviews with stakeholders and cost-benefit analyses of the substrate were also carried out. The treatments with biochar were the most efficient in the germination of *Senna multijuga* and *Trema micrantha*. For *Schinus terebinthifolius*, *Senna multijuga* and *Trema micrantha* the use of biochar in their substrates showed the best cost-benefit. Using biochar as alternative in substrates compounds attracted the interest of the vast majority of the seedlings' producers. We conclude that biochar can be used to improve the performance of the seedlings tested here and decrease the cost associated with the production, substituting part of the substrates used in nurseries.

(5182 - 1645) The effect of using waste water treatment residual from pulp and paper industry on soil pH

Cristiane Pain[1]; Gabriela Naibo[1]; Jaqueline Gaio Spricigo[1]; Jonas Guerra[1]; Whelynton Candido[1]; Everton Skoronski[2]; Mauricio Vicente Alves[3]
University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê/SC, Zip Code: 89820-000, Brazil[1]; Professor, Environmental Engineering Departament, State University of Santa Catarina, Av. Luis de Camões 2090, Zip Code: 88520-000, Lages/SC, Brazil[2]; Professor, University of West of Santa Catarina, 696 - Dirceu Giordani Street, Jardim Tarumã, Xanxerê/SC, Zip Code: 89820-000; Brazil[3]

In the current stage of society development, concerns about the correct destination of residues from the pulp and paper industries, instigate the research to know the effects of the application of this waste in the agricultural soils.The residues applications on the soil can a number of changes in their physical and cheminal properties and consequently affect agricultural production. This study aimed to evaluate the pH of the soil under different doses of waste water treatment residual (WWTR) from a pulp and paper industry, since this residue is abundant in our region. The experiment was carried out at Unoesc, Campus of Xanxerê/SC. The soil was incubated in plastic bags, with 2 kg of soil, one characterized as Dystrophic Red Latosol/Oxisoil (EMBRAPA 2013), and another one from a Latosol B horizon. The chemical characteristics of the used soil in the experiment were: P = 0.55 mg dm^{-3}; K = 36.1 mg dm^{-3}; Al = 1.7 Cmolc dm^{-3}; H + Al = 8.3 Cmolc dm^{-3}; Ca = 1.73 Cmolc dm^{-3}; Mg = 0.78 Cmolc dm^{-3}; SOM = 2.24%; pH = 5.43; pH SMP = 5.44; CEC = 10.9 Cmolc dm^{-3}; Base Saturation = 23.87%; Clay = 61%, evaluated by the methodology described in Tedesco et al. (1995). The experimental design was completely randomized with seven replications. The treatments consisted of different doses of WWTR: Control (only soil), 10 t ha^{-1}, 20 t ha^{-1}, 40 t ha^{-1}, 80 t ha^{-1}, 160 t ha^{-1}, 320 t ha^{-1} and 640 t ha^{-1} of WWTR, calculated on a volume/volume basis (sludge with 23% moisture). Soil samplings for pH determination in water were performed each every 15 days after mixing and incubation, with the total experiment time of 120 days. After each sampling,50 ml of distilled water was added to maintain ideal soil moisture. It was observed that the pH value of the initial soil was 5.43 and an increasing was observed during the experiment, independent of the used WWTR dose. The highest pH value was found at 640 t ha^{-1} of sludge for all collection times. When comparing within the doses, the highest pH value found was 7.47 at time 8, in the treatment of 640 t ha^{-1}. It was observed that there was a tendency for pH stabilization over time and there was a significant increasing on soil pH when increasing the applied waste water treatment residual dose.

(5802 - 1832) Using Phosphorus Rich Biochar to Immobilise Pb in an Urban Contaminated Soil

Pacian Netherway[1]; Suzie Reichman[1]; Mark Laidlaw[1]; Jorge Paz-Ferreiro[1]
RMIT University[1]

There is no safe level of blood lead (Pb), nor is it known to serve any beneficial purpose in any process within the human body. The ingestion of Pb contaminated soils is a significant contributor to blood Pb levels; particularly in children. In soil, Pb can be present in many different mineral forms; some being more soluble than others. Once ingested, Pb travels down in to the stomach; an acidic environment with pH as low as 1.5 units. Generally, the solubility of Pb increases as pH decreases and so the stomach acts to extract Pb from the solid soil matrix, placing it in solution. This amount of Pb extracted is termed the bioaccessible fraction, which continues down to the small intestine where it can cross the intestinal epithelium and enter the blood stream. Pb phosphate minerals are the most insoluble form of Pb across a wide pH range, including in the stomach environment. As such, phosphorus can be added to Pb contaminated soil to facilitate the precipitation of Pb phosphates with the aim of decreasing the bioaccessible fraction. Biochar is the engineered product of heating biomass in an oxygen free environment (pyrolysis). The pyrolysis of feedstocks including poultry litter and biosolids produces high-ash biochar, possessing more available phosphorus than in the feedstock. In this study, these biochars were tested as a means to reduce in vitro soil Pb bioaccessibility. Our results found biochars to be comparable with phosphates for lead immobilization.

C3.3.12 - Sustainable land management in rural basins belonging to the south cone of Latin America

(7943 - 2439) Can we intensify rice-pastures rotations in Uruguay? Midterm impacts on soil organic matter.

Ignacio Macedo[1]; Virginia Pravia[1]; José Terra[1]

Instituto Nacional de Investigación Agropecuaria[1]

Soil organic carbon (SOC) is an important soil quality indicator. Rice-pastures rotations in Uruguay are unique sustainable production systems, challenged in the last decade by an increasing interest of production intensification. We evaluated soil use intensity impacts in a field-scale rice rotation systems experiment (33° 16' 23'' S; 54° 10' 24'' W; 22 MASL). Treatments were established in 2012 in a 34 yr rice-pasture rotation field (Natraquoll), including: 1) rice monoculture (RM, 1 yr), with *Trifolium alexandrinum* (TA) in winter; 2) rice-soybean (RSy, 2yr) with *Lolium multiflorum* (LM) and TA in winter; 3) rice-row crops (RC, 4 yr): rice-soybean-rice-sorghum with the same cover crops as RSy in winter; 4) rice-soybean-short pasture (RSySP, 6 yr) rice-soybean-soybean-rice with TA and LM during winter followed by 2.5 yr of a perennial pasture of *Festulolim sp.* and *Lotus corniculatus*; 5) rice-short pasture (RSP, 2 yr) rice rotating with a biannual pasture (1.5 yr) of LM and *Trifolium pratense*; 6) rice-long pasture (RLP, 5 yr) rice-rice followed by 3.5 yr of a perennial pasture of *Festuca arundinacea*, *Trifolium repens and Lotus corniculatus*. All rotations phases were present in time and replicated in space. Total SOC (TSOC), total nitrogen (TN) and particulate SOC and nitrogen (C-POM and N-POM; respectively, 53-2000 µm) (0-15 cm depth) were used to evaluate soil quality. After five years, no differences were found between rotations in TSOC and TN (29.3 Mg C ha^{-1} and 3.16 Mg N ha^{-1}). No differences were found in C-POM and N-POM when RLP was compared with RSP or RSySP. However, RLP had respectively 18% and 19% greater C-POM and N-POM content than cropping rotations (RSy and RC) (6.06 Mg C ha^{-1} and 0.48 Mg N ha^{-1}), representing around 23.6% and 20% of TSOC for RLP and RC-RS, respectively. The aggregate of data suggests that, for soils under rice-pasture rotations in temperate climates, there are possible pathways for intensification without losing SOC in the midterm. However, the absence of perennial pastures in the rotation can make SOC more vulnerable to loses.

(8880 - 2436) Carbon stocks in Caatinga forest soils under cutting management in a chronosequence

Renisson Nepomuceno de Araújo Filho[1]; Maria Betânia Galvão dos Santos Freire[1]; Fernando José Freire[1]; Rinaldo Luiz Caraciolo Ferreira[1]; Flávio Adriano Marques[2]; Bradford Paul Wilcox[3]; Jason Brossard West[3]
UFRPE[1]; EMBRAPA[2]; Texas A & M[3]

Storage of carbon (C) in soils contributes to C sequestration from atmosphere and has to be improved to achieve sustainability. In tropical humid forests the cutting management of vegetation may be applied at short time intervals because the vegetation grows quickly and promotes the constant uptake of C and its contribution to soil C. However, in dry forests as Caatinga, successive cuttings may change all the dynamics of the C in the soil-plant system. So this study aimed to investigate C stocks and microbial activity in soils under dry forest in Brazil submitted to cutting at different times in a chronosequence. Seven sites representing a chronosequence of forest cuttings: 0.5 year (6 months), 6, 9, 12, 25, 50 years, and undisturbed area (at least 80 years). Soil samples were collected at three depths (0–5, 5–10 and 10–20 cm). And were analyzed in: total organic carbon (TOC) concentration and stock, C in humic substances (FA, HA, HUM), labile-C, and microbial biomass-C. Microbiological activity was evaluated by: basal respiration, microbial quotient, and metabolic quotient, determined for the two shallow layers. C stocks and microbiological activity were changed by forest cuttings, promoting significant C losses related with the management time, especially in the shortest intervals. The return of C levels after cuttings spends long time periods. The recovery of C in soil on these sites is slow, requiring long time periods following disturbance. Maintenance of vegetation for long periods in Caatinga can return C storage to levels close to native areas. We estimate that TOC and C in humic fractions had recovered to only about 32% of the presumed maximum found for the 80-year site 20 years after cutting. At least 33 years between successive cuttings are necessary to recovery 50% of soil C in general. We concluded that forest management in Caatinga dry forests should restrict cuttings campaigns at time intervals longer than 30 years to rebuilt C stocks in soils, very important issue in the context of mitigating climate change on a global scale.

(5561 - 571) Chemical attributes of the soil in the passover / poultry / forest transition on the transamazonic road in the south of the Amazonas

Elilson Gomes de Brito Filho[1]; Alicia Rebeca de Souza Santos[2]; Elyenayra Nogueira Pinheiro[1]; Edivânia de Oliveira Santana[3]; Lucivania Izidoro da Silva[1]; Wildson Benedito Mendes Brito[1]
Universidade Federal do Amazonas[1]; Universidade Federal Rural da Amazônia[2]; Instituto Federal de educação, ciências e tecnologia do estado do ACRE[3]

Along the Transamazonian Highway that finishes in Lábrea a municipality of the South of the Amazon, are found several pasture areas that were once native forest , in Brazil it is estimated that the pasture area is 158,753,865 ha, of these 26,524. 174 ha are located in the North of which 806,300 ha in the State of Amazonas . The conversion of these forest areas into pasture areas ends up exposing the soil to changes, and its attributes are modified according to their use. The objective of this work was to verify the behavior of soil chemical attributes in this pasture / capoeira / forest transition. The study area is located on the Transamazon Highway at 11.5 Km from the center of the municipality of Lábrea in the south of the Amazon, the classification according to Köppen is of type Am. The material was collected in three areas, dirty pasture with predominance of Brachiaria spp. , Capoeira, and native forest, where samples were collected through two depths (0.00-0.10 and 0.10-0.20 m), where from the collected samples, these were used to dry the shade , where fine dry air (TFSA) was obtained after sieving and from this material followed the chemical analyzes (pH in water, phosphorus, potassium, calcium, magnesium, aluminum and organic carbon), and afterwards with the results of the analyzes followed for discussion through the averages obtained by each attribute. In relation to the pH values, this decreased in the transition, ie, it had the highest value in the pasture area (4.48) and the lowest in the forest area (3.83) . As for the values of potential acidity (H + Al), this had high values with the highest values in the forest area , calcium decreased during transition and potassium had no difference between areas. In relation to the organic carbon levels, this was higher in the pasture due to the organic matter already formed and stable and the second larger was the area of forest where it is justified with greater deposit of organic material, but not yet stable, what influence in the values of acidity, aluminum and consequently in low CTC (cation exchange capacity). As aconclusion we have that from the transition it is observed that the attributes change through their use, and that the conversion of the forest area into the pasture area is beneficial for the increase of the chemical attributes in the soil

(1305 - 3020) Comparative hydrology in paired watersheds with

different soil uses in Southern Brazil

Mayara Torres Mendonça[1]; Décio Oscar Cardoso Ferreto[1]; José Miguel Reichert[1]; Miriam Fernanda Rodrigues[1]; Mirian Valente[1]; Karina Wegermann[1]; Thaynara Diuliane Paz[1]; Rosane Barbosa Lopes Cavalcante[1]

Universidade Federal de Santa Maria[1]

Eucalyptus cropping for commercial purposes in southern Brazil has intensified in the least years. However, there is much divergence in the scientific community regarding the possible impacts of this practice on hydrological processes. Therefore, the objective of this study was to evaluate the influence of different soil uses on hydrological processes in two paired watersheds. We describe the water balance components (rainfall – P, interception – INT, streamflow – Q, actual evapotranspiration – ETa, groundwater recharge – G, and soil water storage – S) in a forest watershed (FW; 0,83 km²) with *Eucalyptus saligna* (10 year-old) and another watershed occupied with degraded grassland (GW; 1.10 km²) used for livestock production. The study was conducted from January to September 2017. The input parameters (P quantified by means of pluviometers and pluviograph) and output (INT, soil water percolation and Q, quantified by means of pluviometers, drainage channels and limnigraphs, respectively; and ETa water of the watershed. The ETa was obtained from the difference between the P and the other output variables. The total P occurring in the first, second, and third quarters of 2017 was 638, 559, 564 mm for FW and 535, 554 and 552 mm for GW, respectively. The output variables presented differences for the trimester and watershed studied. The P in the third trimester of 2017 was 563.9 and 552.3 mm for FW and GW respectively, however, the Q in this period was 60.7% higher in GW, which evidences the regularization of Q in periods of greater precipitation. The main water outlet in the FW was by ETa (1262 mm), which represented 71.6% of the P, of this total 38.4% was lost by INT. In the GW, the main water outlet was ETa (729 mm), which represented 44.4% of P. The Q in the first and third trimester of 2017 was 57.3% and 60.7% higher in GW compared to FW, respectively. S in FW was 392.9 mm, 22.3% of P, while G was higher in GW 530.4 mm, 32.3% of P. The different vegetation cover of the soil interfered in the hydrological dynamics of the watershed studied. The watershed with the main use with eucalyptus presented greater losses of water by ETa, being influenced by the greater water loss by plant interception, which contributed to a reduction of the streamflow of this watershed in relation to the watershed with degraded grassland.

(3585 - 2374) Delineating homogeneous management zones according soil fertility – Case study in a watershed in São Paulo, Brazil

Rafael Lacerda Cobra[1]; Mara de Andrade Marinho[1]

UNICAMP/FEAGRI[1]

By starting from the knowledge of the spatial variability of soil properties, the delineation of homogeneous zones of soil management (HZM) is a valuable approach to site-specific soil management. The objective of this work was to develop a procedure for delineating HZM with emphasis on soil fertility. The study was carried out in the Ceveiro watershed (Piracicaba, SP, Brazil). To generate the homogeneous zones according to soil fertility we made use of data from 234 sites distributed along the watershed. The conditioning factors of the soil fertility were the following: soil texture, organic matter content (MOS); potassium content (K^{+}); hydrogen content (H^{+}); exchangeable aluminum content (Al^{+3}); Calcium content (Ca^{+2}); magnesium content (Mg^{+2}); cation exchange capacity (CEC), base saturation (V%) and aluminum saturation (m%). Steps of the methodology included the modeling of the continuous in-depth variation of the soil attributes (up to 100 cm) by using the *spline of equal area* function, the estimation of average values to the depth of 0-40cm for each conditioning factor, and the interpolation of data in GIS environment to generate the maps of each conditioning factor. Each map was reclassified in five classes according to degrees of limitation for soil fertility: null, slight, moderate, strong and very strong. The maps of degrees of limitation were successively combined by addition to obtain the weighted cumulative indexes (WCI). At the end of the process, the value (total sum) of each polygon represented the WCI of that area. Finally, this map was reclassified according levels of the WCI (Lal, 1999) to distinguish the different homogenous zones of management according their deficiency in soil fertility. The final classification is homogeneous zones of very low, low, moderate, high, and very high deficiency of fertility. Results showed that in majority of the area (77%) the degree of deficiency by fertility is moderate. In this case, the soils are medium textured, the *solum* depth varies between 0.5 to 1.0 m, organic matter content varies between 10-20 g kg^{-1}, CEC > 5.0 $cmol_c\ kg^{-1}$, V% > 80%, Al^{+3} < 1 $cmol_c\ kg^{-1}$ and m% < 20%. However, in 18% of the area, the degree of deficiency is strong. We conclude that the methodological approach was efficient to delineate the HZM and segregate areas according to their degrees of soil fertility deficiency. The delineation of homogenous zones is a promisor tool to orient decisions on land use and management.

(4254 - 1358) Evaluation of the impact caused by the urban and industrial development to the natural soil resource in the Cienfuegos municipality.

M Sc Ing. Yodani López Fonseca[1]; M Sc Ing. Yamila Vigo Cuza[1]; M Sc. Mario Fuentes Gallardo[2]

Provincial Department of Soils.Ministry of Agriculture[1]; Agricultural Projects Company[2]

With the objective of updating the inventory of soils altered by the investment process in the municipality of Cienfuegos, as well as, the evaluation of the impact caused to the agricultural surface and the determination of its reduction by agro productive category in the agricultural sector, was developed the present investigation in the Provincial Department of Soils of the MINAG of said province. A participative methodology was applied that included the realization of a Territorial Workshop of this activity with the central provinces and a collective diagnosis, where the performance of the Office of Control and evaluation of the Earth (OCET) was evaluated in relation to the application of the current legislation regarding the change in land use. The information generated from the microlocalization files processed with change in land use was used over a period of 10 years (2006-2015). The analysis of the information obtained was processed by the AGRO Software 24 determining the agro productive categories of the affected soils in the process. With the investigation it was possible to determine the decrease of 240.43 ha of the agricultural area in the evaluated period, the soils with greater affectation were the Red Rendzina, with a total of 187.43 ha, representing 50.4%, the categories III and IV were the most affected, with forest areas having the greatest impact.

(6066 - 3043) Hydrological components in small watersheds with eucalyptus and grasslands: monitoring and SWAT modeling

Miriam Fernanda Rodrigues[1]; José Miguel Reichert[1]; Rosane Barbosa

Lopes Cavalcante[2]

Federal University of Santa Maria[1]; CMPC Celulose Riograndense[2]

Grasslands of the Pampa biome, in South America, are being substituted by crops and commercial eucalyptus, with potential impacts on ecological and hydrological response, especially in hydrological cycle of watersheds and river basins. We evaluated the influence of vegetation cover on hydrological components, by monitoring and modeling with SWAT and describing the water balance in two paired watersheds - one with natural grassland (1.10 km^2) and the other with eucalyptus (0.83 km^2), located in southern Brazil. The study was conducted from October 2012 to September 2014. SWAT model realistically simulated streamflow in small paired grassland and eucalyptus watersheds. Estimated actual evapotranpiration (ETa) and groundwater recharge (G), based on measured water balance components, were respectively 44.0 and 43.5% in FW, and 33.3 and 31.3% in GW. However, ETa and G simulation by SWAT showed ET was 658.7 and 730.9 mm, corresponding to 49 and 45% loss of the annual rainfall by ET for eucalyptus watershed and natural grassland. Model results showed 33 and 47% of groundwater, in eucalyptus and in natural grassland watershed, respectively. The small differences between estimated and SWAT-simulated ETa indicate efficiency of methods to quantify the water balance components, even though the differences in techniques were higher to represent groundwater recharge. Although the forest watershed had greater ETa compared to the grassland watershed, benefits such as greater interception and less surface runoff can be highlighted, for a condition where grassland was degraded and provided low aboveground biomass. Thus, the cultivation of eucalyptus stands may provide better structural conditions and ground cover, greater infiltration and soil water retention, and increased groundwater recharge, with consequent reduction of soil degradation by erosion and increased water availability during dry periods. Water balance in different land use watersheds may be simulated with SWAT model, and calibrated results are encouraging for hydrological processes simulation in small paired watersheds based on “acceptable” statistical indicators.

Keywords: Water balance; evapotranspiration; streamflow; groundwater recharge.

(4134 - 1377) Land systematization for soil and ecosystem services conservation. A Watershed level approach

José Daniel Oszust[1]; Marcelo Germán Wilson[2]; Emmanuel Adrián Gabioud[2]; Roxana Guadalupe Ramírez[3]; María Carolina Sasal[2]; Silvana María José Sione[1]; Celio Ignacion Chagas[4]

UNER Facultad Ciencias Agropecuarias[1]; INTA EEA Paraná[2]; UTN Facultad Regional Paraná[3]; UBA Facultad de Agronomía[4]

Water erosion is one of the main constraints of the current agricultural production, characterized by deforestation of native forest and the simplification of crop sequences. Taking advantage of the existing Soil Conservation Law in Entre Rios province (Argentina) that promotes water evacuation terraces to mitigate water erosion, systematization projects are usually carried out at the plot level and two types of terraces are currently predominant: narrow ridged terraces (non-cultivated) and wide ridged terraces (cultivated). To improve landscape heterogeneity and biological connectivity, the concept of linear elements was incorporated and a new type of terrace was promoted: reservoir terraces. This type, with wider dimensions and specific management guidelines, promotes the conservation of the soil and the conservation of ecosystem services, based on an integral view of natural resources management. It considers the ecosystem as a management intervention scale, inside the limits of the watershed. The objective was to evaluate the benefits of land systematization to reduce the loss of soil by water erosion and to increase the soil carbon stock and vegetable carbon stock. The study area is located in Aldea Santa Maria (Entre Rios province). A watershed of 2474 ha was selected. Three scenarios were simulated: i) reforestation for connection of isolated native vegetation patches and protection of watercourses, including the incorporation of linear landscape elements (i.e. reservoir terraces); ii) incorporation of soil conservation practices, in the plots of the watershed; iii) scenarios 1 and 2 combined. Carbon stock was determined in soil up to 30 cm and vegetable aerial biomass (arboreal, shrub and herbaceous strata) and soil loss was estimated with MUSLE model. Thus, with targeted reforestation, it is possible to increase the area of native forest from 12% to 20.5%, increase landscape heterogeneity and connectivity, which allows increasing structure and functionality to the agroecosystem. Scenario iii showed the best conditions. The soil loss was reduced in 10.16 T ha^{-1} $año^{-1}$ and carbon stock (includes soil and vegetation) was increased in 8% in the watershed.

(9473 - 504) Land use systems: the effect of cryptofauna on stubble decomposition

Cassani Mariano Tomás[1]; Sabatte María Leticia[1]; Perez Silvia Patricia[2]; Sfeir Alberto Jorge[3]; Massobrio Marcelo Juan[1]

Universidad de Buenos Aires. Facultad de Agronomía. Cátedra de Manejo y Conservación de Suelos, 4453 Avenida San Martín, Buenos Aires, 1417, Argentina.[1]; Universidad de Buenos Aires. Facultad de Agronomía. Cátedra de Climatología y fenología agrícolas, 4453 Avenida San Martín, Buenos Aires, 1417, Argentina.[2]; Universidad Nacional del Centro de la Provincia de Buenos Aires. Facultad de Agronomía. Cátedra de Conservación y Manejos de Suelos, 780 República de Italia, 7300, Azul, argentina.[3]

Soil regulates the most significant processes at the ecosystem level: production and decomposition processes. Cryptofauna communities play a key role in the functioning of ecosystems, as they control to a large extent the rate of decomposition of stubble. Cryptofauna is sensitive to disturbances generated by tillage systems. The aim of the work is to analyze the effect of cryptofauna on the rate of stubble decomposition in sites with different use histories. The study area is located in the peripheral hills of Azul, Buenos Aires, the soil is a typical Argiudol. Four sites with different degrees of artificialization of land use were selected (Site 1: 25 years closure, Site 2: no-tillage in favor of the slope for 15 years and no-tillage 10 years, Site 3: grid and weir in favor of the slope for 15 years and 10-year no-tillage, Site 4: 25 years of conventional tillage). Stubble losses were determined using litterbags with different mesh aperture diameters, microfauna ≤ 0.1 mm, mesofauna ≤ 2 mm and macrofauna ≤ 10 mm. Bags were removed from each site, every two months for 6 months, which were weighed after drying in a stove for 48 hours at 60°C. Decomposition was measured by dry weight loss resulting in residual stubble values. The rates of stubble decomposition were calculated for each size. Olson's negative exponential model was used to obtain decomposition rates. As a result, Site 1 showed the highest rates of decomposition and the greatest differences in participation percentages for each size of cryptofauna. Microfauna was responsible for the greater participation in stubble decomposition being followed by macrofauna while mesofauna had a very insignificant degree of participation. On Site 4, decomposition rates are the lowest of the sites, decomposition rates are the most similar among cryptofauna sizes. Sites 2 and 3 do not show any significant differences in the rates of decomposition in relation to Site 2 with Site 1 and the rates of Site 3 with Site 4. Differences in decomposition percentages were observed for these relationships, but not between site 2 and 3. The participation of mesofauna in sites 2,3 and 4 is highlighted, acquiring

increasingly important values in relation to Site 1. The observed results determine that in sites with a higher degree of artificialization, mesofauna becomes more important. The varying degrees of intensity of land use modulate the decomposition capacity of each group of cryptofauna.
Keywords: rate of stubble decomposition, litterbag, microfauna, mesofauna, macrofauna.

(8336 - 1018) Patterns in time and depth of soil water contents at some soil conservation practices. Mediterranean and arid zone of Chile.

Manuel Casanova[1]; Oscar Seguel[1]; Osvaldo salazar[1]; Yasna Tapia[1]
Universidad de Chile[1]

Irregular distribution in time and space of rainfalls in several zones of Chile significantly hinders the development of vegetal cover, triggering severe soil erosion processes. This work aims to evaluate the behavior of some soil and water conservation practices at hillsides level, analyzing the temporal profile of soil water contents with a FDR probe device (DIVINER 2000, Sentek), considering both dry and rainy season. At the Mediterranean rainfed zone (Inceptisol; 33° 28'S – 70° 50'W), soil water contents were measured in the soil profile (0-50 cm) within *Acacia saligna* and/or natural prairie and/or runoff harvesting plots after 15 years from establishment. At the semiarid rainfed zone (Aridisol; 31º26'S - 71º33'W) i) stone-lines with *Atriplex nummularia* and/or goat manure (0-30 cm), ii) half-moons with *A. saligna* and/or goat manure and/or organic emulsions (0-30 cm), and iii) graded soil material deposited above stone check-dams of gullies without vegetation (0-100 cm) were also monitored, after a recent establishments (1-3 years). Water harvesting, tillage and tree canopy influence were important factors in soil water dynamics within Mediterranean rainfed zone, with higher water contents (1-2%) and lower available critical soil water limit, compared with bare soil and not water harvesting system. At the semiarid rainfed zone, only goat manure additions increased soil water contents with a persisting effect in time for conservation practices (i & ii). Besides, natural deposits of sediments behind stony check-dams by runoff (iii) determine poor water storage conditions, but water retention is improved during winter and spring if goat manure in these structures is used or the sediments are artificially sorted in a particular layer sequence in depth with different soil textural classes (coarse-medium-fine). Although for a irrigated agriculture the reported soil water contents may seem unimportant, under degraded dry rainfed conditions these amounts are enough and can be critical for sustain a soil protective vegetal cover.
Keywords: water dynamics; drylands; soil and water conservation practices; water harvesting.

(2673 - 1472) Rate of reaction and neutralization of two calcareous byproducts in acid soils under different productive systems

Maria Paula Codina[1]; Valeria Cejas[1]; Omar Casanova[1]
Facultad de Agronomia, Universidad de la República[1]

The diversity of the soils in Uruguay is consequence of different parent materials and chemical characteristics, therefore each situation requires specific management. After many years of continuous extraction of nutrients by crops, and specifically due to the implementation of direct sowing, a progressive and sustained acidification of soils has occurred, limiting the growth of crops. For that reason, alternatives are needed to mitigate the consequences soil acidification, aiming to eliminate the exchangeable Al, one of the main sources of acidity. The aim of this research was to evaluate liming for soil acidity mitigation, testing two liming materials with different particle sizes, comparing their reaction velocity, as well as their neutralization capacity. The study was carried out under different production systems: grass-legume pastures, silvopasture, olive tree plantation, agriculture, and forestry. Field experiments were conducted in different regions of the country with six treatments: control (without liming), 2000 kg ha^{-1} of fine limestone, 2000 kg ha^{-1} of coarse limestone, 4000 kg ha^{-1} of fine limestone, 4000 kg ha^{-1} thick limestone, 2000 kg ha^{-1} of each material (fine and thick limestone). The soil was sampled at the beginning of the experiment; 30, 60, 120 and 180 days after lime application. With the samples dried, pH and exchangeable acidity were determined. The main result of this research was to demonstrate the differential behavior of the limestone sources, especially regarding their rate of reaction (measured as the change of pH and exchangeable acidity in time). In average the soil with coarse limestone had a pH of 5.8 in the last sampling, while in the soils with fine limestone pH was 5.0. The treatment with fine and coarse limestone showed the highest liming effect (pH 6.2), except in the sandy soils. These soils are extremely acidic, the application of high lime amounts produced a fast reaction, especially when fine lime was used. For both materials, the neutralizing capacity at the end of the evaluation did not show significant differences. As a side effect of the limestone application, there was an increase of mineral nitrogen and available phosphorus that should be highlighted, revealing an extra gain of these nutrients. We concluded that the soil type influenced in the reaction velocity of liming materials, with the highest rates in high fertility soils, while low fertility soils required longer periods to react.
Keywords: Liming; soil acidity; Uruguay.

(6550 - 594) Responses of water resources to land and soil management in a tropical small watershed under a Payment for Environmental Services public policy

Ricardo de Oliveira Figueiredo[1]; Timothy Richard Green[2]; Alexandre Ortega Gonçalves[3]; Matheus Martins Simioli[4]; Talita Varela Utsuni de Camargo Jesus[5]; Patrícia Porta Nova da Cruz[6]; Lucas de Camargo Reis[7]; Marisa de Cássia Piccolo[7]; Plínio Barbosa de Camargo[7]
Embrapa Environment[1]; USDA-ARS, Center for Agricultural Resources Research[2]; Embrapa Soils[3]; CNPq Scientific Initiation Scholarship[4]; FAPESP Technical Training Scholarship[5]; CNPq Pos Doc Scholarship[6]; CENA-USP[7]

The 12-km^2 Ribeirão das Posses Watershed (RPW), which is dominated by Ultisols and Inceptisols, is located in the south of Minas Gerais, Brazil. RPW discharges into the Jaguarí River, one of the most contributing rivers to supply the São Paulo metropolitan area. Over the last century in this watershed, the land use changed from native forests to more homogeneous vegetation for pastures, crops and forest plantations of eucalyptus, which have cumulative impacts on water yield and quality. To address this, a public policy was adopted establishing the Payment for Environmental Services covering three small watersheds of this river basin, including RPW. Since 2004, under such initiative, some small areas with vegetation of native species have been planted, especially in riparian zones, around springs, and at hilltop positions. Also some soil management has been conducted using small dams over the steep slopes and readjusting lines of cultivations to level counters. Therefore it is expected that water and soil ecosystems services will recover over time. The present work compares a streamwater quality monitoring conducted in 2017-2018 to the streamwater chemistry results obtained by other previous studies conducted from 2011 to 2016 in RPW. The main hydrobiogeochemical parameters evaluated here were: flow, temperature, pH, electrical conductivity, dissolved oxygen, carbon,

nitrogen and major dissolved ionic elements as well as suspended particulate matter. The results express how it is important that the stream sampling schedule cover rainy periods, which was possible using an automatic water sampler. Overall only a very small increase in water quality parameters was detected. The same was concluded for stream discharge, which depended primarily on the rainfall over the studied years. In the future, it would be interesting to compare the loss of sediments and nutrients from soils during the larger rainfall events, and how this can be accentuated if the changing climate confirms the increase of such events along with the amplification of dry periods. It is important to be aware that the ecosystem services provided by water in fact derived in part from good soil management, in a way that soil provides many ecosystem services, together with water by providing food, water filtration, regulating nutrient cycling, and other essential goods for life. In fact soil processes and functions are fundamental to assess ecosystem services and the effects of land use on them.

(4419 - 569) Space variability of chemical attributes of the soil with cupuaçu cultivation (Theobroma grandiflorum) in south of Amazonas

Carlos Henrique Gima Relvas[1]; Elilson Gomes de Brito Filho[1]; Elyenayra Nogueira Pinheiro[1]; Milton César Costa Campos[1]; Juliana Malta de Assis[1]; Francisca Xavier Quintino Neta[1]; Anderson Vieria Rodrigues[1]; José Igor Silva Praça[1]; José Maurício da Cunha[1]; Fernando Gomes de Souza[1]

Universidade Federal do Amazonas[1]

The Amazon region is characterized by the enormous diversity of life, both vegetal and animal, as well as human societies. Most of the arable soils of this region are acidic in nature, with low cation exchange capacity (CEC) and low natural fertility. This region is characterized by its advanced stage of weathering, presenting physical characteristics suitable for agricultural use, however with strong nutritional limitations. In the Amazon, edaphoclimatic conditions tend to present limitations on agricultural practices due to soil management or natural conditions. O objective of this study was to evaluate the space willvariat d soil acidity in cupuaçu cultivation area in the settlement project San Francisco in southern Amazonas. The study area is located in the city of Canutama, Amazonas, Brazil, located along the highway BR-319 .F hi conducted a mapping c om mesh 70 x 90, with regular spacing of 10 x 10, totaling 80 points three depth, 0.0-0.05; 0.05-0.10; 0,10-0,20m for determination of soil chemical properties (pH, (H + Al)(Al + M). The soil properties were analyzed by descriptive statistical analysis, assumptions of normality of data performed by the Kolmogorov-Smirnov test (KS) ($p \geq 0.05$) , using Minitab 14 software (MINITAB, 2000). By the analysis of geostatistics , it was possible to obtain the degree of spatial correlation of attributes , using the classification of CAMBARDELLA and t al. At descriptive statistics , mean and median values of the soil attributes were close , tending to a symmetrical distribution of the data, which can be confirmed by the coefficients of asymmetry and kurtosis close to zero , with coefficients s of asymmetry and kurtosis between 0 and 3. By chemical analysis of the soils , were characterized as acid soils, with an average of pH 3.84 , with the highest indexes in the layer of 0.00-0.05 m, which is due to the decomposition of the organic matter releases humic acid. As geostatistics, the s spherical and exponential models were the ones that best fit the data, except for the pH in the 0.00-0.05 layer that presented - PureNitrogen Effect (EPP). The degree of spatial dependence attributes were shown to be strong and moderate, with low spatial correlation range. However, the soil presented acidic, with exchangeable aluminum was the one that presented less degree of spatial dependence and greater reach.

C3.5 - Soil Degradation control, remediation and reclamation

C3.5.2 - Native metallophytes from mine spoils as a potential source for phytoremediation

(9595 - 1334) Accumulation of heavy metals in metalliferous soils of the North Caucasus and *Brassicaceae* species in connection with the reclamation of soils

Natalya Alekseeva-Popova[1]; Jaume Bech[2]; Irina Drozdova[1]; Irina Kalimova[1]; Núria Roca[2]

Komarov Botanical Institute, Russian Academy of Sciences, St. Petersburg, Russia[1]; Laboratory of Soil Science, Plant Biology Dpto, Faculty of Biology, University of Barcelona, Spain[2]

We have studied mining technogenic centers and their specific landscapes within the Karachay-Cherkess Republic (KChR) and the Republic of Dagestan (RD). Pro-mining production is a major source of environmental stress and water pollution. The present study generalizes the heavy metals (HM) distribution in soils of the areas located within polymetallic ore fields of the southern Dagestan, Urupsky sulfide deposit and Bedensky ultramafic massif of the KChR and their bioavailability for *Brassicaceae* plants. Plants and soils were analyzed for Fe, Mn, Zn, Cu, Ni, Cr, Cd and Co. The maximum concentrations of acid-soluble forms of Cu (23000 $mg \cdot kg^{-1}$), Zn (14000 $mg \cdot kg^{-1}$) and Cd (80 $mg \cdot kg^{-1}$) are found in soils of disturbed habitats in the zone of action of the Urupsky copper mining, Pb (89 $mg \cdot kg^{-1}$) – in soils in the area of lead-zinc mineralization on the slopes of the Shalbuzdak mountain in RD and Ni (264 $mg \cdot kg^{-1}$) – in soils of Bedensky ultramafic massif in KChR. The report deals with the specific features of the accumulation of HM in typical *Brassicaceae* species in various geochemical conditions of the North Caucasus. It was revealed the Ni, Cu, and Zn accumulator *Arabis sagittata,* Zn accumulator *Alyssum gehamense* and Ni hyperaccumulator *Alyssum murale.* An experimental study of the accumulation of HM by 7 species of *Brassicaceae* has been carried out on nutrient medium with different doses of Zn, Cd, Ni. It revealed Zn accumulator – *Alyssum gehamense* (1700 $mg \cdot kg^{-1}$) and Ni hyperaccumulator – *Alyssum murale* (12,000 $mg \cdot kg^{-1}$). An experimental study of the accumulation of HM by *Brassicaceae* species has been carried out on nutrient medium with different doses of Zn, Cd, Ni. At the same doses of metals, the maximum accumulation levels were: *Neslia paniculata* (1600 $mg \cdot kg^{-1}$ of Cd), *Alyssum gehamense* (1650 $mg \cdot kg^{-1}$ of Zn) and *Alyssum murale* (3800 $mg \cdot kg^{-1}$ of Ni). Thus, in the experimental conditions the higher accumulative capacity of HM was confirmed for *Brassicaceae* species. These species are prospect for the reclamation of HM enriched soils.

Universidade Federal Rural do Rio de Janeiro - UFRRJ, Seropédica, RJ, Brasil.[1]; Escola Superior de Agricultura "Luiz Queiroz" ” – EsalQ/USP, Piracicaba, SP[2]; Universidade Federal de Minas Gerais – UFMG, Montes Claros, MG[3]; Ecole Nationale Supérieure des Mines de Saint Etienne, GSE, CNRS UMR 5600, F42023 Saint Etienne, France[4]

Silica phytoliths from the leaves of *Setaria vulpiseta* (Lam.) Roem. & Schult growing spontaneously on gold-mine contaminated soil were extracted using the Environmental Protection Agency (EPA) 3052 method (HNO_3+HCl+HF) and analyzed for Cu, Zn, and As content. The leaves of the plants and the soil were also analyzed for Cu, Zn, Cr, Ni, and As content by the EPA-3050 method (HNO_3). The main objective was to determine the amounts of heavy metals present in the soil and organic part of the leaves and inside the structure of the silica phytoliths. The results show that the silica phytoliths comprise 3.9 % of the dry matter of leaves, and retain and store considerable amounts of heavy metals, especially Cu. In addition, we demonstrate that when the metals are estimated by the conventional acid digestion method (without HF), the amounts of metals absorbed by the plants are under-estimated because the silica phytoliths are not dissolved. Therefore, it is necessary to add the amounts of heavy metals found inside the phytoliths to the total amounts found in the organic part of the leaves. The silica phytoliths have high ability to sequester metals and make them unavailable in the environment. Our study should help in developing phytoremediation strategies using plants with high amounts of phytoliths.

(5536 - 513) Earthworms and arbuscular mycorrhizal fungi on the growth of *Canavalia ensiformis* in sandy soil contaminated with copper

Natielo Almeida Santana[1]; Helena Wichineski Trombeta[1]; Fernanda Cantoni[1]; Joice Aline Freiberg[1]; Zaida Inês Antoniolli[1]; Rodrigo Josemar Seminoti Jacques[1]
Universidade Federal de Santa Maria[1]

The high availability of copper in the soil causes reduced growth and even death of plants, and this problem is even greater in sandy soils such as those observed for grape cultivation in the Campanha Gaúcha region, Rio Grande do Sul, Brazil. The objective of this study was to evaluate the effect of arbuscular mycorrhizal fungi and earthworms on the growth of *Canavalia ensiformis* in a sandy soil with high copper content. A sandy soil was collected near a vineyard of the Campanha Gaúcha (30º48º27'00''S and 55º22'42''W), it was autoclaved, fertilized, added with limestone (to pH 6.0), the microbial population was reestablished and it was contaminated with 100 mg kg^{-1} of copper. The experiment was carried out in a completely randomized design in a greenhouse, soil moisture in 75% of the field capacity and four treatments which were: no fungus and without earthworm (control); with fungus; with earthworm; and with earthworm and fungus. Arbuscular mycorrhizal fungi inoculation was performed using 200 spores of *Rhizophagus clarus* and eight earthworms of *Eisenia andrei* were inoculated. Vegetal residue (5 g pot^{-1}) was added to the soil surface in all treatments, as a way of feeding the earthworms. The addition of 100 mg kg^{-1} of copper in the sandy soil resulted in the content of 97.77 mg kg^{-1} of Cu (Mehlich-1). Sandy soils have a low percentage of clay, oxides and organic matter, resulting in reduced cation retention capacity, with most of the copper added to the soil resulting in available forms. The treatments with the presence of arbuscular mycorrhizal fungi had a mean rate of colonization of 37%, not differing from each other. The presence of mycorrhizal fungi and earthworms favored the growth of the plant, with 53 and 50% increase in the shoot and root dry mass, in relation to the average of the other treatments. The earthworms become more active in the presence of mycorrhizal fungi, because they feed on hyphae, modify the bioavailability of nutrients in the soil and with this they favor the interception by the hyphae of the mycorrhizal fungi, increasing the nutrients absorption by the plants which results in greater growth. The mass of nodules was not modified (p= 0.5500) by the presence or absence of fungi and earthworms. The *C. ensiformis* plant present higher biomass production of shoots and roots in the presence of the mycorrhizal arbuscular fungi and earthworm.

(5779 - 2967) Effects of biochar on copper bioavailability and soil microbial communities in a metal-contaminated soils using metallophytes and agricultural plants

Sebastian Meier[1]; Francisca Moore[2]; María-Eugenia González[3]; Jorge Medina[2]; Alex Seguel[2]; Jaime Mejias[1]; Juan Hirzel[4]
INIA Carillanca[1]; Universidad de La Frontera[2]; Universidad católica de Temuco[3]; Inia Quilamapu[4]

The objective of this study was to investigate the effects of BCs on the Cu immobilization and over soil microbial communities in a Cu contaminated soil using a metallophyte and agricultural plants. A Cu contaminated sandy soil (338 mg kg^{-1}) was incubated with chicken manure biochar (CMB) oat hull biochar (OHB) and pine bark biochar (PBB) at the rate of 3 % w/w. The metallophyte *Oenothera picensis* and agricultural plants *Solanum lycopersicum* and *Lolium perenne* were grown in pots containing the incubated soils for three months. The BC promoted the plant biomass production and reduded de plant Cu uptake being its effect dependent of the biochar and plant used. The most evident effect was observed using CMB, which increased the shoot growth untill 14 times, whereas the root growth was increaded 4 times In the other hand, the BCs increased the soil pH (until 3 units), decreased Cu's easily exchangeable fraction and increased Cu bounded in organic matter and residual fractions. BCs provided favorable habitat for microorganisms that was evident in increased basal respiration and DHA activity. However, the BCs did not changed the microbial communities in all seasons and the changes were dependent on the type of BC and the doses applied. The above results suggest that biochars may be utilized to remediate Cu in contaminated soils and provide a favorable habitat for agricultural plants This research was supported by Fondecyt project number 11150480

(6653 - 1140) Geochemical distribution of trace metals in urban soils of Hualpen, Chile.

Pedro Tume[1]; Elizabeth González[1]; Felipe Reyes[2]; Juan Pablo Fuentes[1]; Nuria Roca[3]; Jaume Bech[3]
Universidad Católica de la Santísima Concepción[1]; Universidad Católica de la Santísma Concepción[2]; University of Barcelona[3]

The objectives of this study were (1) to determine the concentrations background of As, Co, Cr, Cu, Ni, Pb, V and Zn in the urban soils of Hualpen (Chile); (2) asses the level of contamination in the urban soil based on different pollution indexes and (3) to identify natural or anthropogenic sources in order to obtain a spatial distribution of the pollutants. A total of 153 samples were collected from the study area as follows: 51 topsoil samples (TS) (0-10 cm), 51 subsoil samples (SS)

(10-20 cm) and 51 deep soil samples (DS) (150 cm). The soils were characterized and the concentrations of trace metals were analyzed by ICP following aqua regia digestion. Multivariate analysis combined with spatial analysis were implemented in order to distinguish the sources. Several simple and robust statistical methods were applied to datasets in order to explore their potential in the evaluation of a useful and robust background values. The degree of contamination along with the geoaccumulation index, enrichment factor and contamination factor were also evaluated. The median concentrations obtained for elements includes As 3 mg kg^{-1}, Co 15 mg kg^{-1}, Cr 14 mg kg^{-1}, Cu 25 mg kg^{-1}, Ni 36 mg kg^{-1}, Pb 5 mg kg^{-1}, V 97 mg kg^{-1} and Zn 51 mg kg^{-1}. Multivariate analysis suggest that Cr, Pb, V and Zn are contributed by external sources. The spatial distribution of Cr, Pb V and Zn displays a spatial pattern extending along industrial environments and emission sources. The estimate background values determined with the DS samples with MAD method includes As 5 mg kg^{-1}, Co 20 mg kg^{-1}, Cr 18 mg kg^{-1}, Cu 33 mg kg^{-1}, Ni 45 mg kg^{-1}, Pb 3 mg kg^{-1}, V 108 mg kg^{-1} and Zn 48 mg kg^{-1}. The ecological indexes register a moderate to considerable contamination in some soil samples.

(2107 - 801) Growth and potential for phytoremediation of native grasses of South American grasslands grown in copper-contaminated soils.

Lessandro De Conti[1]; Lincon Oliveira Stefanello da Silva[2]; Anderson Cesar Ramos Marques[2]; Tadeu Luis Tiecher[1]; Adriele Tassinari[2]; Vanessa Marques Soares[2]; Ricardo Fagam Vidal[2]; Gabriel Sans[2]; Rodrigo Krames[2]; Gustavo Brunetto[2]

Instituto Federal Farroupilha[1]; Universidade Federal de Santa Maria[2]

The application of cupric fungicides gradually increasing copper (Cu) levels in vineyard soils, reaching in some cases, toxic levels to grapevines or cover crop species that co-habit the vineyards. Native grasses may present mechanisms adaptive to adverse soil chemical conditions, which increase the tolerance to excess copper (Cu), enhancing their use in the phytoremediation of these environments. The aim of this study was to evaluate the growth, distribution of Cu chemical species in soil solution and nutritional parameters of native grasses of South American grasslands grown in sandy soil with increasing Cu levels. The soil used in the experiment was collected in natural grassland in southern Brazil. The samples were air-dried; acidity, phosphorus and potassium levels were corrected and samples were then incubated. We used three Cu levels - natural level (Dose 0) and the addition of 40 and 80 mg Cu kg^{-1} (Dose 40 and 80). The soil (4 kg) was placed in 5 L pots. In August, three seedlings of *Axonopus affinis*, *Paspalum notatum* and *Paspalum plicatulum* were transplanted per pot and cultivated for 121 days. We collected soil solution throughout cultivation using Rhizon (MOM) lysimeters. In the solution, the concentration of the main cations, anions, dissolved organic carbon, pH were analyzed and ionic speciation was carried out. At 121 days after transplanting, the plants were collected to determine dry matter and nutrient concentration in the roots and shoots. The Cu accumulated in biomass, the bioconcentration factor and translocation factor were estimated. The growth of native grasses was reduced by excess Cu, diagnosed by the reduction in shoot and root dry matter yield at higher Cu level. Among the evaluated species, the *Paspalum plicatulum* is a grass species of South American grasslands with great potential to be used as cover crops in vineyards with high levels of Cu, because it has a greater capacity to reduce Cu bioavailability (Cu^{+2}) and maintain nutritional balance, which resulted in higher dry matter yield and Cu accumulation. Native grasses of South American grasslands can be used as phytostabilizing plants in Cu-contaminated soils, by accumulating the absorbed Cu predominantly in the roots, verified by the low values of Cu translocation factor, benefiting grapevines grown intercropped.

(4642 - 2176) Mine soil rehabilitation after hydrophilic polyacrylate polymers application and growth cycles with different autochthonous plant species

Erika S. Santos[1]; Luisa Carvalho[2]; Maria Manuela Abreu[2]; Maria Clara F. Magalhães[1]; Amarilis de Varennes[2]; Felipe Macías[3]

CICECO - Aveiro Institute of Materials, Department of Chemistry, University of Aveiro[1]; Universidade de Lisboa, Instituto Superior de Agronomia, Linking Landscape, Environment, Agriculture and Food Research Centre[2]; Departamento de Edafología y Química Agrícola, Facultad de Biología, Universidad de Santiago de Compostela[3]

The use of polyacrylate hydrophilic polymers can improved some characteristics of contaminated soils allowing a rapid herbaceous cover. In order to evaluate the environmental recovery of a soil developed on *gossan* materials (São Domingos mine, Portugal) with these polymers after growth periods with different autochthonous plant species, a mesocosm assay was performed in 3 phases. Four treatments were performed: (T1)control without polymer; (T2)with synthesized polymer; (T3)with polymer removed from diapers; (T4)with cut diapers. Firstly, *Spergularia purpurea* grew for 3 months followed by a plant cover with *Cistus ladanifer*, *Lavandula sampaiona* and natural herbaceous colonization for 10 months and *Erica australis* growth for 55 months. The objective of this study was to assess the chemical and biological characteristics of this remediated soil as well as the development and ecophysiological status of *Erica australis* in the 3rd phase. The initial soil had high total concentrations (g/kg) of Al (3.50–8.60), As (2.55–2.73), Cu (0.13–0.91) and Pb (4.48–6.16). At the end of the 3rd phase, the soil available fractions (rhizosphere method) of the elements were small and no differences were obtained among treatments (except Al, As, Mg). Available concentrations of Al and Mg in the remediated soil were higher than in T1 while the opposite occurred for As. The polyacrylate polymer did not lead to an increase of the pH (≈6.6), fertility ($C_{organic}$, $N_{mineral}$ and extractable P and K) and biological activities (dehydrogenase, β-glucosidase, acid phosphatase, celulase, urease) in the remediated soil compared to T1. Elements concentrations (nutrients, potentially hazardous elements) in *E. australis* shoots and fresh biomass amounts (g; T1: 36.1; Polymers treatments: 30.8-36.2) were similar independently of the treatment. Elements concentrations in shoots were below phytotoxicity except for Cu which can be considered as deficient (≈3 mg/kg). The highest H_2O_2 concentrations were quantified in control shoots (µmol/g; T1: 23.8; Polymers treatments: 8.4-14.8) indicating that these plants can be under stress. Total glutathione concentration in control shoots reached the lowest value while for total ascorbate no differences were obtained. Plants from T3 and T4 had lower concentrations of total chlorophyll, anthocyanins and carotenoids than the control. On the long term, the contribution of the plants seems to be more effective for the soil recovery than the type of polymer applied.

(9141 - 363) Performance of resistant-rhizobacteria bioaugmentation-assisted phytoextraction by grasses applied in multi-metal(loid) contaminated soils

Cácio Luiz Boechat[1]; Filipe Selau Carlos[2]; Patrícia Giovanella[3]; Clésio Gianello[4]; Enilson Luiz Saccol de Sá[4]; Flávio Anastácio de Oliveira Camargo[4]

Federal University of Piauí[1]; Rio Grandense Rice Institute[2]; State University of São Paulo[3]; Federal University of Rio Grande do Sul[4]

Phytoremediation can be enhanced with microbe associations, and it is better if compared with bioremediation or phytoremediation alone. The objective was to investigate heavy metal and bioaugmentation effects on the metal uptake by *Sorghum bicolor* and provide insight for using native bacteria for enhancing heavy metal accumulation. A factorial scheme was used, consisting of two soil samples with less (SS1) and more (SS2) metal concentration, and eight treatments, including the non-inoculated control, single inoculation with metal-resistant bacteria *K. intermedia* (Ki); *K. oxytoca* (Ko); and *C. murliniae* (Cm) metal-resistant rhizobacteria and four bacterial consortia, with five replicates. In plants grown in the SS1 values greater than one (>1) have been observed for the translocation factor for Ba in the control and Cm treatment. However, in the SS2 translocation factor > 1 for Ki; Cm; Ko; Ko + Cm and Ki + Ko + Cm for the Cd; for Ki; Ki + Ko; Ki + Ko + Cm and control for As and to Ki for Ba were observed. Tested metals accumulated primarily in the roots. The restriction of metal absorption and translocation to the shoots may be related to the avoidance mechanism in the roots. All treatments in the SS1 bioconcentration factor values were higher than 1 for cadmium (Cd) and lower for Cr, Pb, As and, Ba, except for Ba in the Ko + Cm treatment. In SS2 the bioconcentration factor values for Cd in all treatments were higher than 1. However, for Cr values were less than 1 in all treatments. The bioconcentration factor values for Pb ranged from 0.8 to 1.2 in SS2, being higher than in SS1. For As they ranged from 0.6 to 1.2 and for Ba they ranged from 1.1 to 1.4 in SS2. This result shows that sorghum plants have mechanisms that prevent the entry of heavy metals when it is at a high concentration in the substrate. Sorghum cultivated in SS1 had both factors higher than one associated with microbiological treatments, so this technology makes the species suitable for use in phytoextraction of these elements. Moreover, species tolerant to heavy metals with high bioconcentration factor and low translocation factor can be used in the phytostabilization of contaminated sites, along with other plant cover. From these studies, it can be concluded that by inoculating the rhizosphere soils with selected metal-resistant bacteria, it should be possible to improve bioavailable metal concentrations for plant uptake and thereby phytoextraction potential in metal-contaminated soils.

Keywords: Metal phytoextraction; Metal bioavailable; Biotechnology; Translocation factor; Bioconcentration factor.

(4334 - 1435) Selection of native tree species for the phytoremediation of copper-polluted soils under tropical climate

Verónica Asensio[1]; Flávia Garcia Flórido[1]; Francisco Ruiz[1]; Fabio Perlatti[1]; Xosé Luis Otero[2]; Tiago Osório Ferreira[1]

Department of Soil Science, University of São Paulo (USP/ESALQ)[1]; Department of Edaphology and Agricultural Chemistry, University of Santiago de Compostela – USC[2]

Mine tailings containing metal sulphides may trigger acid mine drainage and the potential production of highly acidic waters, with high concentrations of sulphate metals. Reclamation of metal-polluted soils with phytoremediation plants have been proved as efficient, low cost and ecologically sustainable. Due to the lack of studies evaluating such technique in tropical soils by using native tree species, the main goal of the present work was to find these type of species for the phytoremediation of copper-polluted soils under tropical climate. The soils located in the abandoned copper mine "Pedra Verde", under semi-arid tropical climate, were selected for the phytoremediation study. Five tree species were selected (Pink Cedar, Yellow Ipê, Copaíba, Jatobá and Sabiá) by taking into account the natural flora of the surrounding area of the mine, a virtual herbarium, the vegetation recorded in a national park near to the mine and a review about Brazilian native plant species tolerant to high concentration of metals. Two more species were selected due to their incidence in the mine area and wide geographic distribution: Embaúba and Aroeira Preta. Seedlings of the seven species were planted in pots with an unpolluted Arenosol and grown under greenhouse conditions. Soils were polluted to rise 60, 100 and 500 mg kg^{-1} Cu, based on the prevention and intervention values for soils in residential areas according to the Brazilian legislation (60 and 500 mg kg^{-1}, respectively). Height and stem diameter were measured 15, 30, 45 and 60 days after planting. Plants were harvested, and biomass and total Cu concentrations were determined in leaves, stem and roots. Copper concentration in soils was analysed by a sequential extraction. The results shown that the seven studied native trees are promissory species for the phytostabilization of copper in soils under tropical climate. All studied species accumulated high concentration of Cu in roots and extracted a considerable amount from the soil within three months. Jatobá, Embaúba and Copaíba were the species extracting more. They took up from 3 to 20 mg Cu from the polluted soils. Embaúba can be considered as hyperaccumulator of copper according to the bioaccumulation factor (BAF). Although these results should be validated under field conditions in a soil naturally polluted with copper, the present study evidence the potential of seven tree species native from tropical regions for the phytoremediation of copper-polluted soils.

Keywords: copper; mine soil; remediation; tree species; sequential extraction.

(3809 - 1352) Selection of winter cover crops for copper phytoremediation

Diogo Vendruscolo[1]; Natielo Santana[2]; Helena Wichineski Trombeta[2]; Alfredo do Nascimento Junior[3]; Rodrigo Josemar Seminoti Jacques[2]

Emater/RS[1]; Universidade Federal de Santa Maria[2]; Embrapa Trigo[3]

Copper is an essential nutrient for the growth of plants, however when it concentrates high levels of Cu in the soil, it becomes toxic to the metabolism of plants. Vine cultivation demands many applications of copper based pesticides for the control of fungal diseases. In Rio Grande do Sul state of Brazil, vine cultivation is widespread and, therefore, many areas are contaminated by copper in the soil. The aim of this study was to select winter soil cover crops that are promising for the phytostabilization and phytoextraction of copper in a soil with high levels of copper. A not contaminated Cambisoil was collected in a region with many vineyards in the Serra Gaúcha. Subsequently, 200 mg kg -1 of Cu in the form of copper chloride (66.66%) and copper sulfate (33.34%) were added. Nine genotypes of winter cover crops were grown under greenhouse conditions: Anahuac Wheat (*Triticum aestivum*), IPR89 Rye (*Secale cereale*), Wintestar Ryegrass (*Lolium multiflorum*), BRS serrano Rye (*Secale cereale*), EMBRAPA Triticale (*Triticosecale rimpaui* Wittm), IPR 111 Triticale (*Triticosecale rimpaui* Wittm), IAC Wheat (*Triticum aestivum*), PFS050 Rye (*Secale cereale*), Ponteio Ryegrass (*Lolium multiflorum*). Soil moisture was maintained

at 80% of field capacity. Results of dry mass production and copper contents in shoot and root system were evaluated. Data were submitted to analysis of variance through the statistical program Sisvar. Among the nine evaluated genotypes, "Ponteio" ryegrass and ryegrass "EMBRAPA" were the ones that presented the lowest dry mass production, probably due to a lower tolerance to high values of copper in the soil. Copper toxicity causes damage to the physiological metabolism of plants, interfering in processes such as electron transport, reduction in the number and volume of chloroplasts, which affects the photosynthetic activity and, consequently, will reduce the production of dry mass. The "Anahuac" wheat genotype, on the other hand, presented higher dry mass production of shoot and root, in relation to the others. Wheat "Anahuac" and "Wintestar" ryegrass genotypes presented a high concentration of copper in the root system and produced the highest root dry mass among the genotypes, in addition, they presented low copper concentration in the aerial part. Therefore, highlighting as potential phytostabilizers of copper in the soil, since in this process the metals are concentrated in the roots and there is a low translocation to the aerial part.

C3.5.3 - Frontier of soil quality evaluation after remediation of contaminated field

(3069 - 1819) Arsenic content and speciation in soil samplesduringrice growth cycle

Napatsorn Notesiri[1]; Prapaipit Srimawong[1]; Onanong Chomsiri[1]; Wirongrong Songarom[1]; Jutharat Yimchaluay[1]; Orathai Sukreeyapong[1]

Office of Science for Land Development, Land Development Department[1]

Arsenic content and speciation in soil samples from paddy field during rice growth cycle of four plots: Pathum Thani1, Khao Dawk Mali 105, Red Hawn Rice and Riceberry were study by sequential extraction. The nine sequential extraction methods include: 1) water 2) ammonium nitrate 3) ammonium sulfate 4) ammonium phosphate 5) ammonium fluoride 6) hydroxylamine hydrochloride 7) ammonium oxalate 8) ammonium oxalate – ascorbic 9) nitric : perchloric. The sequential extraction results from Pathum Thani1 soils expressed arsenic was mostly in bound to Fe oxide (28.6%). Most arsenic in Khao Dawk Mali 105 soils during seedling, tillering and panicle initiation stage are residual form (24.7-26.5%), whereas arsenic in other stage bound to Fe oxide (26.3-28.2%). Arsenic in Red Hawn Rice soils and Riceberry soils were mostly in bound to Fe oxide (23.1-26.9% and 23.6-32.4 respectively). Moreover, arsenic mobility percentage in soil growing rice of Pathum Thani1, Khao Dawk Mali 105, Red Hawn Rice and Riceberry were 21.9, 24.6, 24.5 and 24.4 respectively.

Keywords: Arsenic, paddy field, soil, sequential extraction

(3116 - 738) Attenuation of lead accumulation in rice grains with iron amendment on paddy soil and related to iron oxides formation in rhizosphere

Kai-Wei Juang[1]; Pei-Rong Du[1]; Yu-Cheng Lai[1]; Chien-Hui Syu[2]; Dar-Yuan Lee[3]

Department of Agronomy, National Chiayi University, Chiayi City, Taiwan[1]; Taiwan Agricultural Research Institute, Council of Agriculture, Executive Yuan, Taiwan[2]; Department of Agricultural Chemistry, National Taiwan University, Taipei City, Taiwan[3]

Accumulation of lead (Pb) in paddy soils exposed to various pollution sources has been posing risk to the food safety of rice (*Oryza sativa* L.). So far few studies were conducted on the uptake and distribution of Pb in rice plant, the Pb toxicity to rice plant growth and grain yield, and the differences among rice cultivars in Pb uptake and accumulation from soil. Recently, the iron oxides deposited on both the soil solid and the root surface in the rhizosphere have been found to be related to the Pb accumulation in rice plants. The use of agronomical practices and soil management techniques to enhance iron oxides deposited in the rhizosphere of paddy could prevent Pb levels in brown rice from exceeding the allowable level (0.2 mg kg^{-1}). In this study, a field experiment was conducted to evaluate the effectiveness of iron chloride treatment in paddy soil on reducing the Pb concentration in rice grain and to examine the relationships between iron oxides formation in rhizosphere and Pb accumulation in rice plant. The study site is a paddy field located in Wuxi river basin, central Taiwan, contained soil Pb concentrations in a range about 100-600 mg kg^{-1}. Four cultivars of Taiwan rice, that include three japonica rice (TK9, TK16, and KH145) and one indica rice (TCS10), were used in the experiment for illustration. The treatment level of iron chloride ($FeCl_3$) was as about 1000 mg-Fe kg^{-1}. In the results, the $FeCl_3$ amendment significantly reduced the soil available Pb in rhizosphere and the Pb concentrations in rice plant. The $FeCl_3$ amendment enhanced the Pb sequestration by the iron oxides on rhizosphere rather than on root surface. More strongly sequestered Pb by iron oxides on rhizosphere soil would result in less Pb accumulation in rice grain. In summary, the iron oxides deposited on rhizosphere maybe dominated the Pb sequestration and retarded the Pb absorption by rice plant. One could try to enhance iron oxides deposited on rhizosphere with $FeCl_3$ amendment to reduce Pb absorption by rice plant in a potentially contaminated paddy field.

(9600 - 2957) Can fungi and bacteria counting be used as an indicator of soil recovery?

Thaís Soto Boni[1]; Kátia Luciene Maltoni[1]; Adriana Avelino Santos[2]; Ana Maria Rodrigues Cassiolato[1]

Unesp - Ilha Solteira[1]; [2]

The soil microbiological community study can be useful to indicate if changes are occurring, allowing in a short period of time to evaluate if a degraded soil is in recovery or not. The objective of this work was to evaluate the number of colonys forming units (CFU) of bacteria, and fungi, in a degraded area submitted to recovery processes, to verify if these can be used as recovery indicators of degraded soils. The experiment was conducted in the Cerrado domain, at central-western region of Brazil, municipality of Selvíria/MS, in an area degraded in 1960s, during Hydroelectric Power Plant construction. This area had the vegetation, and soil layers (10 m deep), removed, and remained without signs of recovery for 50 years. To induce the recovery, 3.4 ha of this area were mechanized, conditioned with residues organic (macrophytes, 0.0 to 32 t ha^{-1}) and agroindustrial (ash from sugarcane bagasse, 0.0 and 45 t ha^{-1}), in nov/2011, all with 03 replicates, established in plots of 600 m^2, which received 1,080 seedlings of 10 different Cerrado tree species (feb/2012), with the intention of inducing the soil recovery. After 5 years, the soil colonization by bacteria and fungi was evaluated, from composed samples (6 simple),

from 0.0-0.1 m deep, of experimental area (EA), degraded area without intervention (DAWI) and conserved Cerrado (CER). After sieved (2 mm), 10 g of soil received 90 mL of saline solution (0.85 %), and the serial dilutions (10^{-2} to 10^{-4}) were prepared and inoculated on petri dishes, with specific culture media, which were incubated at 28 °C for 3 days. Agar (pH 6.5) was used as a medium for bacteria, and Sabourad (pH 5.5) medium, plus colony reducer and antibiotic were used for fungi. The results, submitted to variance analysis and Dunnett's test ($p < 0.05$), showed different number of CFU among residue and areas. The number of CFU bacteria was quite high for CER and different of the other areas (966.66, 95.33 and 2.33 x 10-4 CFU mL^{-1} soil, for CER, EA, DAWI, respectively). The number of fungal CFU did not show differences among the considered situations, suggesting that these are common occurrences even in degraded areas. However, the CFU of bacteria pointed up to recovery, approaching the values of the CER and surpassing the DAWI. In this way, the interventions performed were positive, the CFU of bacteria were more sensitive to the treatments, and indicated recovery of the area under anthropic intervention.

(8830 - 1517) Edafic mesofauna in constructed minesoil under different perennial grasses

Eloy Antonio Pauletto[1]; Luiz Fernando Spinelli Pinto[1]; Lizete Stumpf[2]
Universidade Federal de Pelotas[1]; Universidade Tecnológica Federal do Paraná – Campus Dois Vizinhos[2]

The reestablishment of the ecological balance of the post-mining soil depends primarily through the revegetation of the recomposed area, because the plants are responsible for the recovery of the landscape, for the control of the erosive processes and for the re-adaptation of the attributes of the constructed minesoil. Therefore, as already observed in soils under agricultural management, the type of vegetation cover can interfere in the population of the organisms of the constructed minesoil, reducing its density and diversity in relation to non anthropized natural areas. The objective of this work was to evaluate the influence of perennial grasses on chemical attributes and the population of mites and springtails of a constructed soil after coal mining. The study was conducted in a coal mining area, located in Candiota, State of Rio Grande do Sul. The treatments evaluated were: T1 – Hemarthria altissima; T2 – Cynodon dactylon cv Tifton 85; T3 – Paspalum notatum cv. Pensacola; T4 – Urochloa brizantha; T5 – spontaneous vegetation. For comparative effects were used the control treatments: T6 – soil constructed without vegetation; T7 – soil constructed under native vegetation for 15 years and the T8 – natural soil. In 2014, 64 soil samples were collected in 0.00-0.10 m soil layer for the determination of chemical attributes and soil mesofauna. After 11 years of revegetation, the different perennial grasses were efficient in promoting adequate conditions for the survival of mites and springtails when compared to the soil constructed without vegetation and the soil constructed under native vegetation for 15 years. However, in relation to the natural soil, the biological quality of the soil constructed is still much lower. The Hemartria altissima was the species that highlighted positively among the perennial grasses, providing better conditions for the survival of mites and springtails, until the present moment. The chemical soil condition showed a positive relationship with the development of plants and presence of mites and springtails.

(5213 - 227) Effect of diesel and engine oil on the growth and yield of tomato (*Lycopersicon lycopersicum*)

Dr. S. Amhakian[1]; Audu Aminu[1]
Kogi State University, Nigeria[1]

This study evaluates the influence of diesel, engine oil, combined diesel and engine oil, and NPK fertilizer (NPK 15-15-15) on soil physico-chemical properties, growth and yield of tomato (Lycopersicon lycopersicum) during 2014 cropping season. The pot experiment was conducted at Faculty of Agriculture Complex, Kogi State University and the field experiment was conducted at Kogi State University Students Research and Demonstration Farm, Anyigba. The pot experiment was a Completely Randomized Design (CRD) and field experiment a Randomized Complete Block Design (RCBD) with fourteen treatments and three replicates. Results of the research showed that applied diesel, engine oil and mineral fertilizer (NPK) significantly influenced soil physical properties both in pot and field experiments. Application of diesel, engine oil and NPK fertilizer significantly ($p \leq 0.05$) increased nitrogen, available phosphorus, calcium, potassium, lead and copper while combined diesel and engine oil significantly ($p \leq 0.05$) increased organic carbon and soil p^H under both pot and field experiments. In this research, it was observed that all growth parameters (plant height, number of leaves and stem girth) decreased with application of diesel, engine oil and their combinations, while plots treated with NPK fertilizer alone (D0E0+NPK) gave higher fruit yield. However, single rates of diesel and combined diesel and engine oil showed severe decrease in all the growth and yield parameters. This study has demonstrated that diesel and engine oil had negative significant ($p \leq 0.05$) effect by affecting some soil chemical parameters such as Mg and Na, increased copper and lead uptake, and reduced growth performance whereas, mineral fertilizer application encouraged high growth and yield of tomato.

(4698 - 805) Effect of the incorporation of cu and fe nanoparticles in the availability of cadmium in agricultural soil

jonathan suazo[1]; Maria de la luz Mora[1]; Nicolas arancibia Miranda[2]
Universidad de la Frontera[1]; Universidad de Santiga de Chile[2]

The prolonged use of phosphate fertilizers and sewage sludge in Chilean agricultural soils to supply nutrient demand has led to the accumulation of Cd. Cd in soils can be absorbed by plants and subsequently enter the food chain, which can cause diseases such as bone degeneration, renal dysfunction, liver damage in humans. Considering this situation, the use of nanoparticles (NPs) to stabilize and decrease the mobility of Cd is an economical and efficient alternative because they have a high surface area and high reactivity. Accordingly, the objective is to evaluate the availability of Cd in agricultural soils after the incorporation of FeNPs and CuNPs. In this work, Fe and Cu NPs were synthesized according to Qing-ming et al., 2012. The adsorption kinetics were made with 1 g of soil, 10% NPs and 200 $mg \cdot L^{-1}$ Cd^{2+}, 0.01 M KNO_3, at pH = 4.0. For incubation, 27 mL of a solution of Cd^{2+} (200 mg L^{-1}), 0.01 M KNO_3, pH = 4.0 and 10% NPs were added to 100 g of Ultisol soil ((Collipulli, (HA)) and sequential extraction was performed at day 1, 30 and 60. The sorption kinetics of Cd^{2+} in Collipulli (C), and C-10% CuNPs and C-10% FeNPs showed a better adjustment to the pseudo second order model, being the sorption capacity (q_e) by Cd^{2+} C>C-10% CuNPs> C-10% FeNPs. Whereas incubation showed that, after adding 10% CuNPs the availability of Cd^{2+} increased, because it shifted from the reducible fraction to the exchangeable fraction. In similar way, 10% of FeNPs significantly increased the concentration of Cd^{2+} bound to the exchangeable fraction and reducible fraction, in addition to acid components. Therefore, it was concluded that FeNPs and CuNPs increase the availability of Cd^{2+} in agricultural soils.

(2424 - 1611) Identification and classification of strong and severe soil degradation in Capão do Leão municipality, Rio Grande do Sul State, Brazil

Luiz Fernando Spinelli Pinto[1]; Ricardo Decker da Cruz[2]; Pablo Miguel[1]
Universidade Federal de Pelotas[1]; Mineral do Brasil[2]

The Global Assessment of Soil Degradation, GLASOD, has been used to assess the status of worldwide soil degradation considering the type, extent, degree, rate and causes of degradation. The present work aimed to identify, quantify and classify the strong and severe soil degradation in the municipality of Capão do Leão, Rio Grande do Sul State (Southern Brazil), through the use of geotechnologies. Besides the degree of degradation (strong or severe), in order to perform a local scale classification it was proposed a more detailed classification criteria including the identification of the agent of the degradation (agriculture, mining, urbanization, construction activities, borrow areas, flood, etc), the specific agent of the degradation, the erosive activity (weak, moderate, strong, and very strong), and the reclamation complexity type (0 to 4 in order of complexity). A total of 744 degraded areas were identified, varying in size, shape and intensity, totaling 474.9 ha (0.61% of the municipality area). Mining (sand, granite and clay) was the main agent, corresponding to 361.4 ha of the degraded areas (76% of the total), followed by borrow areas (61.8 ha - 13% of the total), mainly for dams and roads. Of the total, 69 areas (224.27ha or 47%) are in a degree of extreme degradation with strong or very strong erosive activity, requiring a reclamation that involves a continuous intervention with topographic conformation (3 and 4 order of complexity), needing redirection of use in some cases (4 order of complexity).

(7068 - 793) *In Situ* Field-Scale Immobilization of Lightly-moderately Cadmium-Contaminated Paddy Soil Using Soil Amendments

Jiachun Shi[1]; Long Meng[1]; Laosheng Wu[2]
Zhejiang University[1]; University of California, Riverside[2]

In southern China, Cd-tainted rice produced in Cd-contaminated acidic paddy soils is a serious health concern. In order to develop effective management practices to reduce Cd uptake from soil by brown rice, four soil amendments(e.g., lime, biochar, soil conditioner and seaweed organic fertilizer) combined with two rice cultivars(Yongyou17, YY-17; and Xiushui09, XS-09) with different Cd accumulation abilities were selected to evaluate the efficacy of in situ immobilization in a lightly-moderately Cd-contaminated paddy soil. Results showed that lime, biochar and soil conditioner significantly increased soil pH and reduced Cd bioavailability compared with control. Linear regression analysis showed that the decrease in Cd bioavailability was significantly and positively correlated with soil pH increase ($P < 0.001$). The Cd concentrations in brown rice were 0.34 and 0.22 mg kg^{-1}, respectively, in controls for the cultivars, while the rice produced from the soil amendment treated plots was lower than the China Food Safety National Standard limit of Cd (0.2 $mgkg^{-1}$). Considering the costs and the convenience of actual practice, the soil conditioner was the best amendment. In conclusion, in situ immobilization combined with low Cd accumulation rice cultivar is an effective approach for food safety in lightly-moderately Cd-contaminated acidic paddy soils.

(4250 - 1715) Mycorrhizal spores distribution in soil under ecological restoration systems of Atlantic Forest in Paraná State, Brazil

carlos alberto casali[1]; Fernando Campanha Bechara[1]; Letícia de Alcântara Dores[1]; Paula Edriane Saugo[1]; Fernanda Gama Siqueira[1]; Bruna Larissa Feix[1]; Luiz Antônio Zeni do Prado[1]; Vinícius Renan Spiassi[1]; Anna FLávia Neri Almeida[1]; Flávia Lima Moreira[1]
utfpr-dv[1]

Paraná state accounts for 20% and 8% of grain and animal Brazilian productions, respectively (SEAB-PR, 2015). Those numbers were reached due to indiscriminate occupation and deforestation of the Paraná Atlantic Forest, mainly araucaria forests. Thus, an ecological restoration of several areas is needed, mainly to adapt rural properties to the new Brazilian forest code (Federal Law 12.651 / 2012). Ecological restoration takes place through human interventions that seek to improve and accelerate ecological succession, including soil. The objective of this study was to evaluate the effect of ecological restoration systems on soil arbuscular mycorrhizal fungi (AMF) in Paraná Southwest, Brazil. The study was carried out in experimental area to Universidade Tecnológica Federal do Paraná, Campus Dois Vizinhos (UTFPR-DV) (geographic coordinates 25º41'40.47 "S and 53º06'12.82" W), with 502 m of altitude on Subtropical Humid climate and average rainfall of 2,044 mm. The Biome is Atlantic Forest with elecotono between Mixed Ombrophylous Forest and Semidecidual Seasonal Forest on a red Nitosol. From the 80's until 2009 the area was cultivated with annual crops. In December 2010, the following treatments were implemented: passive restoration (RP); planting of trees in total area under fill and diversity (PA) lines; and nucleation (NC), under a randomized complete block design and 4 replicates. A marginal secondary forest was used as a reference area. In November 2016 the soil was sampled in the 0-5 cm layer, which were sieved in 2.0 mm and stored in a refrigerator. The AMF spores were extracted according to the wet screening method (Gerdemann; Nicolson, 1963) and computed by Binocular Stereoscope. The data were submitted to analysis of variance and when significant the Scott-Knott's test was applied at 5% probability. There was a significant effect of ecological restoration systems on the total amount of AMF spores in the soil, to the planting of trees differing from passive restoration and nucleation. However, none of the restoration systems reached the amount of spores that where found in established secondary forest soil, indicating that the areas are still in restoration process. In conclusion, planting tree is more efficient ecological restoration technique than passive restoration and nucleation to soil biological conditions improvement in Southwest of Paraná.

(5301 - 485) Optimization of Pollution Induced Community Tolerance (PICT) method for evaluation of soil pollution by heavy metals.

Claudia Campillo-Cora[1]; Vanesa Santás-Miguel[1]; Juna Carlos Nóvoa Muñoz[1]; Manuel Arias Estévez[1]; David Fernández Calviño[1]
Universidade de Vigo[1]

The monitoring of soils under high risk of heavy metal toxicity, as well as the design of actions to minimize the impacts of heavy metal s accumulation in the soils are needed. However, there is an important problem to be solved. What heavy metal concentration must be taken for regulatory and/or remediation actions? The answer is quite complex for multiple reasons. Background levels of heavy metals in soils are highly variable depending on soil parent material, and also, their availability is not usually directly related to their total

concentration in the soil, as it depends on soil parameters such as pH, organic matter content or the diversity and amount of inorganic colloids. Therefore, indicators that provide information about the real effects of heavy metals pollution on soil functions become necessary. Indicators based on soil microorganisms may be useful as they play a key function in many ecosystem services. Among them, the Pollution Induced Community Tolerance (PICT) is one of the most promising and sensitive tools. Thus, if we detect an increase in microorganisms communities tolerance to any heavy metal, then this would be a direct consequence of soil pollution with that heavy metal. However, this method is not well developed yet and it presents different shortcomings that should be assessed and solved before PICT spreading for the assessment of heavy metals pollution in soils. The general aim of this work is to improve the performance of the PICT to heavy metals in soils using bacterial communities extracted from non-polluted soils, and estimate the bacterial community growth using the ^{3}H leucine incorporation method adapted for soils (Bååth, 2001; Soil Biology & Biochemistry 33, 1571-1574). Heavy metals tolerance of the bacterial community was measured essentially according to Fernández-Calviño et al. (2011; Soil Biology & Biochemistry 43, 2324-2331). Bacterial community tolerance to Cu, Zn, Ni, Pb and Cr was optimized in relation with pH, type of buffer and dissolved organic matter (DOM) in order to exclude tolerance detection artifacts. The results showed that 20 mM MES buffer solution at pH 6.0 can be used for a wide range of soils differing in pH (4.0-8.0). The occurrence of DOM in the bacterial suspension did not affect the bacterial community tolerance to Cr, Ni or Zn, but the presence of DOM can overestimate the bacterial community tolerance to Cu and Pb, for which the use of correction factors are needed.

(5540 - 1086) Potential of Dichlorodiphenyldichloroethylene (DDE), and Dichlorodiphenyldichloroethane (DDD) degrading endophytic bacterial strains in enhancing phytoremediation

Ahmad Mahmood[1]; Ryota Kataoka[1]
Faculty of Life and Environmental Sciences, University of Yamanashi, Kofu, Japan[1]

Excessive use of certain pesticides led to widespread pollution throughout the world, and has become serious environmental problem due to their recalcitrant behavior, bio-accumulation potential, and toxicity towards living beings. The removal of such pollutants has been carried out by physical, chemical, and biological methods; where the biological methods include phytoremediation, and bioremediation. However, the integration of both is aimed at showing better results, and recently, the endophytic microbes assisted phytoremediation has gained importance due to potential degradation by the endophytes, stability of the environment, and better remediation. The following study was planned to find potential endophyte strains from *Cucurbitaceae* family which is considered accumulator of organochlorines. Bitter gourd, pumpkin, and zucchini stems from 2 months old plants were cut into small discs under aseptic conditions, and were subjected to endophytic bacterial isolation, after surface sterilization using sodium hypochlorite, and ethanol, spreading the suspension on R2A agar, and potato dextrose agar (PDA). A total of 80 endophytic bacteria, R2A (52), and PDA (28) were isolated, and were checked for possible degradation of Dichlorodiphenyldichloroethylene (DDE), and Dichlorodiphenyldichloroethane (DDD) by growing the strains with 5 ppm DDE, and DDD for two weeks, in broth media, followed by extraction of remaining chemicals using hexane, and measured using Gas Chromatography-Mass Spectrometry (GC-MS) against blank, and a set of standards, subsequently the final values were determined. Certain strains showed the potential of pollutant degradation (~73.2% DDE, and ~57.7% DDD), however, 17 most degrading strains (15.5-73.2% DDE, and 12.7-57.7% DDD) were selected for further analysis including growth in mineral salt medium with the pollutants as sole carbon source, and it was observed that except two, all other strains were found utilizing the either pollutant as sole carbon source on varying extents, and metabolized either, or both pollutants (Degradation percentage: ~38.7% DDE, and ~44.6% DDD). It is concluded that endophytic strains have potential role in phytoaccumulation of certain chemicals, and the synergism can be manipulated for enhanced remediation of polluted soils. The stability of endophytic environment also proposes the use of this alliance in co-contaminated soils, along with possible increase in bioavailability which still needs to be explored.

(4923 - 1603) Quality Reference Values (QRVs) of metals in soils of Alagoas State, Brazil.

Adriano Barboza Moura[1]; Gilson Moura Filho[1]; Leila Cruz da Silva[1]; Guilherme Bastos Lyra[1]; André Moreira de Souza Filho[2]
UFAL[1]; CENPES/PETROBRAS[2]

The Quality Reference Values (QRV) are values that quantify the natural concentration of chemical elements in soils without anthropic influence, creating instruments for diagnostics of soil quality. Due to the distribution of soils in Alagoas, there's a wide variation in regards to the concentration of inorganic substances, however, since there isn't a QRV determined for the state, values developed for other states are used instead, which can bring inconsistences. The objective of this work was to establish Quality Reference Values to soils in Alagoas state, in compliance with the Resolution n0 420, of the 28th of December, 2009, from Conselho Nacional do Meio Ambiente – Conama. 56 soil samples were collected to represent the main classes of soil of the state, in areas under none or minimal anthropogenic action for the subsequent analysis of inorganic substances through the USEPA 3051a method, as well as physical and fertility analysis. The QRVs based on the 90th percentile for the soils of Alagoas state were (mg kg-1): Ag (< 0,003), As (0,66), Ba (133,48), Cd (0,21), Co (11,94), Cu (19,06), Cr (42,93), Fe (28.726,61), Hg (0,11), Mn (591,65), Mo (0,32), Ni (17,69), Pb (19,35), Sb (1,58), Se (1,55), V (42,07) and Zn (26,16). The QRVs established for the soils of Alagoas state were lower than the precaution values preconized by Conama.

Keywords: Heavy Metals, Environment Protection, Reference Values.

(4255 - 621) Revegetation of saline tailings contaminated with arsenic from gold mining

Lorena Abdalla de Oliveira Prata Guimarães[1]; Luiz Eduardo Dias[2]; Igor Rodrigues de Assis[2]; Amanda Longhi Cordeiro[3]
Incaper[1]; UFV[2]; INPA[3]

The processing of gold ores exploited in Paracatu, Minas Gerais, generates sulfide tailings that are challenging for revegetation, mainly because of the high content of arsenic (As) and salinity. The use of cover layers, called top layer (TL) and capillarity break layer (CBL), is an alternative to enable revegetation. The TL serves as a substrate for plant growth. The CBL prevents the capillary rise of solution containing As, metals and salts, avoiding the contamination of the planting substrate. The aim was to compare materials for the composition of these layers. The layers were spread on a blend of tailings of processing of ore B1 and B2 (called blend). The CBL was formed with limestone, when present. The TL was composed of tailings B1, blend, saprolite B1 or topsoil. Six treatments were evaluated: tailings B1 (T1),

blend (T2), saprolite B1 (T3), topsoil (T4), topsoil + limestone (T5), and saprolite B1 + limestone (T6). Thus, CBL was added only in T5 and T6 (TL + CBL). The T1, T2, T3 and T4 were established only with TL. The bottom of plastic containers of 1.0 m^3 was filled with the blend. Then, the CBL was added (when present). TL was deposited at the top (directly on the blend in the treatments without CBL). Seeds of leguminous species (*Crotalaria spectabilis*, *Stylosanthes capitata*, *S. macrocephala*, *Panicum melinis* and *Lolium multiflorum* Lam) were sown in all plots equally. The design was randomized blocks, with three replications. Six months after sowing, shoot dry matter of plants (DM) were evaluated. The DM values in T1, T2, T3, T4, T5 and T6 were, respectively: 0.30, 0.00, 1.94, 1.16, 1.36, and 1.96 t ha^{-1}. The treatments with saprolite B1 presented the highest DM values statistically. The low or absent biomass production in T1 and T2 showed that tailings B1 and blend are not suitable as substrate for plant growth. Possibly the main limiting factors were the high levels of As and electrical conductivity. Results from other studies have shown that factors such as salinity, As availability and physical characteristics of materials used as TL are more determinant for biomass production than the fertility. In the conditions evaluated, the presence of CBL did not provide benefits for the biomass production. It is necessary to use cover layers to enable the revegetation of tailings. The materials most suitable for the TL composition are the saprolite B1 and topsoil, with or without CBL. The saprolite B1 is the most economically viable alternative.

C3.5.4 - Antibiotics and their resistance in agricultural food production

(8405 - 2983) Assessing the impact of vermicomposting on bacterial community size and structure, and antibiotic resistance attenuation

Lorena Uribe-Lorío[1]; Lidieth Uribe[2]; Daniela Vidaurre[1]
Centro de Investigación en Biología Celular y Molecular, Universidad de Costa RIca[1]; Centro de Investigaciones Agronómicas, Universidad de Costa RIca[2]

Worldwide, the use of cow manure and compost like vermicompost as fertilizers it's a common practice in agriculture, and it's considered that this practice have exclusively positive effects in the soil and environment. However, it is now known that manure from cows treated with antimicrobials is a major source for the expansion of the antibiotic resistance gene (ARG) reservoir in the environment. Here, we tracked the abundances of bacteria resistant to Streptomycin, Oxytetracycline and Gentamicin (commonly used in agriculture and veterinary practice in Costa Rica), and the composition and structure of the bacterial communities in manure and vermicompost, using next generation sequencing of V3-V4 fragment of 16S RNA gene. DNA was extracted from fresh samples of cow manure and vermicompost prepared using same manure, and from liquid culture supplemented with antibiotics (10 ug/ ml) inoculated with 0.5 ml of each sample and incubated for 24h at 35 °C. DNA samples were processed in Macrogen Inc. (Korea) using MiSeq platform. The Qiime bioinformatics workflow (www.qiime.org) was used in order to obtain the final OUT table. Statistics were performed using Primer7 software (Quest Research Limited). A total of 366 OTUs were obtained including all the samples, with a minimum abundance of 0.01%. 145 OTUs were observed exclusively from cow manure (39.6%) related samples (raw sample and inoculated broths) dominated by phylum Firmicutes. 51% of the bacteria present in the raw sample grow in presence of antibiotics, 69% of them were Firmicutes, mostly Clostridiales. Resistant bacteria were dominated by tetracycline-gentamicin phenotype. 104 OTUs were observed only in Vermicompost samples, and, contrary to cow manure sample, were dominated by Proteobacteria (55.8%), and Bacteroidetes phylum (26%), with a different composition and distribution of OTUs. Interestingly, only 23% were resistant bacteria present in samples of antibiotic supplemented broth, majorly resistant to streptomycin-gentamicin. These results confirms the presence of abundant antibiotic resistant bacteria in cow manure and suggest that vermicomposting, as a waste management practice, can reduce, but not eliminate, the overall abundance of these bacteria, highlighting the importance to evaluating the use of these materials as bio-fertilizers in the agroecosystems.

(3360 - 554) Root-uptake and dissipation of selected pharmaceuticals in soil-water-plant system

Radka Kodesova[1]; Ales Klement[2]; Oksana Golovko[3]; Miroslav Fer[2]; Olga Koba[3]; Martin Kocarek[2]; Antonin Nikodem[2]; Roman Grabic[3]
Czech University of Life Sciences Prague, Kamycka 129, CZ-16500 Prague 6, Czech Republic (kodesova@af.czu.cz)[1]; Czech University of Life Sciences Prague, Kamycka 129, CZ-16500 Prague 6, Czech Republic[2]; University of South Bohemia in Ceske Budejovice, Zatisi 728/II, CZ-389 25 Vodnany, Czech Republic[3]

Pharmaceutical, which are not entirely removed from wastewater in wastewater treatment plants, can pollute soils, if contaminated water is used for irrigation. Their mobility and potential root-uptake by plants depends on their behavior in soils, i.e., their sorption and degradation that depends on soil conditions. This study focused on a root uptake of one antibiotic sulfamethoxazole, beta blocker atenolol and analgesic carbamazepine from 3 soils: Chernozem, Cambisol and Arenosol. Five plants (radish, arugula, lettuce, spinach and green peas) planted in those soil were initially irrigated by fresh water and next (3 or 4 weeks)with water contaminated by a single compound or their mixture. After the harvest, each plant was divided into separate parts: roots (including bulbs of radish), leaves, stems (green peas) and pods (green peas). Plant tissues and soils were freeze-dried and dry-masses and concentrations of pharmaceuticals and their metabolites were measured. Despite that sulfamethoxazole and atenolol relatively rapidly dissipate from soils, they and metabolites of atenolol were detected in all plants. Carbamazepine is very stable in soils and fractions of its metabolites are usually low. However, very high concentrations in all plants were measured not only for carbamazepine but also for its metabolites. The degree of compounds' transformation depended on a plant family. Larger concentrations of carbamazepine metabolites were measured in leaves of lettuce, spinach and green peas than in leaves of radish and arugula (Order – Brassicales, Family – Brassicaceae).Transformation of compounds in plant bodies is attributed to enzymes CYP450.The impact of soil type on compound's uptake was not proven for all tested plants. The impact of application (single compound versus compounds' mixture) differed for different plants. Antibiotic sulfamethoxazole likely reduced dissipation of other two compounds in soils, which increased concentrations of compounds in plants. Another source of soil contamination is a sewage sludge used for soil amendment. Thus our study also focused on spinach-uptake of pharmaceuticals from seven soils mixed with the sewage sludge. For instance, while large amount of antibiotic clarithromycin (which is strongly sorbed in soils and very stable in this environment) was found in plant tissues, amount of antibiotic clindamycin (that is considerable less strongly sorbed in soils and less stable) was negligible, likely due to its dissipation.

(8795 - 3032) Veterinary Pharmaceutical Adsorption on Soils Amended with Biochar

Gonzalo Tapia Ulloa[1]; Mónica Antilén Lizana[1]; Gustavo Curaqueo Fuentes[2]
Pontificia Universidad Católica de Chile[1]; Universidad Católica de Temuco[2]

Over the last years, it has been of great interest the study related to the fate of the pharmaceutical waste, because around 75% of the administrate fluoroquinolones has been excreted in their bioactive form, that may be retained in soils or be leached to groundwaters. On the other hand, materials with high content of C, like the Biochar, can be used like a remediation system, due to their high capacity to retain organic compounds. The main objective of this study was to evaluate the impact of the biochar in the sorption of three antibiotics on two soils (one of alluvial origin and other of volcanic origin) amended with two different doses of biochar (25 and 50 ton/ha). The biochar comes from pyrolyzed oatmeal husk at 300°C. The physical-chemical characterization was carried out by using recommended methods for Chilean soils and the variable charge surface through electrophoretic migration. Sorption and kinetic studies were conducted by batch-type experiments, where the concentration of the analyte was determined by HPLC-DAD. The results of the characterization of the samples shows a significant variation with high doses of Biochar, while the surface charge present a high variable negative charge. The chromatography method was optimized, obtaining good linearity, precision and sensibility for the antibiotics studied. The results obtained for the kinetic adsorption of Ciprofloxacin in the alluvial soil (control soil and amended soil) shows a fast adsorption, where the maximum adsorption was obtained at 1h between the soil and the antibiotic. From these results it is obtained that the biochar influences on the adsorption of ciprofloxacin, because the samples amended with biochar shows an increase of the maximum adsorption of this antibiotic. With these results it is possible consider the biochar as a potential immobilizer of antibiotics of contaminated soils.

C3.5.5 - Radionuclides in soils: pollution sources and sustainable remediation approaches

(8138 - 1661) Behavior of chlorpyrifos insecticide on two tropical soils

Rafael Marques Pereira Leal[1]; Murilo Martins Bernardino[1]; Indi Assis Rodrigues[1]; Eliane Vieira[2]; Júlia Carina Niemeyer[3]
Instituto Federal Goiano, Rodovia Sul Goiana, Km 01, Zona Rural, Rio Verde – GO, CEP: 75.901-970 - Brasil[1]; Instituto Biológico, Centro de Pesquisa e Desenvolvimento de Proteção Ambiental. Av. Conselheiro Rodrigues Alves, 1252 Vila Mariana - São Paulo, SP, CEP: 04014-002 – Brasil[2]; Universidade Federal de Santa Catarina. Rod. Ulysses Gaboardi, Km 03, Faz. Pessegueirinho, Curitibanos, SC, CEP: 89520-000 – Brasil[3]

The behavior of pesticides and their interactions in the dissipation processes are still poorly understood in tropical climate and soil conditions. The retention and transformation processes of pesticides depend mainly on the physicochemical characteristics of the compound and the soil, in addition to local climatic conditions and management, thus making these processes unique to each type of pesticide. Chlorpyrifos is an insecticide and acaricide belonging to the chemical group of organophosphates, and may have high retention and low mobility. The objective of this study was to determine the sorption coefficients (Kf) of the chlorpyrifos pesticide in two tropical soils of contrasting texture (clayey and sandy), as well as to evaluate the mineralization at different depths, quantifying the percentage of extractable and non-extractable residues connected) on the ground. The soils used in the tests were Latossolo Vermelho distroférrico and a Neossolo Quartzarênico órtico típico. The insecticide 14C-chlorpyrifos was used, the compound being quantified by Liquid Scintillation Spectrometry. The coefficient Kf varied from 21.56 to 41.77 mL g^{-1} for chlorpyrifos in the sandy soil and from 23.11 to 29.85 mL g^{-1} in the clay soil, and the highest values were observed in the layers surface, due to the greater amount of organic matter in these layers. The values found suggest a medium soil retention capacity. The values of the desorption coefficient (Kfdes) ranged from 30.17 ml g^{-1} to 89.0 ml g^{-1}, the highest values being found in the sandy soil surface layer. The chlorpyrifos had a mineralization rate of 20.33% in the clayey surface layer and 13.09% in the sandy soil surface layer after the 62 days of study. The higher pH values in the clay soil may have been the main factor influencing the higher mineralization in this soil. influenced the highest values of mineralization in this soil. It was concluded that in the studied soils, chlorpyrifos had low soil mobility potential and obtained higher mineralization values in clayey soils when compared to sandy soils.

9197 - 1652) Sorption, desorption and mineralization of atrazine in different tropical soils

Murilo Martins Bernardino[1]; Indi Assis Rodrigues[1]; Rafael Marques Pereira Leal[1]; Eliane Vieira[2]
Instituto Federal Goiano, Rodovia Sul Goiana, Km 01, Zona Rural, Rio Verde – GO, CEP: 75.901-970 - Brasil[1]; Instituto Biológico, Centro de Pesquisa e Desenvolvimento de Proteção Ambiental. Av. Conselheiro Rodrigues Alves, 1252 Vila Mariana - São Paulo, SP, CEP: 04014-002 – Brasil[2]

The dynamics and impact of pesticides on highly weathered tropical soils is still poorly understood. In general, highly used compounds, very or poorly sorbed, high persistence and toxicity, should receive priority attention. The objective of this work was to evaluate the commercialized quantities of the atrazine ingredient in the municipality of Rio Verde in the year 2013, to apply the Gus and Goss indices to the preliminary assessment of the environmental contamination potential of atrazine and to study its dynamics in two soils of contrasting texture (9 and 55% of clay), coming from three depths (0-10, 10-20 and 20-40 cm). In the year of 2013, 283.43 tons of atrazine were commercialized, being this the second active ingredient more commercialized in the region, which resembles the Brazilian reality, where atrazine was third more commercialized. Regarding the Gus and Goss indices, atrazine is classified as medium transport potential. In the sorption studies the Kf coefficients ranged from 3.69 to 10.09 mL g^{-1} for atrazine in sandy texture soil and 8.02 to 9.30 mL g^{-1} in clayey soil. These values indicate that atrazine in these soils has a high potential for leaching and, consequently, potential for contamination of the water table. The values of the desorption coefficient ranged from 8.28 ml g^{-1} to 26.77 ml g^{-1}, and the highest value was observed in a sandy soil. The pesticide had a mineralization rate of only 4.71% of the initial concentration applied during 62 days of study. The mineralization was higher in clay soil. It was concluded that, atrazine presented low sorption and mineralization in both studied soils. These results suggest a high transport potential of the pesticide, and consequently a high potential for contamination of water courses.

C3.6 - Salt-affected soils

D3.6.2 - Salinity mapping and modelling salinization processes

(2122 - 1850) Methodological limits for characterizing the hydrostructural behavior of a saline clayey soil (Kairouan region, Central Tunisia)

Montoroi Jean-Pierre[1]; Zarai Bessma[2]; Aroui-Boukbida Hanane[1]; Hachicha Mohamed[3]

IRD, IESS-Paris, Bondy, France[1]; INAT-INRGREF, LRVENC, Tunis, Tunisia[2]; INRGREF, LRVENC, Tunis, Tunisia[3]

In the laboratory, the hydrostructural characterization of a given soil sample consists in measuring the variation of its volume as a function of its mass water content. Firstly, the sample is saturated per ascencum with deionized water, by placing it on a calibrated sand column under a low hydraulic head pressure ranging from -100 mm to -20 mm. Once saturation is reached, the sample is dried in an oven at 30°C. During the desiccation phase, its volume and mass are automatically recorded at a regular time step. The final sample is dried at 105°C, weighted and its final volume measured using the vacuum plastic bag method. The acquired data make it possible to obtain the shrinkage curve of the sample. The approach is based on the implicit assumption that we reproduce the soil moistening by a weakly mineralized rainwater and a soil drying. The same methodology applied to a saline clayey soil of Tunisia shows some singularities. During the moistening phase reaching the most complete water saturation of the soil, it is found that the salinity of the soil solution varies. The 1/5 electrical conductivity measurements ($EC_{1/5}$) made on the initial sample (air-dried before moistening) and the final sample (oven-dried at 105°C) show a significant decrease. In contrast, the $EC_{1/5}$ measurements in the sand column and the EC of the deionized water indicate an increase in values. The continuous changes in the salinity of the soil solution are due to the mineral dissolution of salts precipitated in the porosity and to cationic desorption by the clay minerals. The change in soil salinity will influence the soil structure and, consequently, the shrinkage curve. The interpretation of shrinkage curves, relating to soils with variable salinity, will be more debatable. In conclusion, it would be wise to adapt the saturation method with deionized water when applied to saline soils. The ideal would be to saturate the soil with a water of a salinity and chemical composition identical to the salinity and chemical facies of the soil solution. As soil salinity is usually very variable, there is the question of finding the "ideal" saturation water. A saline groundwater directly supplying a given soil could be suitable. Reconstituting in the laboratory a water of a given salinity and chemical composition is also feasible, but would greatly extend the experimental protocol. In any case, normalization is necessary to compare the hydrostructural behavior of a soil with various salinities.

D3.6.3 - Salinity management and remediation of salt-affected soils

(7541 - 646) Agricultural gypsum as material to improve physicochemical conditions of soils with excess sodium

Johana Ballestero[1]; Amabelia del Pino[1]; Mónica Barbazan[1]

Facultad de Agronomia. Universidad de la República[1]

An excess of sodium (Na) in the cation exchange complex produces a soil with low permeability and porosity that difficult the development of the root system. In Uruguay, the excess of Na in soils has a natural origin and frequently the Na increases with the profile depth. These soils coexist associated with fertile soils, remaining in general as unproductive areas, so they have been little studied. In order to improve the productivity of these soils, the effectiveness of the agricultural gypsum was evaluated under laboratory (microlysimeters) and under field conditions (with an implanted pasture). The Ap horizon of the selected soil was thoroughly mixed with two commercial sources of gypsum, at equivalent rates of 0, 3 and 6 Mg ha^{-1}, and placed in microlysimeters. The leached and interchangeable cations were determined periodically, with destructive soil sampling. In the field experiment, the gypsums were applied on surface, at equivalent rates of 0, 1, 2 and 3 Mg ha^{-1}, in implanted pasture of Festuca arundinacea. In the pasture were determined yield and nutrient absorption, and in the soil, chemical and physical properties were determined at different depth. In the treated soil of microlysimeters, the exchangeable Na decreased 11, 26 and 35%, while the exchangeable Ca increased 63, 70 and 71% at day 90, 180 and 360 after the application of the treatment, respectively. At the end of the study, a lineal and positive correlation was established between exchangeable Ca and total leached Na ($r = 0.72$). In the field experiment, the pasture yield in the treated plots was 50% greater than the control, and absorbed 54% less Na. No significant differences in yield were observed between rates or between sources of gypsum. The treated soils had higher exchangeable Ca and lower exchangeable Na than the control soil, and 37% more moisture content in the first 5 cm of the soil profile after 14 months of gypsum application. The soil pH tended to decrease in time and the difference remained at depth. The resistance to penetration decreased significantly in the treated soils. The agricultural gypsum was effective to improve the soil conditions at layer 0 – 5 cm the profile. More specific studies are needed that include the physical and chemical properties of the entire soil profile to give recommendations for the use of gypsum in our production conditions.

(1519 - 1253) Effects of Biochar and Wood Vinegar on Saline Soil Physical and Chemical Properties and Maize Yield

Zhongyi Qu[1]; Fan Wang[1]

Inner Mongolia Agricultural University[1]

Using biochar and wood vinegar as amendments, this study aimed to investigate the effect of soil amendments with different application amount on soil physical and chemical properties and maize yield, so as to provide theoretical references for improving saline alkali soil and rational utilization of biochar and wood vinegar. Field plot experiments were conducted by 7 treatments with 3 rounds

respectively, as follows: CK, WV(300L·hm^{-2}), T2:WV(450 L·hm^{-2}) ,T3: WV(300 L·hm^{-2})+B(15 t·hm^{-2}) ,T4: WV(450L·hm^{-2}) +B(15 t·hm^{-2}),T5: WV(300 L·hm^{-2})+B(30 t·hm^{-2}), T6:WV(450 L·hm^{-2})+B(30 t·hm^{-2}). The results showed that with biochar application amount less than 30 t hm^{-2}, biochar with wood vinegar compound fertilizer could reduce soil salinity and pH, inhibit the surface accumulation of soil salt. Salt content of T2 treatment reduced by 20.10% during the period from the seedling to jointing stage, and pH of T2 decreased by 0.35 units compared with CK treatment. Different treatments soil organic and nitrogen contentwith application of biochar was positively correlated. With the amount of biochar and wood vinegar dosage increasing, phosphorus and potassium content increased firstly and then decreased, which were all higher than the values in control group. The highest value of organic matter and nitrogen appeared in T6 treatment and increased by 54.91% and 41.63% compared with the values in CK treatment, respectively. Meanwhile the highest values of available phosphorus and potassium appeared in T3 treatment and increased by 44.80% and 42.88%. The highest yield in T3 treatment increased by 23.17% and showed significant correlation with soil nutrient index, while the correlation coefficient between yield and phosphorus reached to 0.923. In summary, With applying biochar of 15 t·hm^{-2} and wood vinegar of 300 L·hm^{-2}, the effect of soil improvement is optimal, and the yield was the highest. It can improve the efficient utilization of agricultural and forestry biomass resources, reduce the risk of environmental pollution

(3580 - 3041) Excessive use of potassium chloride in the banana cultivation: impacts on the vegetative development of the crop

Michele Xavier Vieira Megda[1]; Nayara Ellane Pereira Viana[1]; David Gabriel Campos Pereira[1]; Mickaelly Jordanya Guimarães Silva[1]; Matheus Magno Silva Damasceno[1]; Marcos Koiti Kondo[1]; Marcio Mahmoud Megda[1]; José Augusto dos Santos Neto[1]

Universidade Estadual de Montes Claros[1]

Potassium chloride (KCl) is the most widely used potassium source and, due to its continuous use, the accumulation of salts in soils and plants has been increasing. The excess of ions in the soil triggers a series of physiological disturbances to the plants. The objective was to evaluate the application of KCl associated to nitrogen fertilization in the vegetative development of 'Prata' banana. The experiment was conducted in a greenhouse in a Typic Hapludox. The experimental design was a randomized block with 10 treatments and 4 replicates, consisting of 5 doses of K_2O (50, 100, 200, 300 and 400 mg dm^{-3} as KCl) and 2 doses of N (200 and 400 mg dm^{-3} as ammonium sulfate), besides the control (without K_2O). The results were submitted to variance analysis and the significant interactions, within each dose of N, were performed by means of regression. The increase of the potassium doses increased the electrical conductivity of the soil. At 5 days after fertilization (d.a.f.). the values of electrical conductivity were higher due to the small root development of the culture and, after 120 d.a.f. the values decreased, suggesting that there was absorption of a great part of the salts applied. The salinity index represents the ability of the fertilizer to increase the osmotic pressure of the soil solution. Regarding KCl, for each unit of K, a salinity index of 1.93 is considered high when compared to other fertilizers. According to data in the literature, the banana crop is very sensitive to salinity, and its development is reduced in soils with electrical conductivity higher than 3.0 dS m^{-1}. The values of electrical conductivity are above the values considered adequate for the culture. There was a linear decrease in the production of dry mass of the shoot to the dose of 200 mg dm^{-3} of N, on the other hand, the dose 400 mg dm^{-3} of N promoted increase of production up to 200 mg dm^{-3} of K_2O, being this effect represented by a quadratic regression model. For both doses of N, the increase in the dose of K_2O resulted in a decrease in the production of root dry mass. The use of nitrogen fertilizers associated with potassium fertilization further aggravates the problems of salinization, and the use of ammonium sulfate is not recommended due to its high salinity (3.45). It is concluded that the increase of the K_2O dose associated to the N doses promotes excessive increase of soil conductivity and a significant reduction in the shoot and root development of the banana crop.

(4147 - 740) Exploring the impact of polyhalite application on soil sodium

Lino Furia[1]; Annette Raffan[2]; Huoyan Wang[3]; Timothy D Lewis[1]

Sirius Mineral[1]; Institute of Biological and Environmental Sciences, University of Aberdeen[2]; Soil Fertility and Plant Nutrition, Institute of Soil Science, Chinese Academy of Science[3]

Soil salinization affects approximately 831 million ha of soil globally impacting the availability of land for crop production. Sodium can enter the soil system either naturally (through weathering, seawater intrusion or evapotranspiration) or as a result of human activity (water extraction, irrigation). Remediation is achieved by application of calcium to encourage flocculation of soil particles that lowers tensile strength enabling plant roots to penetration and facilitating soil water drainage. Polyhalite ($K_2SO_4.MgSO_4.2CaSO_4.2H_2O$) is an evaporite mineral that contains potassium (14% K_2O), magnesium (6% MgO), sulphur (48% SO_3) and calcium (17% CaO). The use of polyhalite in soils containing high levels of sodium could be beneficial as the introduction of additional cations should displace sodium. An initial lab based study investigated the effects of on soil physical properties using polyhalite at application rates of 0, 2.5, 5 and 50 t ha^{-1}. This study found changes in soil tensile strength was inversely related to polyhalite application depending on soil type with wastewater irrigated soils showing signs of remediation. Following this trial, a separate glasshouse study was setup in Nanjing, China to characterise the influence of polyhalite on sodium within the soil. Results found a positive relationship between polyhalite application and soil sodium content, indicating potential remediation benefits of polyhalite.

Keywords: polyhalite, flocculation, soil salinization

(4547 - 1283) Influence of Soil ESP and Salinity on Soil Atterberg Limits and Shrinkage

Hans Klopp[1]; Will Bleam[1]; Francisco Arriaga[1]

University of Wisconsin Madison[1]

Soil sodicity occurs from a breakdown of structure in the soil and an increase in swelling of the soil clay fraction. Little research has been conducted relating soil sodicity to the swelling clay fraction behavior of the soil under EC and ESP combinations. Three smectitic soils were treated to salt concentrations between 5 and 40 meq/l and ESP levels between 0 and 50 %. Soil Atterberg limits and shrinkage potential were measured on three soils of differing degrees of sodicity prior to treatment and after soils were treated to the same EC vs ESP combinations. Whole soil liquid limit, plasticity index and shrinkage potential increased for salt concentration of 5 meq/l at an ESP of 25 and 50% and 10 meq/l at an ESP of 50 % in all three soils. Whole soil

swelling behavior is expressed when soil ESP levels are high and salt concentrations are low as would be expected with the behavior of swelling clays. Whole soil swelling behavior and plasticity can be used to determine a soil that is sensitive to soil sodicity but will not show a change until an ESP of much greater than what is considered to be sodic by USDA classification. Some soils such as silty soils that have a low clay content may have a change in soil hydrologic properties due to sodicity but will not increase in clay swelling or plasticity.

(5785 - 3219) Physi-chemical and microbial properties of coastal soils with different salinity classes under natural conditions in Jiangsu, China

Liu Guangming[1]; Zhang Xuecheng[1]; Wang Xiuping[2]; Shao Hongbo[3]
Institute of Soil Science, Chinese Academy of Sciences[1]; Institute of Coast Agriculture, Hebei Academy of Agriculture and Forestry Sciences[2]; Institute of Agricultural Resources and Environment, Jiangsu Academy of Agricultural Sciences[3]

Soil salinity is one of the major problems to overcome around the world, especially in arid and semi-arid areas. Many researchers studied effects of different salinities on soil properties by increasing salt concentration in laboratory, but little of which showed the real effects of salinity on microbial properties at the field. Situ salinity was not always constant and the same microorganisms in saline soil may adapt to different salinities. Therefore, the aim of our study was to investigate how a gradient in salinity under natural condition affected soil physical, chemical and microbial properties. Soil samples were taken from 10 sites with different salinities in Jiangsu province and these sites covered non-salinized (<1 g kg-1), slightly salinized (1-2 g kg-1), moderately salinized (2-4 g kg-1), strongly salinized (4-6 g kg-1) and saline soil (>6g kg-1). Electrical conductivity (EC) ranged from 0.112 to 2.818 dS m-1. The results showed that the pH did not show significant difference in values among 10 sites.Organic carbon (OC), NO3--N, NH4+-N and extractable phosphorus (P) were lower at heavy and saline soils, indicating that the increasing EC can limit the availability of nutrients. Microbial biomass and enzyme (urease, alkaline phosphatase and catalase) activities decreased with the increase of EC and they were all negatively correlated with EC. On the other hand, ions compositions were higher in sites with high salinity and showed positive relationships with EC.
Keywords: soil salinity; soil property; microbial biomass; enzyme activity; salt-soil quality evolution

(4952 - 304) Sodic-saline soil spatial variability characteristics and precision reclamation using farmland scale-based approach

zhiping yang[1]; qiang zhang[1]; haolin zhang[1]; chunhua gao[1]; dongsheng jin[1]
Institute of Agricultural Environment and Resources, Shanxi Academy of Agricultural Sciences[1]

Sodic-saline soil is a major type of saline-alkali soil in the inland regions of China and severely limits crop productivity. This study was designed to investigate sodic-saline soil spatial variability and precision reclamation on 1 ha farmland in Datong basin of Shanxi Province, China, using a RTK network sampling method. Under farmland scale, soil salinization and alkalization exhibited high variability on the surface layer of the sodic-saline soil. Correlations were found between distribution and spatial location of salinization parameters including EC, pH, and Ex-Na. Meanwhile, the level of these salinization parameters was negatively correlated with the biomass yield of maize grown on it. Based on classifications of EC and pH critical values, the optimum rates of chemical conditioners (desulfurized gypsum, weathered coal, and ferrous sulfate) were recommended for the farmland investigated, and precision reclamation was implemented. This approach reduced soil saline variation, increased crop biomass yield, and reduced amount of the chemical conditioners for the soil reclamation.
Keywords: sodic-saline soil, spatial variability, precision reclamation

(2181 - 420) Temporal-spatial features of soil salinity in coastal soil of East China over 3 years

Jianbin LAI[1]; Zhu Ouyang[1]; Lanfang Wu[1]
IGSNRR,CAS[1]

Salt-affected land varies spatially and seasonally in terms of soil salinity. "Bohai Granary" is a newly proposed national-level program which aimed to improve soil quality and mining the potential of grain production in the salt-affected land in east China. In this work, hundreds of soil samples were monthly taken at 11 sites within the Yellow river delta. The spatial distribution pattern of soil salinity were investigated and its seasonal variation over 36 months were discussed. Our findings indicated that the vertical distribution type of soil salinity was bottom-accumulating in the near coastal area while it gradually turned into a type of surface-accumulating for the soil profiles in inner land. The peak of the soil salinity along the soil profile alternately moved upwards and downwards during the growing seasons. However, there was no evidence for the increasing of the total salt amount within the upper 100cm of soil. Moreover, the salt was mostly accumulated in the upper soil (0-40cm) during the late spring and early summer season; and winter wheat was tend to be affected severely at this stage. Therefore, special field practices (e.g. regular irrigation to leach salt, good maintenance of drainage system) should be taken to minimize the threat of soil salinity.

D3.6.4 - Impact of land use change on soil and the environment in dry regions

(6667 - 1761) Sediment yield scenarios and water demands of the Bocaina dam, Brazil

Margarita M. López-Gil[1]; Suzana M. Gico de L. Montenegro[2]; J. C. de Araújo[3]
UESPI[1]; UFPE[2]; UFC[3]

In large water scarcity regions, dams are used to guarantee the necessary flow to different users. This kind of structure is also an artificial means of sediment retention, causing, over time, the lake silting and the reduction of its lifespan. Consequently, silting enhances the risk of not supplying the water demands. Reservoir operation generally disregards the updated silted lake morphology, using the initial (project-based) morphology. The objective of this study was to analyze the effect of a reservoir silting on the future water demands for the Bocaina Dam, located in the semi-arid region of Piauí, Brazil. Siltation was assessed using three land-use scenarios. In order to reach the proposed objective, we performed a bathymetric survey; and calculated sediment yield and associated sediment delivery ratio (SDR). Current and future water demand for the reservoir was computed for the period from 2015 to 2040. The erosive potential of the basin was estimated at 13.54 Mg.ha-1.yr-1; the sediment delivery ratio was 12.4%; and the sediment yield was 1.68 Mg.ha-1.yr-1. The low SDR, typical from the Caatinga biome, is probably due to low connectivity in the basin, caused by intermittent flows in the basin. The sedimentation rate estimated for the Bocaina dam was 0.12

hm3.yr-1, a value slightly below those found in other semi-arid regions. The sediment retained in the reservoir until 2040, according to the three simulated scenarios, resulted in useful volumes above 89% of the original reservoir capacity, which indicates that the demands will be only partially affected by the siltation in regular years. However, should reservoir levels be below 40% of their capacity, operation will have to be adapted to the siltation.

Keywords: Water availability. Water demands. Sediment yield. Bocaina Dam

(3217 - 2247) Spatial and temporal analysis of land use and soil occupation in a small town in the NEB

Luciana Mayla de Aquino França[1]; Rodrigo de Queiroga Miranda[1]; Josiclêda Domiciano Galvíncio[1]

Universidade Federal de Pernambuco[1]

The northeastern region of Brazil (NEB) is constantly in the science spotlight because of its harsh climate conditions. The most prominent characteristics that lead the NEB to be a hostile environment for many tropical species are its high temperatures and low rainfall indices. For this reason, its vegetation has become very adapted, looking mostly dry and thorny. However, in some places in the NEB, the environment may be different. It happens mainly because of high altitudes that makes climate milder. The municipality of Flores is located in the hinterland of the state of Pernambuco (PE), and although it is on a semi-arid zone, it is almost 500 m above sea level, which produces a milder and rainier climate than other municipalities of the region. Given our interest in such discrepant features, the objective of this study is to analyze the changes in land use and soil occupation that occurred over a period of 13 years in the Flores town, PE. For this purpose, two images from the MODIS sensor installed on the TERRA satellite were utilized. More specifically, we used data from the MCD12Q1 product for the years of 2001 and 2013, with which we produced maps and analyzed statistically the land use dynamics in the area. Once analyzed, the classes 6, 7, 8, 9, 12, 13 and 14 that correspond to closed shrublands, open shrublands, Woody savannas, savannas, urban and built-up, croplands and natural vegetation mosaic respectively, represented 98% of the area. The MCD12Q1 product stands out by presenting in a single image the annual average of land use and soil occupation based on images obtained daily by orbital sensors and classified according to the IGBP (International geosphere Biosphere Programme) method. The results showed that there was a decrease of 7% in class 6, 3% in class 8, and 12% in classes 12 and 14/ an increase of 22% in class 7, and 1% in class 9. The class 13 remained unchanged. Considering that the years of 2011, 2012 and 2013 were significantly dry for the countryside of Pernambuco, we suggest that the decrease that we have noticed in the classes 6, 12 and 14 may be related to a lack of rainfall. As the area is dominated by planosols and beans plantations, it causes impacts on the soil due to lack of water.

C4.1 - Soils and the Environment

C4.1.1 - Soil ecosystem services

(7431 - 1348) An Approach to assessment soil ecosystem services in Atlantic Rainforest - Brazil

Gabriel Spínola Garcia Távora[1]; Vanessa Ingrid Carvalho Saraiva[1]; Antonio Soares Da Silva[1]; Luciana Maria Sousa Dos Santos[1]; Samuel Vitor Oliveira Dos Santos[1]; Patricia Quadros Gondim Leite[1]
UERJ[1]

The agro-ecosystems are expanding globally due to increasing human demand for provision. Because of this the different ecosystems are changing to agro-ecosystem. This process of landscape transformation has negatively affected the production of regulatory and cultural services. In the agroecosystems the soil management has directly effects in the ecosystem services provision. Thus, the main goal of this project is evaluate and models the provision of ecosystem services related to a soil in a river basin located in a mountainous region in Rio de Janeiro State. The study is justified because we need to evaluate the influence of agroecosystem for the provision of the ecosystem services. In addition the established hypothesis in the Pito Aceso river basin the soil ecosystem services, specially, regulation ecosystem services are not negatively affect by the agricultural activity. This occurs because the study area has a high degree of preservation and the agricultural management practices not so impacting the environment. For the same reason the provision ecosystem services are also benefited. The adopted methodology is based in a holistic approach and tries to correlate the provision of ecosystem services and soil natural capital. The methodology of this proposal is divided in five steps. The first step is determined the classes of land use and land cover and also identify the ecosystem services provided by the soil and the indicators of ecosystem services. The second part is related to the soil sample collection and the subsequent laboratory analysis. The third stage is rising of the information about the agricultural production in the municipality of Bom Jardim (RJ). The fourth stage is related to the statistical analysis of the collected data, the indicators validation and the evaluation of soil ecosystem services. The last step of this research will deal with the modelling of soil ecosystem services data.

(3283 - 3125) Ecological corridors proposal for interligation of the augusto ruschi biological reserve with the apa of goiapaba-açu, es, using geotechnologies

Utálice da Silva[1]; Alixandre Sanquetta Laporti Luppi[1]; João Luiz Lani[1]; Diogo Antonio da Silva[1]
Universidade Federal de Viçosa[1]

The Brazilian landscapes, in the majority, have remnants of vegetation that are isolated, composing environments different from the original one. Factors such as the reduction of natural vegetation areas and the degree of isolation affect the ecological relations between species, causing a negative impact on the size of the populations. The natural environment is the shelter for several native species and, especially, those species that are migratory. However, these areas are generally in a very fragile position, since the expansion of the agricultural and livestock frontier corresponds to a risk factor for the preservation of species. To know these environments is fundamental to understand the mechanisms of conservation and renewal of the fragments and to propose methodologies for the recovery of areas through biological and spatial elements, generating technical and scientific knowledge, and can be used as a basis for the interconnection between forest fragments. In this way, the establishment of Ecological Corridors is a necessity to extend environmental protection and biodiversity conservation, which is a great national wealth. This study aimed to propose routes for implementation of ecological corridors aimed at the interconnection of forest fragments in the municipalities of John Neiva and Fundão using geotechnology. Using the methodology of distance from the lowest cost four routes have been proposed for implementation of ecological corridors, corridor named A, B, C and D. After analyzing the images of APPs, use and coverage of the Earth and Slope and Land Use Conflict in the APP, was named the Corridor "A", with 2704.23 in length, width 270.42, as the best proposal for the deployment. An important factor for choosing this corridor was the existence of large area of vegetation and area regeneration, larger APPs preserved and have a great potential for tourism and agriculture. From the data obtained and analyzed, it was possible to conclude that: The methodology used by GIS to route routes to the Ecological Corridor proved to be efficient, generating routes with weights of lower cost and smaller path between two points.

(7737 - 3193) Ecosystem services of soil in Coffee Agroecosystem of Colombia

Liliana Bueno López[1]
Universidad Tecnológica de Pereira[1]

Coffee production represents 16% of Colombian agricultural GDP, making it the largest producer of soft washed Arabica coffee and the third largest producer in the world, a situation that It has arrived after an extensive and changing history of coffee production which has generated environmental transformations as a consequence, possibly due to the need of adaptation to achieve ownership of the territory, a situation that is evidenced by the presence of coffee in mountain ecosystems; the last time, most of the coffee farmers have opted for small planting areas in which it is not possible to show a homogeneous structure, nor a single management strategy; In the municipality of Belén de Umbría, the main coffee producer in the department of Risaralda (Colombia), it is possible to appreciate the dynamics described in the integrated management district "Cuchilla de San Juan", a figure that allows the presence of sustainable agroecosystems and an area of conservation. Soil Ecosistemic Services In this occasion, the role of soils in the provision of ecosystem services for coffee agroecosystems is considered important, and in this sense it is worth emphasizing the approach of soil study in a multifunctional way, since they are the various functions which support the delivery of services. For this research, the role played by the ecosystem services of the soils in coffee production of the Association of High Quality Coffee Producers "Cuchilla del San Juan", from the municipality of Belén de Umbría, was investigated, located in the center west of the country, constitute coffee agroecosystems located at the borders of the Cuchilla de San Juan Integrated Management District, an important area in the provision of water for the aqueducts of the surrounding rural and urban areas and the provision of ecosystem services fundamental for the development of their productive activities; despite the importance of this area, there has been a strong pressure on it, possibly due to the expansion of the agricultural frontier, generating changes in the functions of the ecosystem and consequently in the ecosystem services that there they could exist. The ecosystem services of the soil were identified based on some microbial functions and soil characteristics, it was also linked to the recognition of the ecosystem services of the soil, the traditional perception of the coffee grower, establishing strategies that allow sustainable management of the soil and the agroecosystem.

(7808 - 611) Effect of the agrossilviculture of *Euterpe edulis* Martius on physical and chemical soil attributes

Fábio Martinho Zambonim[1]; Paulo Sérgio dos Santos Leles[2]; Paul

Richard Momsen Miller[3]; Milton da Veiga[4]
EPAGRI- Empresa de Pesquisa Agropecuária e Extensão Rural de Santa Catarina[1]; UFRRJ-Universidade Federal Rural do Rio de Janeiro[2]; UFSC-Universidade Federal de Santa Catarina[3]; UNOESC- Universidade do Oeste de Santa Catarina[4]

The agroforestry systems (AFSs) are recognized as sustainable production systems and they contribute to the natural resources conservation. The soil quality monitoring is an important tool for sustainability assessment of this production system. The aim of the current study is to verify the effects of the *Euterpe Edulis Martius* AFSs, performed by farmers from the northern coast of Santa Catarina, as for the physic and chemical soil properties in comparison with the soil properties under other forest uses. Five *E. Edulis* AFS areas (TRAT 1) have been selected, all located next to areas with other forest uses (TRAT 2). The experiment was arranged in full blocks with five replications. Three different depths of layers were used as physical and chemical soil factors indicators (0–5; 5–10 and 10–20 cm), pH rates; organic material levels, phosphorus, potassium, calcium; magnesium, aluminum; the CTC $_{pH\ 7,0}$ index, the base saturation CTC $_{pH\ 7,0}$ index, and CTC $_{pH}$ soil saturation by aluminum index, the bulk density (BD), the mean weight-diameter of aggregates obtained through dry sieving (DMPs), the mean weight- diameter of aggregates obtained through water sieving (DMPu) - and aggregate stability index (ASI). The *E. edulis* AFSs did not show different effects on most soil chemical properties indicators when compared to other forest cover composed primarily of native species of the Atlantic Forest. This result shows that the AFSs did not cause improvements in soil chemical properties and that some possible increases in nutrient exportation of agroforestry systems for bigger harvests may exhaust the natural reserves of soil nutrients. In order to provide increase and chemical fertility maintenance of soils under AFSs, a continuous and careful management of these fertilization systems is recommended. Soils under *E. edulis* AFSs showed a larger soil aggregate stability when compared to soils under other forest uses. The cultivation of *E. edulis* when intercropped with tree species effectively promotes the improvement of soil aggregate stability due to the characteristics of its root system.

(3576 - 2481) Evaluation of environmental soil functions in avocado crops Michoacan, Mexico.

Alma Barajas[1]; Ángeles Gallegos[2]; Francisco Bautista[2]
Escuela Nacional de Estudios Superiores Unidad Morelia, Universidad Nacional Autónoma de México[1]; Centro de Investigaciones en Geografía Ambiental, Universidad Nacional Autónoma de México[2]

Mexico is the first producer of avocado. The 84% of the national surface of orchards is in the state of Michoacán. The crop of avocado has brought a series of consequences, positives and negatives; on one hand the economic spill and on the other hand deforestation for the establishment of avocado. The change of land usage can have negative repercussions on environmental services. It has not been evaluated yet the environmental functions of the soils. The objective of this work is evaluating the environmental soil functions with avocado crop in the municipality of Tacámbaro, Michoacán. The eleventh representative sampling points were selected based on the units of landforms, and also the presence of avocado cultivation was observed. A pit was opened at each site and the soil profile was described. Samples were taken from each soil horizon and analyzed in the laboratory. The soil profiles were classified with the WRB (2015), with the data of the field and the laboratory, were evaluated, four environmental soil functions with the software Soil & Environment: 1) Nutrient Cycle; 2) Site of Food and Biomass; 3) Water Cycle; 4) Content of Organic Carbon. Three soil groups were identified: Andosol, Umbrisol and Alisol. Andosols with avocado crop have an intermediate aptitude of water quality for recharging aquifers, so their filtration capacity is acceptable; about the water they infiltrate, all the Andosols evaluated have a good internal drainage, these also have a very high capacity as a component of the nutrient cycle, which indicates that they have excellent natural fertility and are suitable for agriculture. The evaluated Umbrisols present a natural fertility and a variability of filtration and infiltration capacity. The Alisol with avocado crop presented a good quality and quantity of water for the recharge of aquifers, however, the Alisols with forest cover infiltrated a low amount of water, therefore, contrary to what is known, a cover with crop of avocado allows this type of soil to improve its capacity to permeate the water to the subsoil. The capacity of soils like sites for food production, the results are mostly intermediate, this is due to the capacity of aeration. No significant negative impacts of avocado crop, were observed in the environmental services offered by the evaluated soils, considering their aptitude to perform the environmental functions, all the evaluated soils presented good characteristics for avocado crop, especially the Andosols.

Keywords: Software S&E; Andosols; Umbrisols; Alisols.

(3844 - 1895) Impacts of forest restoration on soil water infiltration: an overview

Sergio Esteban Lozano Baez[1]; Ricardo Ribeiro Rodrigues[1]; Silvio Frosini de Barros Ferraz[2]; Miguel Cooper[3]; Paula Meli[4]
Laboratório de Ecologia e Restauração Florestal, Department of Forest Science, "Luiz de Queiroz", University of São Paulo (ESALQ/USP)[1]; Laboratório de Hidrologia Florestal, (ESALQ/USP).[2]; Department of Soil Science, (ESALQ/USP).[3]; Laboratório de Silvicultura Tropical, (ESALQ/USP)[4]

Over last few decades, forest restoration initiatives have increased around the world. However, effects on soil to the current restoration efforts still require a better understanding, especially due to the potential benefits of restoring forest for ecosystem functions and human well-being. This is particularly important for soil water infiltration, a key hydrological process that influences groundwater recharge and soil erosion. Whether or not forest restoration can improve soil water infiltration is still unclear. We conducted a systematic literature review of restored forests world-wide to assess the impact of forest restoration on soil water infiltration. We selected peer-reviewed articles published in English, Spanish and Portuguese in ISI Web of Science and Scielo. Most studies reported an increase in soil water infiltration after planting native trees in degraded lands, in a wide variety of ecosystems in 11 countries. Nevertheless, in some cases forest restoration per se did not guarantee an increase in water infiltration. The majority of the studies did not report the land use history and usually comprised only a single measurement in time after plantation establishment. Moreover, the information is especially limited for the humid tropics and different restoration techniques. Our results highlight that time required to recover soil water infiltration to a reference condition (old-growth forest) differs considerably due to variations in forest, climate and soil type. We hope that presenting these gaps will encourage the scientific community to produce more information on soil water infiltration in restored forests and improve future research to assess forest restoration success.

(9227 - 765) Is leaf decomposition more accelerated in a Cerradão or Eucalyptus stand on Cerrado soils?

Karla Monique Silva Carneiro Valadão[1]; Marco Bruno Xavier Valadão[2]; Sarah Camelo da Silva[2]; Jonas Inkotte[2]; Alcides Gatto[2]; Reginaldo Sérgio Pereira[2]
Universidade do Estado de Grosso - UNEMAT[1]; Universidade de Brasília

- UnB[2]

Eucalyptus has been one of the main exotic species used in large-scale plantations and with the potential to recover degraded areas since it has a good tolerance for low fertility soils. Eucalyptus has high water and nutrient efficiency and great litter production, which allows the entry of carbon and nutrients with the maintenance of soil physical properties. The leaf fraction is the main material contributed in the soil contributing 50 to 80% of the total litterfall, and its decomposition regulates not only the litter accumulation but also the nutrient cycling. The new Forest Code published on May 25, 2012 (Law no. 12.651/ 012) allows the intercalation of up to 50% of exotic species with native species of regional occurrence in consolidated areas of legal reserve and permanent preservation. Thus, with the ecological role that the litter has the objective of this study was to evaluate the decomposition of eucalyptus leaf in the stand and Cerradão area. The study was carried out at Fazenda Água Limpa (FAL), Brasília - Federal District (15 ° 56'-15 59 'S and 47 ° 55'-47 58' WGr.). The methodology used was that of litter bags, which leaves a clonal hybrid of *Eucalyptus urophylla* x *grandis* with three years of planting were used in 3x3 m spacing. The soil of the eucalyptus stand was characterized as Red-Yellow Latosol (Oxisol), being limed followed by mineral fertilization, and Cerradão was classified as Red Latosol (Oxisol). In which litter bag was filled 20 g of leaves and installed randomly in eucalyptus stand and Cerradão being rescued after 30 and 60 days. To obtain the leaf mass was calculated by the difference between the initial and end of each period, by the equation: Remaining Mass (%) = (Final weight/initial weight) x 100. To evaluate the differences between areas we used independent samples t-Test. At 60 days after the beginning of the experiment, the Cerradão presented greater decomposition. The native area decomposed 27.46% in the stand this percentage was 23.18% ($p < 0.05$). Our results indicate a variation in the rates of leaf litter decomposition among the evaluated areas, which may be related to the forest type presented by Cerradão. This condition provides a more favorable environment with greater shading, greater soil moisture thus benefiting decomposing organisms in the litter layer. This more rapid decomposition can provide input of carbon and nutrients and provide favorable conditions in soils of areas to be recovered.

(6360 - 2701) Key soil microbial-derived ecosystem services in Mediterranean native forests: to what extent are they affected by wildfires?

Claudia Rojas[1]; Juan Pablo Fuentes[2]; Marcia Ricci[3]; Felipe Sandoval[3]
Universidad de O'Higgins, Center for Applied Ecology and Sustainability (CAPES)[1]; Universidad de Chile[2]; Corporación Nacional Forestal (CONAF))[3]

Ecosystem services are the benefits society obtain from ecosystems, and soils are responsible for many of them. Soil microbial communities and their associated functions play key roles in a vast number of soil ecosystem services, as they are essential to maintain the capacity of soils to function as part of the environment and support aboveground life. Soil disturbances compromise the benefits microbes provide since they are very sensitive to changes, which explain why they are widely used as indicators of soil stress levels. Fires represent an important pressure to natural soil functioning worldwide, especially in regions with Mediterranean climates, where dry summers and elevated temperatures are common and where the effects of Climate Change can be more pronounced. The negative effect of fires on soil microbiota is well recognized globally, and the greater sensitivity of soil biological properties to disturbances (compared to abiotic factors) is also established. However, the effects of this pressure on microbial-derived benefits such as biological nitrogen fixation (BNF) and fungi composition/carbon sequestration potential is less understood. This work aims to elucidate the effect of wildfires on soil microbiota and associated key functions in native forests of the Mediterranean Region of Chile. In order to understand the effect of fires in these biological properties, prokaryotes, fungi, and members of the BNF functional group will be studied by high-throughput amplicon sequencing of the 16S rRNA, ITS, and *nif*H coding genes, respectively. Molecular assays will be complemented with litter decomposition and soil respiration studies. Moreover, soil physicochemical analyses including: aggregate stability (dry and wet sieving for macro aggregates/ dispersion rate for micro aggregates); pH (1:1 suspension of air-dried soil: deionized water) and EC (1:5 suspension of air-dried soil: deionized water); nutritional conditions comprising SOM (loss of ignition), SOC (chromic acid digestion), carbon fractions (sequential extraction), TN (Kjeldahl method), P(Olsen method), and Ca, Mg, K, and Na (ammonium acetate extraction) will be included. This work will shed light on the effects of wildfires in microbial-derived ecosystem services crucial for the sustainability and resiliency of sclerophyllous forests of Chile. Moreover, it will provide baseline information to be used in initiatives to restore and protect Mediterranean native forest after fires.

(7482 - 1138) Land degradation, ecosystem services and food security of the Astrakhan region, Russia

Lavrova Aisylu[1]
Lomonosov Moscow State University[1]

Astrakhan region is a unique territory combining high agricultural and recreational potential due to its agro-climatic resources and the presence of Volga River delta, one of the most important geographical elements of the country. However, many of the areas of this region are subjected to the negative effects of unsustainable farming; thus there is a need to outline optimal types of land use for the subsequent conservation of ecosystem services and food security of the area.We compiled a map of the dynamics of the vegetative index NDVI from 2000 to 2015, and selected the most representative reference sites. Field study of these sites was organized in August 2016. The resulting map clearly divided the region into three natural climatic regions: the Volga-Akhtuba floodplain (the vegetation index is insignificant), the northern part of the region located within the steppe zone with the maximum decrease in NDVI (up to 40%), and the southern part located in the semidesert zone with the largest increase in NDVI (up to 20%)., We included in the analysis of the situation the climatic data of three meteorological stations - Verkhniy Baskunchak, Astrakhan and Lagan. The aridity index sharply increased in all three weather stations from 2009 to 2011, but in the following years and in the previous ones, it fluctuated insignificantly 0.15 (Astrakhan), to 0.25 (Lagan).Also the economic indicators of agriculture were analyzed from 2008 to 2014. Most municipal districts have a certain orientation of the agrarian sector (crop or livestock sector). Areas with negative NDVI dynamics are engaged mainly in plant growing. During the review period, there was a negative trend in the productivity of agricultural crops, plant products, and the greatest reduction in the number of agricultural machinery, which indirectly indicated the abandonment of arable land. The growth zone of vegetation index is confined to cattle-breeding areas. During the review period, livestock numbers, livestock production and sales of products increased. Regional agriculture is highly prone to climatic factors, since the lands located in zone of risky farming. Lack of moisture is one of the most acute problems in the region which lead to plant sector concentration in the northern and livestock sector in the southern territories. Thus, climate change threatens the food security and the well-being of the regional population.

(7076 - 763) Leaf decomposition in eucalyptus stands on Latosol (Oxisol) in the Brazilian Cerrado

Marco Bruno Xavier Valadão[1]; Karla Monique Silva Carneiro Valadão[2]; Jonas Inkotte[1]; Alcides Gatto[1]; Eder Pereira Miguel[1]

Universidade de Brasília - UnB[1]; Universidade do Estado de Grosso - UNEMAT[2]

Eucalyptus cultivation in Brazil is the result of decades of research and improvement of crop technologies. Nowadays, eucalyptus plantations are the main source of wood in the country. However, there are persisting doubts about the impacts of this monoculture forest. For this reason, the quality of the litterfall from stands can contribute to the studies about the transformations of vegetal organic matter occurring in the soil. In this work, we evaluated leaf decomposition in eucalyptus plantation 72 months of age in the Cerrado. The work was conducted in the Água Limpa Farm, which belongs to the University of Brasília, situated in the Distrito Federal - DF (15° 56'-15 59' S and 47° 55'-47 58' WGr.). The stand was comprised a total area of 3.29 ha and was established in 2010. The planting of I224 clone *Eucalyptus urophylla* x *Eucalyptus grandis* was performed in a 3x2 m spacing. The soils were described as dystrophic Red Latosol (Oxisol) with low base saturation (V<50%) and high aluminum saturation (m). Fertilization was practiced along the planting line by application of 100 g of super simple phosphate + 100 g of NPK (4-30-16); liming was not performed previously. A total of 40, 10x10 m plots were randomly marked for monthly monitoring the leaf decomposition in each plot. Leaf decomposition rate was verified by means of the confinement of freshly fallen leaves into litter bags (20 x 20 cm) made of 2 mm nylon mesh. Each litter bag was filled with 21.00 g of leaf material and placed on the ground in each of the 40 plots for monthly redemption during the year of study. Leaf decay was calculated as a function of mean biomass losses over time with the following equation: remaining mass (%) = (final mass/initial mass) × 100. The constant *k*, calculated for 30, 60, 120, 240 and 365 days after the start of the experiment (5 periods) and also monthly (12 periods), was obtained through the simple exponential equation; where $X_t = X_0.e^{-kt}$, (X_t= dry weight of material remaining after *t* days and X_0 = dry weight of material at t = 0). Half-life time was calculated by means of the equation $t^{1/2} = \ln(2)/k$. Data of decomposition were compared by analysis of variance, followed by Tukey´s test to identify significant differences between monthly means. The constant *k* was 0.0008, $T^{1/2}$ 866 days and the estimate of decomposed biomass 1.70 Mg ha^{-1}. The results showed great recalcitrance of eucalypt leaves.

Keywords: dystrophic soil, k decomposition constant, litter bags

(8618 - 539) Macro- and micronutrients in western Amazonian forests and their influence on palm (Arecaceae) communities

Kristiansen, Søren M[1]; Muscarella, Robert A[2]; Cámara-Leret, Rodrigo[3]; Balslev, Henrik[2]

Aarhus University, Department of Geoscience, Denmark[1]; Aarhus University, Department of Bioscience, Denmark[2]; Royal Botanic Gardens, Kew, United Kingdom[3]

The vegetation of tropical rainforests is shaped by soil and climate, but the response of individual species to soil nutrients remains poorly understood. As Amazonian rainforests sustain one of the world's richest floras, understanding the soil controls of plant community structure is critical for conservation and land-use planning. In this paper, our aim is to present soil chemical variability within and between geomorphological landscape types, and to demonstrate how this variability influences the assembly and composition of palm communities in western Amazonian rainforests. We compiled data from 382 Amazon lowland rainforest transects, each of 5 x 500m (0.25 ha), across four countries (Bolivia, Colombia, Ecuador, Peru). Based on satellite images and field observations, transects where placed within areas of homogeneous landscapes and forest cover in order to represent local soil variation. Three soil samples were collected at 0-10 cm depth below the organic layer at each transect. Geomorphological landscape units included: terra firme, flood-plains (varzeá including restinga, igápo), terraces, white-sands and pre-montane hills. Floristic data included counts and identifications of 619,281 palm individuals from all life history stages, corresponding to 110 Neotropical palm species. Soil analyses included pH, loss on ignition, exchangeable acidity, exchangeable Al, exchangeable bases (Ca, Mg, Na, K), phosphorus, as well as carbon, nitrogen and particle size. Soil macronutrients and micronutrients (B, Cu, Fe, Mn, Zn) were extracted in Mehlich-III solution and analysed using ICPMS. In addition, site topography, palm community composition and satellite images were used to predict palm community composition. This unparalleled palm-soil dataset can be used to explore the relative importance of soil macro- and micro-nutrients in controlling the assembly and composition of palm communities in the Amazon. We demonstrate that palm phylogenetic structure in western Amazonia is strongly influenced by edaphic factors, and that canopy and understory species have significantly different mean optima for soil P and greater mean niche width along Ca, K, Mg, P, and B gradients. Overall, our analyses advance ecological niche theory about palms, and reveals that the main environmental correlates for palm species distribution are soil nutrient levels and inundation (possible in combination with Al toxicity), while clay content surprisingly is of less importance.

(3807 - 1910) Meaning of soils and vegetation in the context of urban heat island and health challenges

Norra[1]

Karlsruhe Institute of Technology[1]

Urbanization is a global phenomenon directly linked to economical development. Since about ten years, more than half of the world's population is living in urban regions. This causes an enormous intensification of buildings and land development. Valuable soils are lost by this ongoing process. They become excavated, sealed, polluted or intensively disturbed. But not all soils will be affected by constructions, some will be used e.g. as parks, small lawns, roadside greenery, playgrounds, gardens or will be abandoned. During the last decades the need for such free areas became obvious. Intensive and dense development produce urban heat islands. The related health consequences will be intensified by the warmer temperatures caused by climate change. Decreased life expectancies for citizens are predicted. Furthermore, lack of green areas (including soils) in cities negatively influencephysiological, psychological and social health. Therefore, urban soils provide an enormous value regarding the ecosystem services for human beings. Nevertheless, urban development is extremely often not considering these benefits of soils in urban systems. To protect agricultural fields and nature, the urban development policy of some countries, such as Germany, follows a paradigm that prefers inner urban densification against urban spatial extension. A paradigm that produces health disadvantages in the city for the benefit of the non-urban areas. Here, the approaches of the assessment and montezation of soil's ecosystem services contribute arguments for the protection of open areas within the city's built-up area. The implementation and protection of fresh air lanes, cold air formation areas, green roofs and facades, the general support of evapotranspiration processes and the improved understanding of the meaning of soil water for the benefit of citizen's health is urgently needed to improve the living conditions in our cities. Examples for the interdependencies between soil and building structure with respect to the generation of specific micro-climates will be given for the cities of Karlsruhe and Mannheim in South-West Germany.

Furthermore, the challenges to protect and provide sufficient areas of open soils and vegetation in the urban development process are subject of discussion for the situation of those two cities that are located in one of the warmest regions of Germany that faces intensive urban development due to population growth and land use conversions.

(6887 - 1873) Molecular identification of ectomycorrhizal fungi occurring in pecan orchards in Rio Grande do Sul / Brazil

De Andrade, Nariane[1]; Bevilacqua, Caroline B[1]; Sulzbacher, Marcelo A[1]; Antoniolli, Zaida I[1]; Jacques, Rodrigo J[1]
UFSM[1]

The culture of *Carya illinoinensis* (Wangenh.) K. Koch was introduced in Brazil at the beginning of the last century, and became commercially important after the 1960s, mainly in the southern region of the country. The pecan is proven to be an ectomycorrhizal symbiont, forming several mutualistic associations with mycorrhizal fungi. The main objective of this study was to identify the fungal isolates from commercial pecan plantations in the State of Rio Grande do Sul. For this purpose, the basidiomas were collected, which were photographed and described macroscopically still fresh and subsequently dehydrated to Microscopic analysis, according to traditional methodology in Mycology. Part of the isolated material was conserved in 2% CTAB (cetyltrimethylammonium chloride) at -20 ° C until DNA extraction, amplification and sequencing, using the ntDNA region primers ITS1 and ITS4 (ITS1-5.8S-ITS2). The extraction was performed by DNeasy® Plant Mini Kit (Qiagen). In order to detect the presence or absence of DNA in the sample, the electrophoresis of the PCR products in 1% agarose gel was performed. After the amplification, the presence of bands was verified by the electrophoresis of the PCR products in 1.5% agarose gel. For the purification of PCR products, KitGenElute PCR clean-up (Sigma, Saint Louis, USA) was used. After sequencing, Sequenced fragments were analyzed using the Staden Package 2.0.0b program for obtaining consensus sequences. After this, the consent sequences were deposited in the GenBank and a comparative search by means of BLASTn was perfomed. For the identification of fungus, all the sequences were aligned. The phylogenetic relationship of the specimens was reconstructed based on analyses of the ITS region, with the analysis of Maximum Likelihood (ML) in a total of 1000 replications for all reconstructions. The model of nucleotide substitution General Time Reversible model was estimated as the best model to solve the data, performed with Gamma distributed with Invariante sites and parameters for partial exemption (95%). The following potentially ectomycorrhizal fungi were identified: *Astraeus* sp., *Hymenogaster* sp., *Inocybe* sp., *Pisolithus arhizus*, *Russula* sp., *Scleroderma bovista* and *Scleroderma* spp. From these results, it is possible to continue with research aiming at the next stages of identification and phylogenetic analysis.

(7847 - 1891) Monitoring soil management to assess ecosystem services provision in Atlantic Forest, Rio de Janeiro

Joyce M. G. Monteiro[1]; Azeneth E. Schuler[1]; Rachel B. Prado[1]; Elaine C. C. Fidalgo[1]; Ana P. Turetta[1]; Alba L. Martins[1]; Aline P. de Oliveira[1]; Guilherme K. Donagemma[1]
Embrapa Soils[1]

Monitoring soil management to assess ecosystem services provision in Atlantic Forest, Rio de Janeiro. Joyce M. G. Monteiro[1], Azeneth E. Schuler[1], Rachel B. Prado[1], Elaine C. C. Fidalgo[1], Ana P. Turetta[1], Alba L. Martins[1], Aline P. de Oliveira[1], Guilherme K. Donagemma[1] Embrapa Soils, Rua Jardim Botânico, 1024. Jardim Botânico Rio de Janeiro, RJ Brazil, 22460-000 Soil conservation management includes practices that help to preserve the quality of soil, water and biodiversity, promoting sustainable agriculture and ecosystem services supply. In Rio de Janeiro state, Brazil, in the region of Atlantic Forest biome, some agriculture conservation practices have been reported as capable to provide soil ecosystem services (ES) and also to increase productivity and rural income. The monitoring of the conservation practices and related ecosystem processes is essential to understand and evaluate their impacts on ecosystem services provision, as well as to subsidize conservation policies and programs. This study highlights aspects to be considered in monitoring based on a review of researches on conservation management practices in the state such as minimal tillage, crop rotation, agroforestry systems, rotational grazing and fallow. A key point concerning the monitoring of agroecosystems and their potential to provide ES is to define indicators to evaluate the impact of soil management on ecosystem services. The selection of indicators to link agroecosystems and soil ES provision requires identifying key features that represent the compositional, structural, and functional components of the system important for ecosystem services provision. The monitoring must deal with the complex dynamics of land management and ES provision in order to quantify and model them connected to ecological and soil processes in multiple spatial and temporal scales. We found that major challenges of monitoring are related to the needs of: (i) multidisciplinary studies to understand how land management affects soil ES considering the set of biotic and abiotic parameters involved, (ii) a suitable approach to analyze these parameters together, and (iii) participatory monitoring skills to promote the exchange of local stakeholders' knowledge on the ecosystems and the impacts of land management on ES . The efforts to overcome these main challenges are mandatory in order to build gathered solutions to the communities' needs concerning to the agricultural management potential to provide soil ES.

(8633 - 1370) Overview of methods to assess the impacts of management practices on ecosystem services to control erosion and soil loss in Latin America.

Marllus Henrique Ribeiro de Paiva[1]; Dirlane de Fátima do Carmo[1]; Rachel Bardy Prado[2]
Pós-Graduação em Engenharia de Biossistemas - Universidade Federal Fluminense[1]; Embrapa Solos[2]

The land use and land cover dynamic, as well as soil and water management in agriculture can influence the amount of nutrients and sediments leached by erosion processes, jeopardizing the provision of the ecosystem services. This work aimed to identify the state of the art of methods applied in Latin America to assess management practices impacts on ecosystem services to control erosion and soil loss. For that, a bibliographic survey was done and data base was carried out, containing information on indicators and models currently used. 85 indexed articles were selected from 3.018 in the Scopus and Web of Science database (1990 to 2016). The keywords applied were: Esosion Control, Landscape, Methods, Land Use, Land Cover, Monitoring, Ecosystem Services, Indicators, Sedimentation and Latin America. The most used indicators in these studies were soil erodibility, rainfall erosion, precipitation, turbidity and flow. Among the models, there was a greater application of the USLE (30.6%), RUSLE (9.35%), MUSLE (8.5%), and SWAT (5.1%) to measure the rates of erosive potential and sediment generation (63%) under management practices. Few (6%) applied methods integrated indicators to evaluate the landscape. 75% of the studies were developed in agricultural areas. Most of them were developed in Brazil (65%), followed by Chile (5%), Costa Rica/Argentina (2.5%) and others (27.5%). This study concludes that the applied methods are similar and need to be addressed, taking into account landscape ecology, multiple scales and the provision of ecosystem

services.

(1261 - 2441) Pedodiversity in Brazil: recognizing and valuation

Rosangela Garrido Machado Botelho[1]; Katia Leite Mansur[2]
Instituto Brasileiro de Geografia e Estatística, Diretoria de Geociências, Coordenação de Recursos Naturais e Estudos Ambientais[1]; Universidade Federal do Rio de Janeiro, Instituto de Geociências, Departamento de Geologia[2]

Geodiversity is a concept that has been increasingly discussed by the geoscientists in this millennium. In a few words it is the abiotic equivalent of biodiversity and has been defined as the natural variety of geological (rocks, minerals, fossils), geomorphological (landforms, processes), hydrological and pedological features, including their assemblages, relationships, attributes, interpretations and systems. However, mainly in Brazil, the soil features or pedodiversity has not been recognized and valued enough in spite of its great range in the territory. This work aims to point out the high diversity of pedological heritage (soil features with different values including the scientific one) in Brazil and the importance of identifying, mapping and conserving it for the future generations. The own existence of a wide and robust Soil Classification System reveals that diversity. Considering only up to the fourth level of this System, there are 880 different kinds of soils. The role of some types of soils (ex. Nitisols) in the occupation and development of regions in Brazil, as the coffee zone in South and Southeast, and soils originated by human activities (anthrosols) in Amazonia Region are examples of the meaning of soil to our history and economy. The paleosols also can tell about past environmental conditions, reflect former human environment interactions and can guide the society to sustainable use and management. Some areas are under intensive exploitation and negative impacts due to specific soil properties as high values of sand (ex. Arenosols) by the building sector. Others (ex. Gleysols) are used as raw material to ceramics, sculptures, jewels and different kinds of art products. Besides this, soils are a live system with interactions to biological processes that are essentials to ecosystems functioning. Thus, soils can have scientific, historic, economic, ecological, educating and cultural values that need to be recognized and protected. But in the inventory carried on by the Brazilian Committee of Geological and Paleontological Sites there are 116 geosites published from several categories but there are no pedosites. These ones are very significant for science development, teaching, geoturism and even recreation activities. So, it is mandatory that pedologists and soils institutes, universities and organizations gather efforts to identify soil heritage in Brazil and defend its protection.

(3873 - 1754) Physical and water attributes of the soil and the water production of in hydrographic basin

Hudson Carlos Lissoni Leonardo[1]; Miguel Cooper[2]
ITAIPU Binacional[1]; Universidade de São Paulo[2]

The adequate use and management of the soil associated to the mechanical practices of soil and water conservation improves the infiltration of water in the soil, instead of runoff and, consequently, contributes to the recharge of water table, processes present in the hydrographic basin, but are not linear according to the spatial scale of the basin. Among the benefits of this land use and management suitability, there is an increase in water availability for the electrical sector from the storage of water in the soils of the reservoirs contribution basins, the recharge of the water table and the regulation of the flow of streams and rivers from the drainage network that supplies the reservoirs. Thus, the objective of this work is to quantify the environmental services in terms of production and regulation of the water production, provided by an agricultural hydrographic basin under no-tillage since 1987, with the implanted terracing system and established riparian forest. It is a first-order basin with an area of 1.03 square kilometers, localized coordinates 24 ° 48 '59 "S and 53 ° 33' 09" W, in the region of the third plateau paranaense. The regional relief is predominantly slightly wavy to wavy. The representative topossequence of the basin consists mainly by Oxisols. In order to do so, will be characterized and quantified soil physical and water attributes (granulometry, soil water retention curve, soil density, particle density, micromorphometric analysis, hydraulic conductivity of the saturated soil, hydraulic conductivity of the unsaturated soil) and combined with the monitoring between 0 and 2 meters deep of the moisture and the total soil water potential, soil temperature and precipitation, will be characterized the subsurface vertical and lateral water flows in toposequence. The water table is also being monitored by means of wells along the toposequence and the flow of the basin by means of parshall gutter and radar type sensor. All the described variables are being monitored with a resolution time of ten minutes. To date, only partial data have been used, which indicated a time of concentration of the basin in the order of twenty minutes and the presence of subsurface flows, both vertical and lateral. For medium intensity rains there is a trend of infiltration values higher than the surface runoff.

(8465 - 715) Potential of agroecosystem services. The case of Slovakia.

Jarmila Makovníková[1]; Boris Pálka[1]; Miloš Širáň[1]; Beata Houšková[1]
National Agricultural and Food Centre/ Soil Science and Conservation Research Institute Bratislava, Slovakia[1]

Applying the mapping of agroecosystem services potential appropriately can help to show the possibilities of regional sustainable land use management as well as trade-offs between diferent ecosystem services. For evaluation of agroecosystem services potential in Slovakia, we have created a mapping unit by combination of four input layers (slope topography, climate units, soil texture and land use) with the use of tools offered by geographic information systems. In Slovakia 29.14% of agricultural land has very high potential for provisioning services, 27.47% of agricultural ecosystems has very high potential for water regime regulation of and 92% agroecosystems have a high to very high potential for water erosion regulation . Out of the total Slovak land used in agriculture 41.67% of ecosystems have very high potential for soil purification, they are mainly ecosystems of arable land with high carbonate content without anthropogenic and geochemical deposition. The percentage distribution results of various categories for climate regulations potential (sequestration of organic carbon in the soil) are significantly influenced by the ecosystems of arable land due to the high share of area of these ecosystems to the total area of agricultural land. The capacity of ecosystems to provide recreational services depends on the particular uniqueness of the site, its accessibility and the surrounding infrastructure. Agroecosystems of arable land have predominantly very low (50.7 %) to low potential (15.7%) and permanent grasslands have high and very high potential of natural conditions for recreation (53.82%). Ecosystem services are non-linearly linked and changes in one service influence the other in positive or negative way. High potential of provisioning service is linked to the high potential of water regime regulation, pollutants filtration and soil erosion. The opposite trend has the potential provisioning services to potential of climate regulation and potential of natural conditions for recreation. The synergistic effect is between the provisioning agroecosystem service, regulation of water regime and soil purification. Climate has the most significant impact on agroecosystem services. Warm, dry and lowland regions have higher potential of provisioning services, regulation of water regime, filtration of pollutants and control of soil erosion in comparison to moderately warm and cold regions.

(6860 - 1455) Soil organic matter quality as indicator of ecosystem services

Ana Paula Turetta[1]; Etelvino H. Novotny[2]; Catarina Mendes Rebello[3]
Brazilian Agricultural Research Corporation - Embrapa[1]; Brazilian Agricultural Research Corporation[2]; Federal University of Rio de Janeiro State[3]

Soil organic matter (SOM), although a minor component in most soils, is primarily responsible for structure, function and sustainability of the ecosystems. Regarding the effects of soil degradation, those associated to SOM have importance and complexity, since changes in the quantity and quality of SOM may occur as a function of agricultural management practices. Ecosystem services (ES) are the benefits that humans obtain from ecosystems and so is necessary to develop methodologies capable to assess the potential of agroecosystems to provide ES; to subsidize public policies that encourage the adoption of conservationist agricultural practices and; consequently, the payment of ecosystem services (PES). For this, is necessary to identify parameters that can act as indicators of such services. Since SOM is a key component in soil ES provisioning, its characterization is mandatory to this discussion, and ^{13}C nuclear magnetic resonance (NMR) spectroscopy is one of the most powerful tools for this purpose, making possible, with the aid of multivariate analysis, to compare different soil management practices for ES evaluation. For the evaluation of a new management model, tested in Pito Acceso watershed, in Bom Jardim/Rio de Janeiro State, Brazil, with typical soils of mountain environment under the Atlantic Forest cover, we analyzed soil samples from four land uses/soil management: forest; permanent conventional crop; annual conventional crop and annual implemented crop, in two depths: 0-5 and 80-100 cm. Three pseudoreplicates from each area were collected. The extraction of the humic acids (AH) was carried out according to the method suggested by the International Humic Substances Society. The HA were analyzed by solid state NMR in a Varian INOVA (11.74 T) spectrometer. To help in data interpretation, the technique "Multivariate Curves Resolution" was used. The superficial layer (0 – 5 cm), the implemented crop presented AH similar to those obtained from the forest, with predominance of aliphatic structure. In depth (80 - 100 cm) there is a relative accumulation of aged (partially oxidized) pyrogenic C and carbohydrates, which probably percolated through the soil. The HA composition, determined by NMR, proved to be efficient in the evaluation of the soil potential to provide ES and can be used as an indicator of ES or as a reference method for the validation of other low-cost indicators.

(9678 - 1127) Spatial Bayesian belief networks: A participatory approach for mapping soil vulnerability at the Itatiaia National Park, Brazil

Elias Mendes Costa[1]; Laura Poggio[2]; Helena Saraiva Koenow Pinheiro[1]; Robson Altiellys Tosta Marcondes[1]; Lúcia Helena Cunha dos Anjos[1]
Federal Rural University of Rio de Janeiro[1]; The James Hutton Institute[2]

The Itatiaia National Park (INP) is a conservation unit, with a multitude of species of the Brazilian fauna and flora, some endemic. The INP is the origin of 12 watersheds that contribute to the rivers Rio Grande and Paraíba do Sul, important rivers in southern and south regions of Brazil. It is one of the parks that receive most visitors in Brazil due to the landscape and biodiversity characteristics. The aim of this study was to assess the soil vulnerability in the INP by integrating the information of physical environment with knowledge of experts, to reconcile demand for public use and of ecosystems conservation. The method used was spatial application of a probabilistic model known as Bayesian Belief Network (BBN). Soil data (such as carbon content, texture, depth, and capacity to store water) were integrated with data derived from remote sensing (e.g. land use) and relief (elevation and slope) and with the expert opinion of land managers, decision makers and researchers that work with the INP or surrounding areas. Integrating environmental factors and expert opinion is a suitable approach to assess the soil vulnerability in INP. The most fragile areas were identified with soils with high levels of carbon, profiles less developed (shallow), with accentuated slopes, and a vegetation cover with herbaceous graminoid plants, with a predominance of Cyperaceae and Poaceae (high altitude fields). This approach will help decision makers to identify priority areas for intervention, in order to reduce soil degradation in the areas with high vulnerability. The results could also be used as a basis to support the INP management plan, as well as to contribute to other researches, especially those related with ecosystem services in the Atlantic Forest Biome.

(7195 - 1946) Sugarcane straw removal for bioenergy production in Brazil: short-term effects on soil functions and plant yield

Maurício Roberto Cherubin[1]; Izaias Pinheiro Lisboa[2]; Lucas Santos Satiro[2]; Aijânio Gomes de Brito Silva[2]; Brigitte Josefine Feigl[3]; Carlos Eduardo Pellegrino Cerri[2]
University of São Paulo, "Luiz de Queiroz" College of Agriculture, 11 Pádua Dias Avenue, Piracicaba, SP 13418-900 Brazil (cherubin@usp.br) / University of São Paulo, Center for Nuclear Energy in Agriculture, Piracicaba, SP 13416-000 Brazil[1]; University of São Paulo, "Luiz de Queiroz" College of Agriculture, 11 Pádua Dias Avenue, Piracicaba, SP 13418-900 Brazil[2]; University of São Paulo, Center for Nuclear Energy in Agriculture, Piracicaba, SP 13416-000 Brazil[3]

Brazil is the largest sugarcane producer in the world, accounting for about 40% of the global production. Despite that, growing demands for bioenergies and market opportunities have raised the industry's interest for removing the sugarcane straw left on the field during stalk harvesting to produce bioelectricity and/or cellulosic ethanol. However, the straw maintenance in the field has a key role for preserving or improving soil functioning and plant growth. Therefore, indiscriminate straw removal management can deplete soil quality, decreasing its capacity to sustain suitable biomass production over time. In light of that, a multi-local study has been conducted since 2014 across central-southern Brazil. We investigated the impacts of sugarcane straw removal rates on soil and plant growth aiming to produce a useful scientific base to the sector for supporting decision-making. In nine study sites, we assessed straw decomposition, multiple soil properties (chemical, physical and biological) and sugarcane biomass production under increasing amount of straw that representing 100, 75, 50, 25 and 0% of removal straw. After two years of study, the short-term effects indicated that indiscriminate (total) removal of sugarcane straw from the field induced negative impacts on key soil functions, such as cycling and storage of C and nutrients, thermal regulation, plant-available water storage and resistance to structural degradation, especially in the surface layers (up to 10 cm). Soil functions were little or no impacted by moderate straw removal (~50%). In terms of plants, straw removal affected positively plant sprouting, but it had none or a slight negative effect on the sugarcane yield. Both, soil and plant responses varied according site-specific conditions of soil, sugarcane variety and climate, confirming that

these factors have to be taken account for more sustainable straw management. Our findings indicated that in high straw-producing fields, partial straw removal seems to be (at least in the short term) a sustainable strategy to increase Brazilian bioenergy production with minimal degradation of soil functions and negative impacts on biomass production.

(3628 - 989) The activity of earthworms and their influence on the soil of an Atlantic Plateau hillslope in São Paulo State under primary forests

Geraldo José Diogo Filho[1]; José Pereira de Queiroz Neto[2]
Escola Superior de Agricultura[1]; Universidade de São Paulo[2]

Very little is known of the impacts of topography on soil faunal communities. Therefore, the focus of this research is the activity of earthworms and their influence on the soil of an Atlantic Plateau hillslope in São Paulo State. Our area of study is surrounded by environmental preservation areas, it has primary forests in good conditions, warm climate and precipitations above 2,000 mm per year. Three different extraction techniques were used for the survey of annelid communities. Twenty seven monoliths of 25 cm x 25 cm x 30 cm depth were sampled, using the Tropical Soil Biology and Fertility (TSBF) method. Qualitative samples were taken by digging ten holes of 50 cm x 50 cm x 50 cm deph and worms hand sorted. We also used a behavioural extraction technique that induces earthworms to emerge from the soil (onion extract solution) in twelve sites. The collected organisms were weighed, counted and identified at the species level and its distribution was analyzed along the topography. We found a variation of earthworm populations in the three sectors of the slope, with the highest densities in the foothills and lower densities in the top. The density of these invertebrates was influenced by the type of soil along the topography. There is an intense activity of these organisms in the soil and they are not equally distributed in the vertical profile, concentrating on a few layers, sometimes in topsoil, sometimes in subsoil. We also observed the presence of exotic species in disturbed areas. The activity of oligochaetes changes the morphology (bioaggregation), the physical (macroporosity), and chemical (P, K^+, Ca^{2+}, Mg^{2+} and organic matter dynamics, sum of bases and cation exchange capacity) attributes of soil, affecting many pedological processes and soil formation. With their feeding and builder ecological behaviors, worms create galleries, channels and produce casts, helping in soil aeration, the water dynamics and nutrient cycling processes. Despite the role they play in the formation of soil mantle, most of the ground surveys does not include the biogenic aggregates, therefore, we gave special emphasis on the descriptions of such morphologies.
Keywords: topography, pedological coverage, oligochaetes, biogenesis, bioturbation.

C4.1.2 - Climate change and adaptation of soil functions

(1588 - 1399) Assessing the potential of a Ferric Luvisol in climate change adaptation.

Daniel Okae-Anti[1]; Pane Jeanne D'arc Coulibaly[2]
University of Cape Coast[1]; INERA[2]

Luvisols are considered productive soils because of their moderate stage of weathering and high base saturation. Soils at the study site had developed from granite rock as parent material. These soils have upper horizons of sandy loam texture to sandy clay and generally continuous and massive structure. The study was conducted at Saria in the Central region of Burkina Faso, where contrasting climatic conditions were prevalent, to assess the genotypic performance of two Sorghum varieties, *Kapelga* and *Sariaso 14*, local and improved varieties respectively. Three experiments were carried out under three climatic conditions of a hot dry, cold dry and rainfed seasons. The design was a split-plot. Physico-chemical characterization was done on soils at the 0-20 cm and 20-40 cm depth for particle size distribution, pH, N, P, K, Org C, Ca, Mg, CEC. The crops were evaluated for root growth, reproductive cycle, yield and yield components. Results indicated that yield of sorghum declined with variations in climate. However, the dry cold season was found to be the most productive giving a shortened reproductive cycle with *Sariaso 14*. The soils were sandy loams, slightly acidic and low in N, P, K, Ca, Mg and CEC. Productivity of the soils can be boosted with nitrogen fertilization and some irrigation.
Keywords: Climate change, Sorghum genotypes, Luvisols, Hot dry, Cold dry and Rainfed seasons.

(3687 - 2189) Biometric variables in young plants of Khaya ivorensis A. Chev. under phytoremediation of Cadmium.

Vitor Resende do Nascimento[1]; Cândido Ferreira de Oliveira Neto[1]; Josilene do Carmo Mescouto de Sousa[1]; Thays Correa Costa[1]; Jessica Taynara da Silva Martins[1]; Liliane Correa Machado[1]; Denilson Pontes Ferreira[1]; Susana Silva Conceição[1]; Diana Jhulia Palheta de Sousa[1]; Jessica Suellen Silva Teixeira[1]
Universidade Federal Rural da Amazônia (UFRA)[1]

Soil contamination by cadmium represents a potential agricultural, food-producing, and environmental hazard throughout the world. Faced with the problems caused by this and other metals it is necessary to remove or stabilize the same of the soil, so that there is no contamination of the ecosystems. One of the options for recovering the activity and the diversity of these environments is phytoremediation. With this, the objective of this work was to evaluate the biometric responses in plants of Khaya ivorensis A. Chev. submitted to different doses of $CdCl_2$. The experiment was conducted at the Federal Rural University of Amazonia (UFRA), Belém campus, from December 2015 to April 2016. A completely randomized experimental design with 5 treatments (Control, 10 $ClCd_2$ mg/L^{-1} , 20 $ClCd_2$ mg/L^{-1}, 30 $ClCd_2$ mg/L^{-1}, 40 $ClCd_2$ mg/L^{-1}) and 7 replicates. With the increasing doses of the metal, the plants of Khaya ivorensis A. Chev., presented in response a decline in the biometric parameters, but did not cause the death of the plants. The Khaya ivorensis A. Chev species proved to be an excellent alternative for the phytoremediation method in areas contaminated with cadmium.

(7004 - 3101) Deep Soil Carbon in the Critical Zone: climatic controls on the amount and turnover of carbon in weathered bedrock

Kimber Candice Moreland[1]; Zhiyuan Tian[2]; Asmeret Asefaw Berhe[1]; Anthony O'Geen[2]; Karis McFarlane[3]
University of California-Merced[1]; University of California-Davis[2]; Lawrence Livermore National Lab[3]

Up to 60-80% of the Carbon (C) stored in soils is found below 30cm and deep CO^2 efflux changes seasonally showing the direct connection between atmospheric conditions and deep soil C dynamics. Despite this link there is very little data on C storage and stability in weathered bedrock or saprolite. The overall objective of this research is to investigate how climate regulates organic matter (OM) storage, composition, stability, and stabilization mechanisms. Expecting that the amount of OM stored in deep soil and the stability are a function of soil thickness and availability of weathering products (i.e. reactive minerals),

the stock and stability of deep SOM is expected to follow a similar relationship with climate, as does the intensity of weathering. This research is conducted in the NSF funded Southern Sierra Critical Zone Observatories that is located along a climosequence, the western slopes of the Sierra Nevada Mountains of California. Here we will present results derived from characterization of soils and weathered bedrock using elemental and stable isotope elemental analysis, Fourier Transformed Infrared Spectroscopy as a proxy for decomposition of bulk OM, and Accelerator Mass Spectroscopy to determine the turnover time of C from the topsoil down to 10 meters deep. Our findings show that adding in subsoil and weathered bedrock C stocks increases estimates of soil C stock by 23-29%, that weathered bedrock is an active cycling pool of C, and that the turnover time generally increases with depth and responds to climate regime.

Keywords: C stocks, turnover

(4805 - 784) Effect of temperature and soil moisture on soil: atmosphere greenhouse gases exchange on an aridity gradient

Everaldo dos Santos[1]; Luciana Mayara Mendonça de Almeida[2]; Alexandra Rodríguez[3]; Jorge Durán[3]; Laura García-Velázquez[4]; Fernando T. Maestre[5]; David Fangueiro[6]
Instituto Federal do Paraná[1]; Universidade Federal de Alagoas[2]; Centre for Functional Ecology Coimbra University[3]; Universidad Pablo de Olavide[4]; Universidad Rey Juan Carlos I[5]; Instituto Superior de Agronomia Universidade de Lisboa[6]

Climatic models project an increase of temperature and aridity in many regions of the planet. Soil responses to these changes in drylands are still poorly understood, especially regarding the release and uptake of greenhouse gases (GHGs) by soil microorganisms. In this context, we evaluated the effect of temperature and humidity on the exchange of methane (CH_4), carbon dioxide (CO_2) and nitrous oxide (N_2O) between the soil and the atmosphere in a natural aridity gradient. To do so, we selected and surveyed 24 stabilized dunes located along a natural aridity gradient in the Iberian Peninsula. Collected soil samples were subjected to 10-day laboratory incubations following a full-factorial design with two temperature (25ºC and 30ºC) and two moisture (30% and 60% Water Holding Capacity - WHC) levels. We calculated potential rates of nutrients transformation and GHGs exchange for each combination of temperature and soil moisture. Preliminary results of this experiment show a significant effect of temperature on the soil: atmosphere exchange of all the studied gases ($P < 0.001$). Interestingly, whereas we did not find a significant effect of soil moisture on the GHGs exchange (CH_4: $P = 0.366$, CO_2: $P = 0.781$, N_2O: $P = 0.836$), we found a significant interaction between temperature and soil moisture for soil CO_2 emissions ($P < 0.05$). These results suggest that soils from this gradient can maintain similar levels of functioning under different levels of soil moisture. However, increases in temperature are likely to lead to increased GHGs emissions, which represents a positive feedback to climate change.

(1285 - 561) High temperature and water stress affect the plant nutrient levels of *Panicum maximum* under future climatic changes

Dilier Olivera Viciedo[1]; Renato de Mello Prado[1]; Carlos Alberto Martinez[2]; Eduardo Habermann[2]; Kolima Peña Calzada[3]; Alexander Calero Hurtado[1]; Rodolfo Lizcano Toledo[1]
São Paulo State University (Unesp), School of Agricultural and Veterinarian Sciences, Jaboticabal, SP- Brazil.[1]; University of São Paulo, Department of Biology, FFCLRPRibeirão Preto, São Paulo, Brazil, 14040–901[2]; University of Sancti Spiritus Jose Marti Perez, Sancti Spiritus, Cuba[3]

Panicum maximum Jacq. 'Mombaça' (C4) was grown in field conditions with sufficient water and nutrients to examine the effects of warming and water stress (Ws) on the growth, accumulation and efficiency of nutrients in the metabolism of tropical grass C4, from November 6th to 27th, 2016. Plants were exposed to both the ambient temperature and good soil moisture (Control); water stress (Ws); canopy warming (+2°C above regular canopy temperature, eT); or water stress and canopy warming (Ws+eT). The temperatures in the field were controlled by temperature free-air controlled enhancement (T-FACE). The plots with normal moisture were irrigated frequently to maintain soil moisture at 80%. Soil of the experimental area was an Oxisol clayey. The temperature increase with adequate humidity (eT) significantly influenced the nutrients accumulation N, K, Ca, B and Cu with relation the control treatment (C). The treatment under water restriction (Ws) presented the worst performance, with the absorption of nutrients being limited. In relation to the nutrient use efficiency (NUE) a behavior similar to the nutrient accumulation could be verified, being the (eT) treatment the one that stimulated a greater nutrients use efficiency N, P, K, Cu, Fe, Mn and Zn in relation to the control treatment (C). This behavior can be explained because the higher temperature promoted a higher photosynthetic, improving the efficiency of water use, nutrients, being reflected in the greater production of dry matter. Therefore, with sufficient water and nutrients in this forage, the accumulation and nutrient use efficiency could be partially offset by elevated temperatures, achieving a greater production of P. maximum foliage and decreasing the fertilization costs under the future effects of climate change. Dry matter was also favored with the increase of temperature and adequate humidity (eT) presenting an increase of 20% in relation to the control treatment (C), 16% with the (Ws + eT) treatment and 33% with the water stress (Ws) respectively. Interesting result how the treatment subjected to water stress and high temperature (Ws+eT) presented a better performance than the one subjected to water stress in an isolated form, which is probably influenced by a better use of water as well as stomatal opening and closing.

Keywords: Nutritional efficiency, nutrient absorption, environment, climate.

(8649 - 1088) Relationship of Nitrous Oxide Production and Consumption By Collapsed Palsa

Yuta Takatsu[1]; Nako Achiwa[1]; Leo Vainio[1]; Teemu Tahvanainen[2]; Yasuyuki Hashidoko[1]
Hokkaido Univ[1]; University of Eastern Finland[2]

Nitrous oxide (N_2O) is known to be one of the strongest greenhouse gases, which is 300-times stronger than CO_2. N_2O is also recognized as a disrupter of the ozone layer. Now-a-day, the permafrost including the palsa mire in subarctic tundra has been melting due to global warming. After this topogeological collapse of palsa hills, active N_2O emission was predicted in this area. Generally, N_2O is emitted in acidic conditions, but in the palsa, N_2O emission is accelerated in weak alkaline conditions. Stable palsa mire generally sustains acidic conditions in soil, water, and heathy vegetation. In the culturing system, N_2O emitters isolated from the ombrotrophic ecosystems indicated similar tendency. Furthermore, consumption of N_2O that had been produced by N_2O emitters was implied in varying conditions and we predicted that N_2O-consuming

bacteria are present and act as an N_2O quencher in the palsa soil. We attempted to find the N_2O emitting bacteria and N_2O consuming bacteria in the degraded palsa soil, Finland, Kilpisjärvi. A 10 mg potion of the soil was suspended in 10 ml Milli Q water and 100 µl of the resulting supernatant was inoculated into a gellan gum medium for N_2O production assay, allowing culturing at 25°C for 14 days. Headspace gas (22.6 mL) in the vials was then analyzed by ECD-gas chromatography to search for hyperactive N_2O emission bacteria, and some of the highly N_2O emitting bacteria were confirmed as the community members in the soil. These cultures were analyzed by the next generation sequencer together with the soil itself to reveal intact or biased bacteria community structures, including those N_2O emitting bacteria. The result of the microfloral analysis administered prediction that *Chitinophpaga* sp., which has been found in reclaimed tropical peatland, in Sarawak, Malaysia, and andisol farmland in Hokkaido, Japan, was also confirmed in the collapsed place of subarctic palsa soils, in Lapland, Finland. The proportion of *Chitinophaga* spp. at the low N_2O emitting soil tended to be large. These results strongly suggested that N_2O quenching system by *Chitinophaga* sp.is distributed in global scale throughout tropic to subarctic zones. Currently, we are attempting to elucidate mechanisms of this N_2O quenching process.

(7160 - 2223) Response of soil microarthropods assemblages to different precipitation patterns

Bruna Raquel Winck[1]; Felicia Fischer[1]; Ricardo de Alencastro[1]; Daniela Hoss[1]; Bruna Claudia da Silva Jorge[1]; Valério D. Pillar[1]

Universidade Federal do Rio Grande do Sul[1]

Soil fauna assemblages can influence several ecosystem services related to organic matter decomposition and nutrient availability. Previous studies suggest that soil biota is very sensitive to impacts such as climate change and can be indicator of environmental disturbance. One of the effects of climate change is on precipitation patterns, causing extreme weather events such as drought and intense rainfall. Here we investigate how extreme weather events can influence epigeic soil fauna community in natural grassland in southern Brazil. We simulated two extreme weather conditions: drought (93% rainfall reduction with rainout shelters) and excessive rainfall (93% rainfall addition with irrigation). Two additional controls were used: natural rainfall and upside down rainout shelter (simulating only the microclimate under shelter). We focused our attention on collembolan community (a representative microarthropod of soil) as proxy for soil biodiversity. We measured: community composition (MANOVA), abundance, richness, taxonomical diversity, dominance, evenness, functional diversity and functional redundancy. Our findings showed that collembolan composition (P = 0,0001), abundance (P = 0.025), richness (P = 0.05) and functional diversity (P = 0.04) were significantly affected by rainfall treatments. MANOVA revealed that drought (93% rainfall reduction) was strongly different from the other treatments, indicating that soil moisture reduction and temperature increases caused by precipitation reduction can affect species composition. Collembolan abundance was high in rainfall addition and in natural conditions (77 and 90 individuals, respectively), possibly due the better habitat conditions (higher soil moisture and lower temperature). Species richness was also higher in rainfall addition and natural conditions (both with 12 species) when compared to drought conditions (9 species). Higher species richness can explain the higher functional diversity (0.41 and 0.40) in these treatments when compared to drought and control with shelter (0.38 and 0.36). Comparing the treatment of drought and control with shelter, we observed that abundance, richness and functional diversity were statistically similar, suggesting that the microclimate can also influence Collembola community. Even so, our findings revealed that changes on soil habitat caused my climate changes, mainly drought, can strongly affect fauna communities and consequently ecosystem services they provide.

(6091 - 1880) Soil organic carbon store in Honduras

Arévalo Gloria[1]; Manueles Alexandra[1]; Guevara Mario[2]; Olmedo Guillermo[3]

Zamorano University, Honduras[1]; 2University of Delaware, Department of Plant and Soil Sciences, Newark DE, USA. 19713[2]; 3INTA EEA Mendoza, San Martín 3853, Luján de Cuyo, Mendoza, Argentina, M5507EVY and FAO-Global Soil Parthership, Viale delle Terme di Caracalla, 00153, Rome, Italy.[3]

Soil organic carbon (SOC) and also Soil Organic Matter (SOM) buffers the impact of climate extremes on soils and crops by regulating water supply to plants, reducing erosion by decreasing runoff, and providing sites for nutrient retention and release (FAO and ITPS 2015). The SOC map was building on basis for the preparation of the Global SOC Map of the Global Soil Partnership (GSOCMap-GSP). Honduras is located at the middle of Central America. It has 112,492 km² and about 70% of irregular landscape. Intermountain rivers give origin to alluvial valley of various shapes and extensions. This conditions generates a great variability of landscapes, subjects to common cycles of soil erosion and flooding. Since the country is located 16 degrees North of the Equator, with various thermal levels in the soils as well as in the atmosphere. Rainfall has a very strong effect in (SOC). More than 2200 soil profiles were collected and reviewed from various sources. It was necessary to locate the each information point: master horizons and their depth, color, texture and coarse fragments volumes. Bulk density was calculated on basis of this information. With these parameters (SOC) were calculated end extrapolated by the Kriging Method. Therefore, the genesis and content of SOC varies across the country, mainly taking into consideration a very distinct climatic patterns between The Caribbean and The Pacific Ocean Coast. It can be predicted that Climate Change will have a decrease on SOM of the soils, punctuated by years of heavy rainfall with signicant with draughty ones which result in SOM losses in the soils. The work was presented as a major effort of the Republic of Honduras to mitigate Climate Change and to improve soil sustainability. Highest correlations of available SOC data and were found with temperature across Honduras. Terrain slope and temperature are the best correlated variables with available data. Higher uncertainty and a relatively low density of SOC per unit of area was found in Honduras.

(5942 - 1631) Soil organic carbon turnover rate prediction in the framework of global warming: an approach to determine the role of climate and geochemestry.

Marcela Hidalgo[1]; Manuel Casanova[2]; Cristina Muñoz[1]; María de los Ángeles Sepulveda[1]; Erick Zagal[1]

Universidad de Concepción[1]; Universidad de Chile[2]

The role of soil as a sink or source of atmospheric CO_2 is not sufficiently elucidated. As well as the knowledge of geochemistry and climate influences in the stabilization and decomposition process of organic matter. This knowledge is needed to improve prediction of carbon (C) storage under the new sceneries of global warming. Thus, the main goal of the research is to evaluate the organic matter mineralization rate through soil profile in order to understand geochemical and climate interaction as control factors in the soil C feedback to climate change. By the determination of $\Delta\delta^{13}$ using NIRS as a tool to predict the C turnover

rates in a latitudinal climatic gradient. The gradient includes 38 different sites across Chile (between 32°-47°S, 4000 km) with different climate zones as hot, temperate and cold as well as humid and arid zones. Soil samples were collected in 40 different sample sites at three different soil depth (0-10; 10-30; 30-60 cm). Geochemistry parameters will be analysed as well as SOC turnover rates by soil respiration until 70 days of soil incubation, relating these results to $\delta^{13}C$ values ($^{0}/_{00}$) obtained through NIRS method. Our study will help unravel climate and geochemistry effects on patterns of vertical $\delta^{13}C$ leading to a better understanding of SOC turnover both for the top and sub-soils. And consequently to improve CO_2 prediction in a changing climate. Currently measurement are been performing on $\delta^{13}C$ values ($^{0}/_{00}$) from soil incubations using NIRS technique, and these results will be available by May 2018.

(1698 - 632) The heat on the surfaces of the Federal Rural University of Rio de Janeiro

Thallison Rodrigues de Oliveira[1]; Adriana Soares de Schueler[1]
Universidade Federal Rural do Rio de Janeiro[1]

The solar irradiation when focuses on Earth provides five physical phenomena: reflection, transmission, scattering, absorption and emission. Find out how these phenomena work is important for determining the reflectance of the waves and consequently the balance of the short waves. Among these physical phenomena the scattering which is called the albedo or coefficient of reflection which may vary according to the conditions of the Earth's surface. In this paper were collected soil samples from specific locations on the Campus of the Universidade Federal Rural do Rio de Janeiro, located in SeropeFRRJdica-RJ. By means of a thermal imager equipment (Flir-E63900) solar emissions of samples of soil were measured and compared with the values obtained in the literature, concerning the texture characteristics obtained in the laboratory. This way you can know the temperature difference obtained in the literature and in the field. It is observed that Seropedica was considered a rural and planting area, today it has a feature of urban rural fringe, what may be observed by it new soil uses and what interferes interferes in the urban temperature. Notes that in recent years have increased the urban agriculture initiative that contributes to the reduction of the effects of heat islands and the improvement of air quality.

(4479 - 781) Use of adaptive legumes genotypes to constraint factors in soil as strategy to improve agricultural sustainability in different cropping system

Luis A. Gomez Jorrin[1]
Soil Institute of Cuba[1]

Use of “adaptive” legumes genotypes to constraint factors in soil and effective *Rhizobium* strain as strategy to improve agricultural sustainability in different cropping system. Luis A. Gomez[1]; Tomas Shagarodsky[2]; Vincent Vadez[3]; Graciela Dueñas[1]; German Hernandez[1]; Amalia N. Morales[1]; Helene Valhe[4]; Catherine Pernot[4]; Jean J. Drevon[4]. Soil Institute, MINAG, Havana, Cuba; 2. INIFAT, MINAG, Havana, Cuba; 3. ICRISAT, Patancheru, Andra Pradesh, India; 4. URM 1222 Eco & Sol. INRA-IRD-SupAgro, Montpellier; France. E-mail address: gomezjo@isuelos.cu Legumes are main protein source of Cuban´s peoples, but at the present Cuban Agriculture faces fertilizer deficit with the consequences negatives impact upon the agricultural production and the soil fertility. Soils nutrient deficiencies *(nitrogen and phosphorus), drought* and *salinity* mainly in small farmer agricultural areas are the principal constraint factors that limit crop production. One solution way to these problems is use of “adaptive” genotype to theses adverse conditions. In this context, several experiences were developed under controlled conditions and field, where agronomy response of 110 common bean (*Phaseolus vulgaris L.*), 48 cowpea (*Vigna unguiculata L. Walp*), 42 chickpea (*Cicer arietinum* L.) and 12 mungbean (*Vigna radiata (L) Wilzeck*) genotypes were evaluated. “Superior genotypes” in interaction with specific Rhizobia were selected on basis of grain, shoot and nodule biomass production, efficiency of utilization of rhizobia symbiosis, proportion N_2 derived from air (%Ndfa) using isotopic techniques, root traits, phosphorus use efficiency and adaptation to salinity. The strategy the use of effective Rhizobium strains in combination with “superior genotypes” in fourth different agro-ecosystem (Pinar del Rio, Artemisa, Mayabeque and Holguin) showed that it is possible to i) obtain average %Ndfa between 40 and 60 % , ii) to increase grain production, iii) incorporation of biomass residues and nitrogen to soil in farming cropping system. It was recognized by Cuban agricultural authorities that this strategy improved the agricultural sustainability of the legumes cropping system and it allowed obtaining earnings of 173 $USDha^{-1}$ with regard to the conventional systems. (8196 - 1713) Soil Habitat Characteristics for a Rare Cactus Can Guide Energy Development, Soil Reclamation, and Plant Reintroduction

Janis Boettinger[1]; Eugene Schupp[1]; Jeanette Norton[1]; Jeremiah Armentrout[1]; Kourtney Harding[1]
Utah State University[1]

Sclerocactus wetlandicus, a rare cactus endemic to northeastern Utah, USA, is threatened by non-renewable energy development. While we have a basic understanding of vegetation characteristics of *S. wetlandicus* habitat, there are no data quantifying soil characteristics of occupied habitat, whether these characteristics differ from those of unoccupied habitat, and how closely reclaimed well pads resemble undisturbed sites in these characteristics. An understanding of soil characteristics of *S. wetlandicus* will help: 1) guide energy development compatible with conservation, 2) identify areas suitable for introduction of additional populations, and 3) determine the suitability of reclaimed well pads for cactus reintroduction. The objectives of our study were to determine: 1) Soil properties of cactus-occupied vs. cactus-unoccupied sites, 2) Whether *S. wetlandicus* is associated with mycorrhizae, and 3) If soil properties of reclaimed well pads are similar to cactus-occupied sites. Five populations were identified and occupied sites were created around them. These were paired with unoccupied sites with similar geologic features. We also selected unoccupied sites far away from known cactus populations. Lastly, 18 reclaimed well pads were selected. We excavated soils to describe and sample material for laboratory analyses. We sampled and analyzed cactus roots for mycorrhizal analysis. The cactus was associated with vascular arbuscular mycorrhizae (VAM). Properties of undisturbed soil at occupied sites were not significantly different from undisturbed soils at unoccupied sites. However, properties of undisturbed soils at both occupied and unoccupied sites differed significantly from the soils of well pads ($p<0.05$). Well pad soils were significantly higher in available P, electrical conductivity, and soluble B, S, Na, Mg, and K; and contained human transported/altered materials. Compared to undisturbed sites, well pads had significantly lower slopes because they had been excavated/constructed to be a level surface. Bare soil cover was much higher and biological crust cover was much lower on well pads than on

undisturbed soils. In conclusion, soils of occupied and unoccupied undisturbed sites are indistinguishable, and reclaimed well pads do not resemble undisturbed soils. Also, cactus association with VAM could help in plant reintroduction.

C4.1.5 - Carbon sequestration potential of soils

(2876 - 2736) A preliminary study of soil respiration from a semiarid ecosystem of Caatinga at northeast Brazil

Renato Francisco da Silva Souza[1]; Victor Junior Lima Felix[1]; Emanoel Lima Martins[1]; Vânia da Silva Fraga[1]; Bruno de Oliveira Dias[1]; Borja Ruiz Reverter[1]; Antonio Celso Dantas Antonino[2]

UFPB[1]; UFPE[2]

Soil respiration from semiarid ecosystems plays an important role in the interannual variability of the global carbon cycle, but the drivers that control such variability are still under debate since studies of this kind on semiarid ecosystems are scarce in the literature. In our preliminary work, we quantify the CO_2 efflux from a Caatinga located in northeast Brazil and study the influence of soil temperature and soil moisture on it. For that we used a LI-8100 chamber measuring on 12 points along a straight transect of 360 m. Measurements were taken bimonthly from August to October 2017. Overall, we found that soil respiration varied between 4.78 and 0.38 µmol m^{-2} s^{-1}, with a standard deviation of 1.86 µmol m^{-2} s^{-1}. Averaging each field campaign, the highest CO_2 efflux was 2.49 µmol m^{-2} s^{-1}, which coincided with the highest soil moisture (0.18 m^{-3} m^{-3}). On the other hand, the least averaged CO_2 efflux values (0.72 µmol m^{-2} s^{-1}) were associated with the least soil moisture (0.09 m^{-3} m^{-3}). Soil temperatures showed little variation during the measurement period as they remained tightly between 25.8 °C and 30.3 °C. We therefore conclude that soil moisture and not temperature is the main driver of the soil CO_2 emissions, which is in fact characteristic of semiarid ecosystems.

Keywords: Keywords: CO_2 efflux; closed chamber; Caatinga.

(9213 - 1316) Beyond infrared spectroscopy and spatial analysis: SOC stocks mapping in volcanic soils of Reunion Island.

Allo Myriam[1]; Todoroff Pierre[1]; Jameux Magali[1]; Stern Mathilde[1]; Rosies Blandine[1]; Ramos Marion[1]; Quero Solene[1]; Albrecht Alain[2]

CIRAD[1]; IRD[2]

As high carbon content soils with high human carrying capacity, volcanic soils of Reunion island highlight the importance of “carbon hotspots” to face the challenges of climate change and food security trough carbon sequestration. In addition, the ‘4 per mille’ initiative demonstrated that agricultural soils can play a crucial role for these global issues but knowledge on soil organic carbon (SOC) stocks of agricultural soils is still needed in tropical areas. Reunion is a young tropical volcanic island in the Indian Ocean, 700km east of Madagascar, with three major agricultural land uses (sugarcane crops, pastures and gardening) on a volcanic rock weathering gradient from Andosols to Ferralsols. A stratification method has been used to map SOC stocks in Reunion. First, 1000 soil samples (0-30cm depth) on the major agricultural land uses across the island from a huge database containing more than 45 000 soil analyses since 1993, have been selected. Mid-infrared spectra were acquired on these dried and thieved 1000 soil samples using a portable spectrophotometer. Spatially homogenous soil units have been defined by a clustering method (K-means) from laboratory analyses (SOC content, CEC, N, …) and mid-infrared spectra of these 1000 soil samples. Secondly, since 2016, soil samples have been collected in the field on the major agricultural land uses per spatially homogenous soil units to developed a mid- and near- infrared (MIR and NIR) spectroscopy method, both in the field (fresh soil samples) and in the laboratory (dried and thieved samples) to predict SOC stocks on 0-30 cm depth. Overall, SOC stocks can be predicted with satisfactory accuracy and directly by NIR and MIR spectroscopy in volcanic soils. In order to spatialize these results, an average SOC stock has been calculated for each combination of soil unit and agricultural land use. Then, each average SOC stock has been attributed to every agricultural field to map SOC stocks of the whole agricultural area in Reunion. The proposed methodology will produce a strong spatial baseline that will enable simulations of impacts of land use changes on SOC stocks at the island scale.

(3270 - 777) Cacao agroforestry system as a strategy for soil carbon sequestration

Emanuela Forestieri Gama-Rodrigues[1]; Paulo Henrique Marques Monroe[2]; Gerbeli de Mattos Salgado[3]; Antonio Carlos Gama-Rodrigues[1]

Soil Laboratory, North Fluminense State University[1]; Soil Laboratory, UESB[2]; UEMASUL[3]

Cacao (Theobroma cacao L.) is the main agricultural commodity in many tropical countries. In Brazil, southern Bahia is the largest planted area and is in the central corridor of the Atlantic Forest, one of the main centers of endemism of this biome, which has gone through a continuous elimination and fragmentation process. Two typical cacao production systems are used by both smallholder (5–8 ha) and large farmers (approximately 300 ha) in this region: (1) traditional cultivation system, wherein the cacao plantations are implanted under natural forest; and herbaceous, shrub and individuals of the upper canopy are eliminated to provide increased light input, resulting in extensive agroforestry called ‘cabrucas’ with 600 cacao ha^{-1}; (2) cacao plantations are established in areas where all native forest has been removed; cacao plants, in a density of 1100 cacao ha^{-1}, are shaded with banana and *Erythrina glauca* or *Hevea brasiliensis*. Agroforestry systems (AFS) based on cacao may play an important role in capturing carbon (C) aboveground and storing it belowground (soil) through continuous deposition of plant residues. C occlusion in soil aggregates could be a major mechanism of C protection in these soils. Therefore, it is important to know the amount of soil C storage across different soil aggregate classes at different soil depths and identify the extent of the sequestered C that is occluded in the soil aggregates. A range of shaded cacao systems and an adjacent natural forest and pasture were selected in different soil classes in Bahia, Brazil. Soil samples were collected from five depth classes up to 1 m depth and separated by wet-sieving into three fraction-size classes (>250 µm, 250–53 µm, and <53 µm)— and analyzed for C content. The SOC stock ranged from 300 to 200 Mg ha^{-1}. In some cases, converting secondary forests into AFS did not decrease the SOC stock up to 1m. However, in other cases this conversion showed a decrease from 34 to 72 Mg ha^{-1} compared to secondary forest. Macroaggregates were the most abundant fraction with great contribution of occluded C storage in the upper soil. The reduced amount of micro-size fraction is probably a result of slow macroaggregate turnover, induced by low tillage, in these AFS. Around 50% of the SOC accumulated under AFS were occluded in the aggregates up to 1 m depth, which is a favorable strategy to C accumulation and will contribute to reduction of CO_2 emissions.

(6259 - 1999) Carbon sequestration in agroforestry systems in the south Peruvian Amazon

Joel Peña Valdeiglesias[1]; Julio Alegre Orihuela[2]

Universidad nacional Amazonica de madre de Dios[1]; Universidad Nacional Agraria La Molina[2]

In the South Peruvian Amazon, there is a risk of degradation of the Brazilian nut (*Bertholletia excelsa*) due to illegal extraction of wood and mining. The study was conducted in 40 farmer's plots with agroforestry systems (AFS) of different ages in the south Peruvian Amazon in Puerto Maldonado to measure C sequestration in order that associated farmers have the option of to get environmental services and reduce gas emissions and maintain the productivity of Brazilian nut. Most AFS are base on several prototypes with Brazilian nut as main component in different associations with cacao (*Theobroma cacao*), copoazu (*Theobroma grandiflorum*), naranja (*Citrus sinensis*), plátano (*Musa paradisiaca*), piña (*Ananas comosus*), araza (*Eugenia stipitata*), achihua (*Jacaranda copaia*), pashaco (*Schizolobium amazonicum*), lupuna (*Cavanillesia umbellata*), caoba (*Swietenia macrophylla*), cedro (*Cedrela odorata*), guaba (*Inga sp*), sapote (*Matisia cordata*), tornillo (*Cedrelinga catenaeformis*), teca (*Tectona grandis*), caucho (*Hevea brasiliensis*), cetico (*Cecropia sp*), tahuari (*Tabebuia serratifolia*), pijuayo (*Bactris gasipaes*), aguaje (*Mauritia flexuosa*), capirona (*Calicophyllum megistocaulum*) and shimbillo (*Inga sp*). To measure above ground carbon (C) was used allometric equations and soil C was measured in the layers of a pit of one-meter depth and each soil layer was analyzed the C concentration with the Walkey and Black method. Carbon in above ground biomass including roots fluctuated from 8.37 to 142.24 t/ha and the systems that accumulated more C was the Brazilian nut associated with the species of copoazu, piña, pijuayo, and achihua. The average C in soil at one meter depth was 54.91 t/ha and the average total C in above ground and soil at one-meter depth was 94.35 t/ha. There was a high correlation between the aboveground C, soil C and the age of the prototype AFS.

Keywords: amazon, Brazilian nut, agroforestry systems, allometric equation

(5047 - 2711) Carbon storage capacity in natural and intervened land covers in the Andean zone of Southern Colombia.

Felipe Zúñiga[1]; Jenny Huertas[2]; Gabriela Guerrero[2]; José Dörner[3]; Jairo Sarasty[4]; Hernán Burbano-Orjuela[5]

Doctorado en Ciencias Agrarias, Escuela de Graduados, Facultad de Ciencias Agrarias, Universidad Austral de Chile, Valdivia, Chile[1]; Programa de Ingeniería Ambiental, Facultad de Ingeniería, Universidad Mariana, San Juan de Pasto, Colombia[2]; Instituto de Ingeniería Agraria y Suelos, Facultad de Ciencias Agrarias, Universidad Austral de Chile, Valdivia, Chile[3]; Facultad de Ciencias Agrícolas, Universidad de Nariño, Torobajo, San Juan de Pasto, Colombia[4]; Centro de Investigación en Ciencias Agrarias, Facultad de Ciencias Agrícolas, Universidad de Nariño, Torobajo, San Juan de Pasto, Colombia[5]

FAO projections indicate that Latin America has potentially around 800 million hectares available for cropland expansion. The conversion of natural ecosystems to ecosystems to agro-ecosystems, is one of the main sources of increasing GHG (e.g. CO_2). Since soils are considered to be a potential carbon sink they play a key role in the regulation of the carbon dynamics of terrestrial ecosystems. This research evaluates the carbon storage capacity (OC_{mass}) along altitudinal gradient of land cover change in Nariño, the Andean zone of Southern Colombia. Nine sampling sites were selected, ranging from natural ecosystems (e.g. páramos and native forest) to agro-ecosystems (e.g. grasslands and croplands). From each site, disturbed material in each soil horizon (z) was collected to measure their chemical properties using specific dissolution extractions (ammonium oxalate, pyrophosphate extractions, NaF pH), cation exchange capacity (CEC) and total organic carbon (C). Undisturbed material was collected to measure bulk density (dB). i) the organic carbon mass, which was calculated as: OC_{mass}= C [%]*dB*z*100, varied between 697 to 173 Mg ha^{-1} for native forest and croplands, respectively. ii) the highest values of C were found for páramo azonal [21.5%] but because the dB was low [0.18 Mg m^{-3}] the OC_{mass} sampled is not the highest. iii) a significant correlation (r= 0.64) was found between NaF pH vs. Al_o+½Fe_o (y= $9.78x^{0.07}$; R^2 =0.35). iv) 50% of the soils investigated had Al_o+½Fe_o ≥; 61% dB < 0.9 Mg m^{-3} and 66% had NaF pH values > 9.4. These indicators suggest that andic properties, dominated by amorphous colloidal material, especially the colloidal organic fraction, are related to iron linked with soil organic matter [Fe_p/Fe_o >0.5 = 82%]. 25% of Al_o-Al_p presented negative values, in grassland and croplands, suggesting that these soils have mainly crystalline clays. This is reflected in low values of CEC [23 $cmol_{(+)}$ kg^{-1}] compared with native forest and páramo azonal which reached CEC 82 and 76 $cmol_{(+)}$ kg^{-1}, correspondingly. These results suggest that the OC_{mass} accumulation in these soils depends on land cover and is regulated by colloidal properties such as clay type and soil organic matter.

(6199 - 694) Climate determines the response of soil carbon to no-till

Denis Angers[1]; Murilo Veloso[2]; Cimelio Bayer[2]

Agriculture and Agri-Food Canada[1]; Federal University of Rio Grande do Sul[2]

Adopting no-till (NT) in agro-ecosystems has been widely recommended as a measure to sequester soil organic C (SOC). However, ranges of positive and negative results have been obtained, and the reasons for this variability are still unclear. A data set of long-term tillage studies was compiled from a survey of the scientific literature worldwide, including studies from previous meta-analyses. Studies were included in the data set if the following criteria were met: (i) studies compared NT and conventional tillage (CT) systems; (ii) studies were replicated experimental designs; (iii) SOC was sampled to 0-5 ±2.5 cm soil layer and 0-30±2.5 cm soil layer, and (iv) tillage treatments were applied for at least 5 yr; (v) soils with clay content between 150 and 350±20 g kg^{-1} were considered. For each study, we calculated the relative response of SOC to NT compared to CT, and investigated its relationship with climate variables. A total of 28 studies were included in the analysis from four continents. In all cases, there was a positive effect of NT on SOC in the 0-5 cm soil layer where the relative SOC accumulation under NT was best fitted to mean annual precipitation (MAP) using a hyperbolic curve (R^2 = 0.59; p<0.002). When the 0-30 cm soil layer was considered, the SOC response to NT followed the same tendency, and was still dependent on MAP. High accumulation at high MAP was possible only with increased input or reduced decomposition under NT, whereas high accumulation at dry sites (< 500 mm $year^{-1}$) was also possibly due to the mulch effect; i.e. leaving the residues at surface slows down their decomposition. At around 800 mm $year^{-1}$, the relative SOC accumulation under NT was around zero, which is attributable to the higher SOC in deeper soil layers under CT, which compensates for the gains in the surface layer under

NT. We conclude that at the global scale the response of SOC to NT is highly dependent on climate, especially precipitation. However, the mechanisms explaining these effects are still not fully understood and generally not well represented in our predictive models.

(1456 - 354) Effect of designer acidic biochar on coastal saline-sodic soil properties and okra growth

Zhenyu Wang[1]; Le Yue[1]; Lin Fu[1]; Zhenggao Xiao[1]
Jiangnan University[1]

Soil health is essential and irreplaceable for plant growth and global food production, and has been threatened by climate change and soil degradation. Degraded coastal soils are urgently required to reclaim using new sustainable technologies including biochar technology promotion, but the modification of original biochar is still needed due to the intrinsic alkalinity and available nutrient deficiency. In present study, the acidic phosphorus-rich biochar was prepared by using 2 acidified methods. The response of Okra (*Abelmoschus esculentus*) to the application of the modified biochar into a coastal soil was also investigated using a pot experiment. The 3 acidified biochars showed the pH of 2.81, 3.02, and 2.71, respectively (original biochar, 8.19), and the phosphorus acid pre-modified biochars showed a specific surface area of 17.99 m^2g^{-1}(approximately treble the area of original biochar), whereas a slight reduction in the surface area was found with monocalcium phosphate modified biochar. The phosphorus acid post-modified biochars contained a significantly higher amount of water-soluble cations (e.g., K^+ and Ca^{2+}) compared to other biochars. The 3 acidified biochars significantly decreased the pH of saline-sodic soil by 0.729-0.225, while increased soil Olsen- phosphorus content, EC and CEC by 38.3-387.8, 8.89-22.3% and 7.29-22.2%, respectively. The 3 acidified biochars significantly elevated the root length and surface area of okra by 143.7-165.4% and 38.2-135.3%, respectively, while the original biochar showed no obvious effect on okra root development. The monocalcium phosphate modified biochar significantly enhanced the shoot biomass of okra by 38.2%, and all the biochars increased the okra yield by 24.0-151.4%. Moreover, the monocalcium phosphate modified biochar showed the best okra growth and yield performance, which led to an increase of 28.59-39.56% and 90.3-104.1% in okra biomass and fruit yield, respectively. This was mainly attributed to the enhanced phosphorus availability, resulting from the biochar-improved soil quality and fertility. Additionally, the elevated bacterial activities and abundances of the bacterial taxa responsible for phosphate solubilizing and C-stabilizing also contributed to the enhanced primary productivity. The study proposed a promising method to design biochars by phosphorus and monocalcium phosphate modification to reclaim the degraded coastal soil and benefit in soil and food security.

(7465 - 1340) Impact of sugarcane cultivation on soil carbon dynamics in a semi-arid Brazilian Vertisol

Leandro Reis Costa Santos[1]; Adriana Bezerra dos Santos[1]; Andressa Silva de Oliveira[1]; Pablo Acácio dos Santos Souza[1]; Everardo Valadares de Sá Barretto Sampaio[2]; Ana Dolores Santiago de Freitas[1]; Sueide Karina da Silva[1]
Universidade Federal Rural de Pernambuco[1]; Universidade Federal de Pernambuco[2]

Changes in land use can alter soil carbon stocks, increasing carbon dioxide (CO_2) emission, aggravating the greenhouse effect. The impact of irrigated sugarcane (*Saccharum* spp) cultivation on C dynamics in soils of semi-arid regions, where conditions favor the rapid degradation of soil organic matter, is little known. The stock, origin and mean residence time of C in a soil under native vegetation (caatinga) and cultivated with irrigated sugar cane after 10, 20, and 30 years of caatinga removal were determined in Juaziero municipality, Bahia state, Brazil. Three trenches 60 cm deep were opened for each situation, and disturbed and undisturbed samples were collected in the 0-10, 10-20, 20-40 and 40-60 cm layers for physical and chemical characterization. Due to the similarity of the sampled environments, the experimental was established as a completely randomized design. The data were submitted to analysis of variance and the means compared by the Tukey test, at 5% probability. Cane cultivation for 30 years promoted a significant increase in the amount of soil C, with an increase of approximately 84.4 Mg ha^{-1}. The C mean residence time is relatively low, about 19 years in the 0-10 layer and 82 years in the 40-60 cm layer. This rapid C degradation becomes clear analyzing the contributions of the two different C sources to the stock in the cultivated areas. There was enrichment of ^{13}C in the cultivated areas, resulting in more than 90% of C from plants with C4 photosynthetic cycle in the superficial layers. The soil C dynamics is very fast, and the C from the native vegetation decreases rapidly after conversion of caatinga to sugarcane. However, the input from the cane straw and roots more than compensates for this loss.

(3121 - 1934) Lithology controlled soil organic carbon stocks and stabilization processes in Paramo grasslands of the Peruvian Andes.

Songyu Yang[1]; Erik Cammeraat[1]; Boris Jansen[1]
UvA-IBED[1]

Paramo grasslands of the Neotropical Andes have high soil organic carbon (SOC) stocks. Most studies on SOC in these alpine grasslands focus on volcanic-ash soils, while non-ash soils, which also cover large areas in the highlands of the Andes, are far less studied. Our objective was to compare SOC stocks for two sites with a non-ash lithology, and also to study their stabilization processes in paramo grasslands in Cajamarca, Peru (7°11"S, 78°35"W). We sampled soils developed on limestone and granite, on stable, non-disturbed locations at about 3700 m altude. We analyzed SOC stocks and researched organic matter (OM) stabilization mechanisms, using ammonium oxalate, sodium pyrophosphate and citrate-dithionite extracted Fe, Al and C fractions, exchangeable cations and soil aggrgegation. Our results showed that organic carbon (OC) in limestone soils (405±42 T ha^{-1}) was significantly higher than in granite soils (226±6 T ha^{-1}). Both values are much higher than reported in literature. For OM stabilization, we found (i) positive correlations between pyrophosphate fractions and OM related variables in both limestone soils and granite soils, (ii) high ratios of C to pyrophosphate extracted metals and robust correlations between exchangeable Ca and OC in limestone soils only, and (iii) clear differences in soil macro- and micro-aggregation. Our results suggest that the formation of organo-metallic complexes plays a key role in the high OM stabilization rates in both limestone and granite soils, and we found strong indications that OM-mineral association and/or aggregate is an important stabilization mechanisms in limestone soils only. Furthermore, we found no evidence to support that OM is stabilized by non-crystalline Fe and Al (hydr)oxides, crystalline Fe (hydr)oxides or Al toxicity.

(7782 - 2644) Litter Decomposition and Microbial Biomass in Clonal Teca Plantation

Luisa Carla Cotta[1]; Valéria Santos Cavalcante[1]; Juana Amaral figueira[1]; Júlio César de Lima Neves[1]; Caroline Moreira Análio[1]; Emanuelle Mercês Barros Soares[1]
Federal University of Viçosa[1]

Deciduous and evergreen forests present distinct biogeochemical cycling of nutrients. This phenomenon is closely related to the dynamics of carbon (C) present in soil organic matter (SOM). The objective of this study was to evaluate the dynamics of the SOM decomposition in 5 years old Teca (Tectona grandis) plantations. The experiment was set up in an area near to the city of São José do Rio Claro, Mato Grosso state, following a systematic design with four replications. In each plot, 72 litter bags filled with litter, previously collected (during the dry period), were distributed directly on the soil. Six litter bags were collected in each time (August / 2015, November / 2015, March / 2016, May / 2016 and July / 2016) for total organic carbon (TOC) determination. At the same time, soil samples were collected (0-20, 20-40 and 40-60 cm) below the litter bags for C (CMB) and nitrogen (NMB) microbial biomass determination. The half-life ($t_{1/2}$) of the litter was approximately 9.12 months. During the experimental period, TOC levels increased approximately until 7 months. CMB and NMB (0-20 cm) showed a marked decrease in the first three months, increasing again at 9 months, respectively. These results indicate that the litter deposited by Teca is difficult to decompose by soil microorganisms. Also, the higher CMB and NMB values at the beginning and end of the experiment indicates a specific microbiota to decompose the C present in the organic residues deposited by clonal Teca trees.

(1632 - 828) Long-term effects of different organic and inorganic fertilizer treatments on soil organic carbon sequestration and crop yields on the North China Plain

Nan Zhao[1]; Zhichen Yang[2]; Yizhong Lv[3]; Rongliang Qiu[4]
College of Resources and Environment, China Agricultural University, Beijing, 100193, China (zhao.nan.466158602@163.com);School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou, 510006, China[1]; College of Resources and Environment, China Agricultural University, Beijing, 100193, P.R. China;Institute of Agricultural Integrated Development, Beijing Academy of Agricultural and Forest Science, Beijing,100097, China[2]; College of Resources and Environment, China Agricultural University, Beijing, 100193, China[3]; School of Environmental Science and Engineering, Sun Yat-sen University, Guangzhou, 510006, China[4]

The aim of the study is to analyze the effects of different fertilization of organic and inorganic fertilizers on soil organic carbon (SOC) sequestration and crop yields after a 22 years long-term field experiment. The crop yields and SOC were investigated from 1981 to 2003 in Dry-Land Farming Research Institute of Hebei Academy of Agricultural and Forestry Sciences, Hebei Province, China. The dominant cropping systems are winter wheat - summer corn rotation. There were totally sixteen treatments applied to both wheat and corn seasons: inorganic fertilizers as main plots and corn stalks as subplots and the main plots and subplots all have four levels. The results revealed: after 22 years, mixed application of inorganic fertilizers and crop residuals, the SOC and crop yields substantially increased. Higher fertilizer application rates resulted in greater crop yields improvement. In 2002–2003, wheat and corn for the highest fertilizer inputs had the highest yield level, 6,400 kg ha-1 and 8,600 kg ha-1, respectively. However, the SOC decreased as the excessive inorganic fertilizer input and increased with the rising application of corn stalks. The treatment of the second-highest inorganic fertilizer and the highest corn stalks had the highest SOC concentration (8.64 g C kg-1). Pearson correlation analysis shows that corn and winter wheat yields and the mineralization amount of SOC have significant correlation with SOC at $p < 0.05$ level.

(8537 - 2818) Panoramic view of the soil carbon stocks of Zona da Mata region, Minas Gerais state, southeast Brazil.

Geraldo Cesar Rocha[1]
Universidade Federal de Juiz de Fora[1]
It is well known that soils are important carbon reservoirs, containing more of this element than the atmosphere and terrestrial vegetation combined. Otherwise, climate change, land use/degradation and biodiversity loss, have put soils as one of the most vulnerable resources in the world. The protection and monitoring of carbon stocks at national and global levels still face complicated challenges, including, in the case of Brazil, the knowledge of the carbon stocks of the various soil types and even the geography of its distribution. In a way to contribute to enhance the knowledge and to fill this gap of scientific information, this work shows a view of the soil carbon stocks of the called Zona da Mata region, located at the state of Minas Gerais in southeast Brazil. The data was compiled from researches of the author, as well as from other literature works. First of all, it is important to consider the diversity of land use in the region, as well as the predominance of oxisols (latossolos in the brazilian soil classification system). Some researches show that the carbon stock is higher at the soil surface horizons; meanwhile, the author noted that this is not a general rule, finding increment in the carbon stock in B horizons of oxisols of the region. In general, it is agreed that the carbon stock is higher in forest soils, but that do not always occurs, as can be seen in a research by the author comparing soil carbon stocks from a forest, eucalyptus plantation and a natural grass field. It is recommended more works comparing different kinds of soils, types of land use and also a standardiization of methodological procedures.

(4471 - 2885) Potential global climate, soil and food security via enhanced weathering of rocks applied to croplands

Binoy Sarkar[1]; Michael E Kelland[1]; Jonathan R Leake[1]; Mark E Hodson[2]; David J Beerling[1]
Leverhulme Centre for Climate Change Mitigation, Department of Animal and Plant Sciences, The University of Sheffield, Sheffield, S10 2TN, UK[1]; Environment Department, Wentworth Way, University of York, Heslington, York, YO10 5DD, UK[2]

Limiting future climate change requires urgently decreasing CO_2 emissions and developing approaches for carbon dioxide removal (CDR) from the atmosphere. Both IPCC and the US National Research Council have called for research effort into effective CDR strategies. Enhanced weathering (EW) is a CDR option achieved by amending the soils of managed croplands with crushed fast-reacting silicate rocks. EW increases C capture by locking up C in soils as aqueous CO_2 reacts with the silicate minerals, and eventually deposit C in the oceans. An additional pathway is that the cations (e.g., Ca^{2+}, Mg^{2+}, $Fe^{2+/3+}$) released during EW attract both inorganic and organic C compounds in soils and lead to carbonate precipitation, organic polymerization, coating of rock grains with highly stable organo-mineral complexes, formation of stable particulate organic matter, secondary minerals, and ultimately soil aggregates. EW also has potential co-benefits for sustainable soil and food security by replenishing eroded soils, decelerating soil erosion, ameliorating soil acidity, increasing yields via Si and other nutrients uptake by crops, conferring crop protection from pests and diseases, and reduced uptake of toxic heavy metals in crops' edible parts. Similar to any other CDR approaches, EW also warrants field-scale trials across the continents in order to evaluate its global CO_2 sequestration potential and plausible co-benefits, and thus make the

technology socially and environmentally acceptable. This requires detailed risk assessment of the technology, wider public participation and transparency in communication. (1170 - 515) Soil Analyses after Growth of Six Winter Cover Crops

O.W. Freeman[1]; M.B. Kirkham[2]; K.L. Roozeboom[2]; A.J. Schlegel[3]; S.A. Staggenborg[4]

Central State University, Wilberforce, Ohio 45384 USA[1]; Kansas State University, Manhattan, Kansas 66506 USA[2]; Southwest Agricultural Research-Extension Center, Tribune, Kansas 67879 USA[3]; Chromatin, Inc., Lubbock, Texas 79424 USA[4]

Little information exists concerning the appropriate cover crop to grow during the winter in the Great Plains of the USA. Therefore, we compared legume and non-legume winter cover crops grown at two locations in Kansas: Manhattan, in the northeastern part of the state, and Hutchinson, in the south-central part of the state. The cover crops were planted and terminated at times corresponding to how they might be used in a corn (*Zea mays* L.) or forage sorghum [*Sorghum bicolor* (L.) Moench] rotation. At Manhattan, the soil was a Bismarckgrove-Kimo complex, and, at Hutchinson, the soil was a Funmar-Tarver loam. Here we report the soil analyses after one year's growth of the winter cover crops (2010-2011). The soil was analyzed for pH, organic matter (OM), total nitrogen (N), and total carbon (C) in the fall before the cover crops were planted and in the spring after the cover crops were terminated at times to correspond with the corn and sorghum rotations. The residue of the cover crops was left on the ground after termination. Analyses of soil growing the leguminous cover crops were similar to those growing the non-leguminous cover crops. The pH's of the two soils were similar, but the OM, N, and C were higher in the soil at Hutchinson than in the soil at Manhattan. At both Manhattan and Hutchinson, the OM and N before planting the cover crops and after their termination were similar. However, C increased in the soil after planting the cover crops. At Manhattan, the average value (with standard error) before planting was 0.43±0.02% C; for the cover crops terminated at sorghum planting time, the average value was 0.50±0.01%, and for the cover crops terminated at corn planting time, it was 0.48±0.02% C. At Hutchinson, C increased only in the sorghum rotation (1.17±0.02% C before planting the cover crops; 1.21±0.01% C after termination). The results showed that winter cover crops increased C in the soil after one season's growth. The increase in soil C at Manhattan was 0.07% for the sorghum rotation and 0.05% for the corn rotation; at Hutchinson the increase was 0.04% in the sorghum rotation. The United Nations Paris climate accord, signed in December 2015, included a commitment to increase soil C by 0.4 per cent each year. Thus, the increase we observed in the soil carbon after one season's growth of winter cover crops would satisfy about 0.1 to 0.2 of this commitment.

(4750 - 339) Soil carbon stocks under integrated crop-livestock-forest system in the Brazilian Atlantic Forest region

Alberto C. de Campos Bernardi[1]; Sergio N. Esteves[1]; Jose Ricardo M. Pezzopane[1]; Teresa C. Alves[1]; Alexandre Berndt[1]; Andre F. Pedroso[1]; Paulo H. Mazza Rodrigues[2]; Patricia P. Anchao Oliveira[1]

Embrapa Pecuária Sudeste[1]; VNP / FMVZ / USP[2]

Integrated crop-livestock-forest systems (ICLFS) are one of the leading strategies of the Brazilian government program "Low-Carbon Agriculture" to reduce or compensate the carbon emissions, with simultaneous improvement in harvest efficiency. ICLFS provide a strategy for sustainable agricultural production which integrates annual crops, trees, and livestock activities on the same area, and in the same season. The system is based on crop rotations and no-tillage practice that contributes to the quantity and quality of residues input and increasing soil organic matter content. Farmers are adopting ICLFS, but there is still a lack of quantitative data on C stock primarily for the integrated systems. This research aims to address the soil carbon stocks under different management systems in Atlantic Forest biome. Soil carbon stocks were estimated to a depth of 100 cm in a 30-ha ICLFS in São Carlos-SP, Brazil (21°57'S, 47°50'W, 860m alt). The soil classified as a sandy-clay-texture dystrophic Red-Yellow Latosol and climate is Cwa. The experimental area included: i) intensive (INT) grazing of palisade grass; ii) crop-livestock (CLS), one-third of the area is renovated with corn intercropped with palisade grass; iii) crop-livestock-forest (CLFS), CLS planted with *Eucalyptus urograndis* (333 trees per ha); iv) livestock-forest system (LFS), with palisade grass and *Eucalyptus*; v) extensive pasture (EXT) of signal grass, and the control of vi) natural Atlantic forest. After five years soil C stocks (in Mg ha^{-1}) were: LFS, 179.9; INT, 173.1; CLFIS, 160.2; LFIS, 136.4; and EXT, 121.0 Mg ha^{-1}. LFS, INT, and CLFIS stocks were significantly ($p<0.001$) higher, and EXT significantly lower than C stocks under natural Atlantic Forest (129.7 Mg ha^{-1}). Results indicated that under the local edaphic and climatic conditions of the study both agroforestry systems (CLFIS and LFS) and intensive managed pasture (INT) lead to high SOC accumulation even in the short term such as five years study. Land use change, based on adequate farm and soil management strategies, such balanced nutrient management, improved grazing, no-till farming and crop rotation increased soil carbon accumulation.

(9068 - 2805) Soil CO_2 emission in no-tillage areas with residues from summer and off-season crops

Clariana Valadares Xavier[1]; Mara Regina Moitinho[1]; Gustavo André de Araújo Santos[1]; José Eduardo Corá[1]; Newton La Scala Júnior[1]

São Paulo State University, Campus of Jaboticabal[1]

Soil CO_2 emission (FCO2) in agricultural areas is a dynamic and complex process resulting from different edaphoclimatic factors. This study aimed to quantify and characterize the relationship between FCO2 and soil physical and chemical attributes at the end of the agricultural year in no-tillage areas managed with the same arrangement of summer and off-season crops for more than 15 years. Sixteen assessments of FCO2, soil temperature, soil moisture, and soil physical and chemical attributes were carried out over a period of 51 days. We used the remaining straw from the combination of three summer crop sequences (corn monoculture, soybean monoculture, soybean-corn rotation) with five off-season crops (corn, millet, pigeonpea, grain sorghum, and crotalaria). For FCO2, soil temperature, and soil moisture, analysis of variance was performed in a randomized block design and observations were repeated over time. Multivariate exploratory analyses of hierarchical clustering and factors were carried out to verify the interdependence relationships between FCO2 and soil attributes as a function of the assessed managements. FCO2 was related to the quantity and C/N composition of remaining residues on the soil surface

in the assessed systems. In this case, grain sorghum grown off-season after corn monoculture was the management that presented the lowest FCO2 values. The highest values of FCO2, clay content, organic matter, macropores, sum of bases, as well as the lowest values of soil bulk density contributed to characterize FCO2 process in soils managed with residues from summer and off-season crops in no-tillage areas. The sequences soybean-corn rotation and corn monoculture differed from each other only in relation to the off-season crop, with a distinction between grasses and legumes. Soybean monoculture differed from the other managements regardless the off-season crops under study. When analyzing the behavior of the variables related to CO_2 production, a significant difference was observed between managements, evidencing that the soil attributes retained in the exploratory analysis, when analyzed separately, respond differently as a function of the transport and gas production processes, demonstrating the complexity of FCO2 dynamics under this no-tillage system.

(7321 - 1184) Soil organic matter formation under different plant species mixture during 50 years in a temperate region

Karin Kauer[1]; Rein Viiralt[1]; Kerttu Tammik[1]; Henn Raave[1]; Alar Astover[1]
Estonian University of Life Sciences, Institute of Agricultural and Environmental Sciences, Kreutzwaldi 1, Tartu, 51014, Estonia[1]

Soil organic matter (SOM) formation is a long-term process depending on the amount and quality of organic matter input. For evaluation of the effect of various plant species on the SOM formation, long-term field experiments are of vital importance. The long-term experiment was established in 1964 close to the city of Tartu in Estonia (N 58°22'04.09", E 26°39'41.47"). The initial soil originating from the BC horizon from a nearby field was almost free of SOC (1.28 g kg^{-1}) and total nitrogen (N_{tot}) (0.18 g kg^{-1}). The soil texture was sandy loam (61.1% sand, 24.8% silt and 14.1% clay). The aim of the trial was to study the SOM formation under different plant species and species mixtures. There were five treatments with different plant species (barley, grasses, clover-grasses, galega, hybrid lucerne) and one bare fallow treatment that have been without vegetation at the start of the experiment. In autumn 2014, soil samples were collected from three depths: 0-5, 5-10 and 10-20 cm in each plot. The SOC and N_{tot} contents were measured. The stock of SOC was calculated separately for each layer (0-5, 5-10, 10-20 cm) and for the 0-20 cm soil layer, the SOC stocks were summarized. The aboveground biomass was monitored during 1981-2014. Using aboveground biomass crop-specific C allocation coefficients based on Bolinder et al. (2007) the C inputs were calculated. The SOC and N_{tot} contents were significantly affected by the plant cover and increased up to average of the treatments with plant cover 7.2 and 0.47 g kg^{-1} (average of the treatments with plant cover), respectively. During 1964-2014 the annual SOC stock change in 0-20 cm soil depth varied by 0.11-0.46 t ha^{-1} y^{-1} and the highest increase was in the treatment with hybrid lucerne. In 2014 the SOC stock of 0-20 cm soil depth was 9.4-27.2 t ha^{-1}. The lowest SOC stock was in bare fallow treatment. The SOM was accumulated mainly in the upper soil layer, 41-47% of the 0-20 cm SOC stock was in 0-5 cm soil layer depending on treatments, averagely 29% was in 5-10 cm and 29% in 10-20 cm layer. Also in barley treatments where tilling of plots (mixing of soil layers) takes place every year the SOC stock declines in the lower soil layers. There was positive relationship between average C input into soil and SOC stock change. SOC sequestration efficiency was higher in treatment with annual crop (barley) and lower in treatment with perennial grasses.

(8991 - 1172) The effect of biosolids application on organic carbon dynamics in soil

Hasintha Wijesekara[1]; Nanthi S. Bolan[1]; Ramesh Thangavel[2]; Peter Matthews[3]; John Bennett[4]; Aravind Surapaneni[5]; Balaji Seshadri[1]; Christopher Saint[6]

Global Centre for Environmental Remediation (GCER), Advanced Technology Centre, Faculty of Science, The University of Newcastle, Callaghan, NSW, 2308, Australia[1]; Indian Council of Agricultural Research (ICAR) Complex for North-eastern Hill Region, Umiam, Meghalaya, 793103, India[2]; Cleanaway Organics, 390 Princes Highway, Bomaderry, 2541, NSW, Australia[3]; National Centre for Engineering in Agriculture, Toowoomba Campus, University of Southern Queensland, Darling Heights, QLD, 4350, Australia[4]; South East Water, 101 Wells Street, Frankston, Victoria, 3199, Australia[5]; Natural & Built Environments Research Centre (NBERC), University of South Australia, Mawson Lakes, South Australia, 5095, Australia[6]

Biosolids produced at wastewater treatment facilities have been extensively applied to agricultural land and degraded mine sites to improve soil health, and increase soil organic carbon (SOC) stocks. The relationship between biosolids application and carbon retention or CO_2 fluxes however has not been studied in detail under the field scale for Australian soils. Thus a field study was conducted on two texturally different soils to determine the influences of biosolids application on selected soil chemical properties and CO_2 fluxes. Two sites, located in Manildra (clay loam) and Grenfell (sandy loam) in New South Wales, Australia were selected for this study. Each site was treated at a single level of 70 Mg ha^{-1} biosolids. Over the four months study period, soil samples were analyzed for SOC fractions including total organic carbon (TOC), labile and non-labile carbon, humic acid contents and carbon stocks. Liquid-state ^{13}C and ^{1}H NMR spectroscopy was applied in order to understand the major constituents present in the humic acid fraction. The natural abundances of soil $\delta^{13}C$ and $\delta^{15}N$ were also measured as isotopic tracers to determine the fate of carbon in biosolids and native carbon in soil. An automated soil respirometer (LICOR LI-8100A) was used to measure in-situ diurnal CO_2 fluxes, soil moisture and temperature. Application of biosolids increased the surface (0 – 15 cm) soil's non-labile and labile organic carbon fractions. For example, TOC was increased by > 45 % at both sites and was attributed to the direct contribution from residual carbon in the biosolids as well as from increased biomass production. Humic acid content increased by 66 % in biosolids amended soils at the Grenfell site. The NMR results revealed strong alkyl carbon peaks in biosolids treated soils comparative to the control soils. Soils amended with biosolids showed depleted $\delta^{13}C$, and enriched $\delta^{15}N$ indicating the accumulation of biosolids residual carbon in soils. The in-situ respirometer data demonstrated enhanced CO_2 fluxes at the sites treated with biosolids, indicating limited carbon sequestration potential. Decline trends were also observed in the carbon stocks on both sites. The application of biosolids on both the clay loam and sandy loam soils however was found to be effective in building SOC rather than reducing it; indicating potential sequestration of carbon in soil.

(8165 - 2842) The state of the art of the negative impacts in Brazillian carbon stocks due to bad practices

Lucas Henrique Ribeiro Reis[1]; Rodrigo de Queiroga Miranda[1]; Josiclêda

Domiciano Galvíncio[1]; Valéria Sandra de Oliveira Costa[1]
Universidade Federal de Pernambuco[1]

Brazilian soils accumulate an average of 0.5 mg C ha-1 year-1. The soils are considered as the main reservoir of carbon in the world, presenting 4.5x more carbon than our biota and 3.3x more than the atmosphere. However, this reservoir is controlled by a delicate process, in which any modification, as poor use of the soil, can produce an imbalance in nature. In Brazil, 46.4 million tons of carbon dioxide were emitted in the period between 1975-1995. Brazilian studies on the subject have been showing that carbon stocks, mainly in form of gas, are concentrated on layers with 0-30 cm of depth. Therefore, planting systems that were poorly developed can result in a dispersion to the atmosphere of the gas found in the soil, which would contribute negatively to the greenhouse effect, leading to serious future climate problems. In order to mitigate this emission by up to 33 million tons annually, it would be interesting to adopt conservation practices (no-tillage system). That would promote the addition of organic matter in the soil, and then, retention of organic carbon in it. In addition, worldwide studies have been indicating that, for temperate soils, just the conversion of natural areas to agriculture may correspond to more than 60% of carbon losses in the organic matter reserve; and more than 75% for tropical soils. In Brazil, the well-known soil control systems based on conventional tillage is promoting big losses in the reserve of organic matter in the soil, affecting even nearby natural forest. These kind of damages contribute to the intensification of negative effects in the atmosphere, which in turn, might worsen climate changes.

(3107 - 1171) The use of plant lipids as molecular proxies to trace the origin and dynamics of soil organic carbon

Boris Jansen[1]; Guido Wiesenberg[2]
University of Amsterdam[1]; University of Zürich[2]

The use of plant lipids as molecular proxies to trace the origin and dynamics of soil organic carbon *Boris Jansen and Guido Wiesenberg* Tracing the origin and dynamics of soil organic matter is an important tool to unravel mechanisms that lead to (de)stabilization of soil organic carbon (SOC). A very hot topic indeed given its direct link to climate change on the one hand (1), and the ongoing scientific debate on what drives SOC (de)stabilization and sequestration (2). Plant lipid based molecular proxies are (groups of) specific lipid molecules that can be linked to (groups of) specific plant species or plant parts. The last decade has seen a dramatic increase in their application to study SOC dynamics through time (3). However, the use of molecular proxies to trace the origin and dynamics of soil organic carbon is also subject of fierce scientific debate. On the one extreme end there are those colleagues who see biomarkers as a cure-all solution to all organic matter tracing problems. On the other end of the spectrum there are experts who claim that the concept of molecular studies is so intrinsically flawed that it can never yield meaningful information about carbon transformations except in the most specific cases. We believe that neither vision is correct. In our presentation we will discuss the merits and drawbacks of using molecular proxies to study SOC dynamics based on our recently published review article (2), and examples of the application of molecular proxies from our own research focusing on the link between molecular SOC dynamics and C sequestration in plaggen soils in Northwest Europe and volcanic ash soils in the South American Andes. (6317 - 2289) When the forest drops acid: threshold behavior in carbon cycles upon acidification

Karen Vancampenhout[1]; Bart Muys[2]
KU Leuven[1]; [2]

Soils hold the largest terrestrial carbon pool, essential to a multitude of ecosystem services. Forest soils are particularly relevant, containing about 40% of the global soil carbon stocks. The drivers and mechanisms of soil carbon storage in forests therefore are particularly relevant in the context of climate change and soil-based mitigation solutions. In current models, the soil carbon cycle is projected as a continuous microbial funnel where decomposition follows a consistent and predictable path of chemical change. Molecules are exempt from this funnel only if occluded in aggregates or adsorbed on mineral surfaces, while substrate quality and chemical properties of organic matter are no longer regarded as relevant. Environmental and edaphic challenges on decomposer communities are described via static, linear relationships and soil organisms are largely perceived to have redundant functionality. We argue that soil carbon turnover may be much less deterministic than currently assumed. Based on data from several forest experiments in Europe, we evidence that ecosystems adapt their carbon decomposition strategies in a non-linear way to the constraints imposed by their environments, in casu acidity, nutrient imbalances and aluminum toxicity. For forest soils near the pedogenic threshold between the cation and the aluminum soil process domain, small increases in soil acidity have the potential to dramatically shift soil communities to a point where decomposition is forced to switch to alternative pathways. Edaphic and biological feedback loops further substantiate the new, acidic state. Carbon accumulates in particulate fractions that are poorly mixed with soil minerals and devoid of lignin, making carbon dynamics in acid soils upon anthropogenic change particularly difficult to predict. Furthermore, we explore if choice of overstory species can amplify or mitigate soil acidification and we assess if non-linear behavior can also be applied in a positive trajectory, i.e. to increase the efficiency of restauration efforts. As a large part of the European forest soils are close to a pedogenic threshold, our results have important implications for climate-smart forest management. Moreover, acknowledging non-linearity and threshold behavior in the soil carbon cycle implies recognizing that uncertainty, resilience and resistance may be just as important for managing environmental change below-ground as they are above-ground

C4.2 - Soils, food security, and human health

C4.2.1 - Soil and Human Health

(9781 - 1468) A brief history of soils and human health studies

Eric C. Brevik[1]; Lily Pereg[2]; Thomas J. Sauer[3]
Dickinson State University, USA[1]; University of New England, Australia[2]; UDSA-ARS, National Laboratory for Agriculture and the Environment, USA[3]

The idea that human health is tied to soils is not a new one. As far back as circa 1400 B.C. the Bible depicts Moses as understanding that fertile soil was essential to the well-being of his people. In 400 B.C. the Greek philosopher Hippocrates provided a list of things that should be considered in a proper medical evaluation, including the properties of

the local ground. By the late 1700 and early 1800s, American farmers had recognized that soil properties had some connection to human health, and in the early 1900s scientists worldwide were recognizing the importance of soils to human health. However, by the end of the 1900s there was still a need for well-designed scientific studies into soils and human health. In the modern world, we recognize that soils have a distinct influence on human health. We recognize that soils influence 1) food availability and quality (food security), 2) human contact with various chemicals, and 3) human contact with various microorganisms (both pathogenic and beneficial). Soils and human health studies include investigations into nutrient supply through the food chain and routes of exposure to chemicals and pathogens. We now know that healthy soils make for healthier people and that soil biodiversity is important to soil health. Therefore, the study of soil organisms has taken on an increasingly important role, and it is recognized that climate change and how it will affect the soil environment/ecosystem going into the future is another variable affecting the relationship between soils and health. The tools to conduct studies, including laboratory and field equipment as well as computers and statistical techniques, have improved dramatically. Inter- and transdisciplinary studies have become more common, and academic disciplines that have not worked together in the past are now seeking to do so. However, making strong, scientific connections between soils and human health can be difficult. There are multiple variables to consider in the soil environment, meaning traditional scientific studies that seek to isolate and manipulate a single variable often do not provide meaningful data. Future successes in soils and human health research will require effectively addressing difficult issues such as these.

(7228 - 2340) Agronomic biofortification of potato (*Solanum tuberosum* L.) through foliar and soil fertilization with zinc and its interaction with cadmium

Pedro Pablo Gutierrez Vilchez[1]; Ruby Vega Ravello[1]; Rolando Egúsquiza Bayona[1]; Peter Kromann[2]

Universidad Nacional Agraria La Molina[1]; Centro Internacional de la Papa[2]

Agronomic biofortification is the application of mineral micronutrient fertilizers to increase the micronutrient content in edible crops. Zinc (Zn) is one of the most important micronutrients for human health. Its deficiency in population has been considered a limiting factor for the normal growth of children, especially in developing countries. In addition, Cadmium (Cd) uptake by plants is a risk for living beings. Generally, there is a competitive interaction between Cd and Zn into plants, where Cd uptake and accumulation are reduced by Zn. Therefore, agronomic biofortification in agriculture is being considered as the most accessible way to increase the amount of zinc in food; also, it could be an alternative to reduce Cd in plants. During 2017 cropping season, experimental fields were installed in moderately alkaline soils of the Peruvian coast to study the response of potato crop (Solanum tuberosum L.) to zinc fertilization. The plots were distributed in a randomized complete block design (RCBD) with four replicates. The treatments considered applications of zinc to the soil in rates of 0, 20 y 40 kg Zn ha^{-1}, and in some cases application of Zn to the foliage (5 kg Zn ha^{-1}). The response variables were yield (t ha^{-1}) and concentration of Zn and Cd in leaves and tuber (skin and pulp). The statistical analysis did not reveal significant effects in the Zn soil fertilization for potato production. However, concentration of Zn in leaves and tuber was greater with foliar Zn application. In the treatments with foliar application, the Zn concentrations in the leaves, skin and pulp were 166.0, 49.3, and 24.6 mg Zn kg^{-1}, respectively; while the values in treatments without Zn foliar were 69.7, 41.4, and 18.5 mg kg^{-1}, respectively. Statistically, there no was evidence Zn application reduced Cd.

Keywords: biofortification, zinc, potato, cadmium

(8391 - 2654) Detection of *amp*C beta-lactamase from agricultural and forest soils in Nova Friburgo, Rio de Janeiro, Brazil

Eliene dos Santos Lopes[1]; Camila Costa de Oliveira[1]; Ramon Loureiro Pimenta[1]; Daniele Rodrigues Barbosa[1]; Shana de Mattos de Oliveira Coelho[1]; Miliane Moreira Soares de Souza[1]; Irene da Silva Coelho[1]

Universidade Federal Rural do Rio de Janeiro[1]

Beta-lactams represent the first class of antimicrobial agents discovered, and include penicillin derivatives (penams), cephalosporins (cephems), monobactams and carbapenems. These antimicrobials are a class of broad-spectrum antibiotics, consisting of all antibiotic agents that contain a beta-lactam ring in their molecular structure. They are among the main antibiotics prescribed in clinical practice because of their efficacy and low toxicity. In addition, beta-lactams are often associated with preventive veterinary drugs or as zootechnical additives in animal production, especially in aviculture, in order to enhance performance. Most of them act by inhibiting the synthesis of the peptidoglycan layer of bacterial cell walls. A mechanism of bacterial resistance to these antimicrobials is associated to hydrolysis of beta-lactam ring by beta-lactamase enzymes, encoded, for example, by the *amp*C gene. In this perspective, the present study aims to detect the *amp*C gene in soil from agricultural and forest areas in Nova Friburgo, Rio de Janeiro, Brazil. Soil samples from 10 agricultural and 10 forest areas were collected at 0-20 cm depth. Total DNA extraction was performed, followed by amplification of *amp*C gene by PCR (Polymerase Chain Reaction). The *amp*C gene was detected in most soil samples, where poultry manure was used as organic fertilizer and also in forest areas. The presence of this gene even in forest soils is justified because bacterial resistance is not a recent phenomenon. Beta-lactamases can be encoded by chromosomal genes or genes present in plasmids, and they have been identified before the use of penicillin in large scale. It is believed that bacterial resistance evolved from the selective pressure made by microorganisms that produce beta-lactam compounds present in soils, but the use of these antibiotics in large scale has been contributing to increase the selection and to spread resistance genes. These finding reinforces the importance to study the antimicrobial resistance in a one health approach, that recognizes that the health of people is connected to the health of animals and the environment.

(1053 - 2583) Detection of the colistin resistance gene (*mcr*-1) from agricultural and forest soils in Nova Friburgo, Rio de Janeiro, Brazil

Camila Costa de Oliveira[1]; Eliene Santos Lopes[1]; Daniele Rodrigues Barbosa[1]; Ramon Loureiro Pimenta[1]; Shana de Mattos de Oliveira Coelho[1]; Miliane Moreira Soares de Souza[1]; Irene da Silva Coelho[1]

Universidade Federal Rural do Rio de Janeiro[1]

Antimicrobial resistance has emerged as one of the principal global public health problems. Increasing number of infections caused by multiresistant gram-negative bacteria has reduced therapeutic options commonly used. Colistin, which is a member of the polymyxin family, is currently the last-resort antimicrobial for treatment of infections caused by these pathogens. Its mode of action involves inducing changes in the permeability of the cell membrane by binding anionic lipopolysaccharide molecules and displacing calcium and magnesium, thus causing cell leakage and death. One of the polymyxin resistance mechanisms is mediated by the enzyme phosphatidylethanolamine transferase, encoded by the *mcr-1* gene. The enzyme transfers a phosphoethanolamine residue to the lipid A present in the cell membrane of gram-negative bacteria. The altered lipid A has much lower affinity for colistin and related polymyxins resulting in reduced

activity of the antimicrobial. Therefore, the present study aimed to detect the *mcr-1* colistin resistance gene in agricultural and forest soils in Nova Friburgo, Rio de Janeiro, Brazil. Twenty soil samples with known physical-chemical characteristics were collected at 0-20 cm depth, including 10 from agricultural areas and 10 from forest areas. Total DNA was extracted, and the detection of the *mcr-1* gene was performed by Polymerase Chain Reaction (PCR). The *mcr-1* resistance gene was detected in agricultural soils. The addition of poultry manure as organic fertilizer can contribute to an increase of this gene in soils. However, the *mcr*-1 gene was also detected in forest soils. Although the emergence of antimicrobial resistant strains is often interpreted as a modern phenomenon, these findings reinforce it is a natural phenomenon that precede the antibiotics era. Nonetheless, the excessive use of antibiotics in animal production and the use of manure from these animals in soil can increased the dissemination, selection and spread of resistance genes. These results further support the role of soil as source and reservoir of antimicrobial resistance and the need to addressing the rising threat of antimicrobial resistance in a One Health approach that recognizes that the health of humans is connected to the health of animals and the environment.

(3507 - 210) Eastern European Pollution Assessment via Portable X-ray Fluorescence Spectrometry: Soils and Vegetation

Laura Paulette[1]; David C. Weindorf[2]; Somsubhra Chakraborty[3]; Bogdan M. Duda[2]

University of Agricultural Sciences and Veterinary Medicine[1]; Texas Tech University[2]; Indian Institute of Technology - Kharagpur[3]

Toxic metals released into environment from anthropogenic sources accumulate in soils and pose serious risks to organisms and human health. Elevated environmental concentrations of toxic metals and other chemicals have been linked to many acute and chronic health conditions including poisoning, allergies, neurological/dermatologic/respiratory problems, and cancer, accelerating mortality. Environmental exposure to toxic metals is concerning but also presents a remediation serious challenge. Soils featuring toxic metals pose a threat both for vegetative uptake of metals or via metal-laden dust deposited on plants, either of which may be inadvertently consumed. In Romania, soils in many localized areas are known to be polluted with toxic metals from former smelters in Zlatna, Copşa Mică, Baia Mare, and other locations. However, few data exist regarding the spatial extent of pollution and the potential impacts toxic metals are having on the health of local residents. As such, we used portable X-ray fluorescence (pXRF) spectrometry to scan multiple elements in-situ. Surface soils (0-2 cm) were scanned with kriging interpolation applied for rapid soil pollution hotspot mapping. Also, various vegetation types were scanned (e.g., bark, deciduous leaves, grasses, herbaceous materials, organic thatch) to identify potential vegetative pathways to human exposure. In each area evaluated, the spatial extent of certain metals exceeded the Romanian action limits. For example, the spatial area in which Pb exceed Romanian action limits was 99% in Zlatna, 100% in Copşa Mică, and 91.09% in Baia Mare; As, Cu, Zn, Co, and Cd exceeded limits in >50% of the areas scanned. Hotspots were easily and rapidly identified by kriging interpolation. In vegetation, thatch and bark showed the highest toxic metal concentrations. In conclusion, pXRF was shown to be a valuable tool for rapidly assessing smelter pollution in soil and vegetative matrices. Even newer research is investigating its efficacy in for liquid matrix analysis in support of comprehensive environmental quality assessment.

(9886 - 1141) Metal and metalloid contaminated soil from an ancient gold Mine - Mina de Chico Rei – Ouro Preto/MG – Chemical extraction studies

Alcylane Caldeira Santos[1]; Mônica Cristina Teixeira[1]

Universidade Federal de Ouro Preto[1]

Soil contamination by metals and metalloids is of environmental concern since even very small amounts of some those elements could be hazardous for human beings. In Ouro Preto, some underground ancient gold mines are actually located at residential neighbourhoods. Chico Rei, Santa Rita and Mina Velha mines are some good examples of the aforementioned. Arsenic content in their soils may vary from 465.0 to 1829 $mg.kg^{-1}$ (Lopes, 2014). However, according to legislation, the maximum recommended As soil content for residential areas is 55 $mg.kg^{-1}$ (BRASIL, 2009). As contents above that should be investigated. Besides As, also other potentially toxic elements (PTE) like Cd, Pb, Co and Cr were found. During this study, chemical extraction efficiency in removing metals and metalloids from Chico Rei mine soil samples was tested. Extractant solutions tested were organic acids (0.1 M); $CaCl_2$ (0.2 mM) and distilled water (negative control). For each test, a 5g solid sample was soaked with 25 ml of the extractant (1:5). Samples were agitated (150 rpm) and kept at constant temperature (30ºC) for 1h, 24h or 48 h. Samples were centrifuged (5000 rpm, 15 min), liquid fraction was recovered, filtered and acidified with HNO_3 prior to ICP-OES chemical composition analyses. As maximum extraction achieved was 28.0062 $mg.L^{-1}$ (after a 48h contact time with organic acid solution). This result corresponds to an extraction efficiency of 7.3%. Additionally, elements like Al, Fe e Mn were largely extracted, metal solubility was higher than the equipment detection limits (i.e. 10ppm), even after dilutions. Cd, Cr, Pb, Cu e Zn were also solubilized with extraction efficiencies of 9.33, 1.62, 26.0, 14.0 and 51.5%, respectively. $CaCl_2$ extraction efficiency was not relevant when compared to organic acid solution, only the easily exchangeable elements were extracted from soil. Nevertheless, even a diluted acid solution was efficient in removing PTE from a contaminated soil sample. This feature demands further investigations relative to bioaccessibility and bioavailability of those potentially hazardous elements, mainly As, since the studied material was obtained from a densely populated residential area were the deposition of organic waste material is likely and may causes organic acids generation which by it turns, decreases soil pH, thus facilitating metals and metalloids solubilization.

(2809 - 3016) Soil and house dust as environmental media of human exposure to trace elements in an historically contaminated area of central Chile

Maite Berasaluce[1]; Pedro Mondaca[1]; Alexander Neaman[1]

Pontificia Universidad Católica de Valparaíso[1]

The Puchuncaví valley has been exposed to a large amount of contamination caused by the emission of trace element (TE) rich particulate matter from the Ventanas copper smelter into the local atmosphere. Pollution in mining areas can expose the local population to TE. However, biomarkers as a tool to confirm health risk have not been considered as a possible monitor of this problem in Puchuncaví. While, it is known that incidental ingestion of both soil and dust are exposure routes of TE, the contribution of each media is not yet known. Consequently, the present study aims to (1) determine the relationship between TE in environmental media (soil and dust) and TE in human samples (hair and toenails), and (2) characterize the contribution of different environmental media to human exposure to TE, through determination of chronic daily intake (CDI). A total of 100 households from three areas (highly contaminated, moderately contaminated, and

not contaminated) were studied. For each household, the following samples were collected: outdoor dust and/or soil, indoor house dust, and hair and toenail samples from the residents. Additionally, exposure factors associated to the behavior of the residents were obtained by surveys. This information was used to estimate the chronic daily intake as an index of exposure. Trace element concentrations of As, Pb and Cd in environmental media were determined using AAS; biological samples were analyzed via ICP-MS. Moreover, the CDI was calculated to characterize the health risk of each environmental media. TE concentrations in our samples are broadly consistent with previous studies, showing a higher concentration of TE near the copper smelter. In addition, results show that TE concentration of samples depends on the environmental media, as indoor house dust consistently showed higher concentrations of TE, followed by outdoor dust and soil. Despite these results, no significant correlation was found between TE in biological samples and TE in environmental media. However, exposure estimation of TE through CDI demonstrated a significant correlation with TE in biological samples. As-CDI is correlated with As concentration on hair and toenail samples; furthermore, Pb-CDI and Cd-CDI demonstrate a correlation with Pb and Cd in toenail samples, respectively. In addition, our results indicate that As is the TE of concern for human health in this province, specially for populations under 18 years old living near the smelter.

(7048 - 2932) Spatial distributions of soil lead across scales in the Twin Cities Metropolitan Area, United States

An-Min Wu[1]; Ashley Hansen[2]; Kat LaBine[2]; Nic Jelinski[2]
University of Southern California[1]; University of Minnesota[2]

Soil lead (Pb) in the urban environment has been linked to elevated blood Pb levels with long-term health effects to young children. Urban soil Pb levels are generally higher than background levels (10-50 ppm) due to historical usage of lead paint and leaded gasoline (Mielke and Reagan 1998). Because Pb is a legacy contaminant that accumulates on the soil surface, lead-contaminated soil continues to pose a high risk to children in some urban areas (Laidlaw and Flippelli 2008). In the Twin Cities metropolitan area in Minnesota, U.S.A., urban soils typically have Pb levels in 1-2 orders of magnitude higher than those in rural areas (Mielke et al. 1984). Understanding soil Pb distributions throughout the Twin Cities over time are thus crucial for researchers in identifying population and health relationships with Pb contamination in this urban environment and for city officials in land use planning and regulations. The objectives of this project are to: 1) Build spatially-explicit models for soil Pb in the Twin Cities metropolitan area; 2) understand the spatial relationships between soil Pb and social environmental parameters related to urban lead sources including traffic volume, housing density, and age of houses; and 3) Identify whether samples collected in various time and spatial scales provide matching results about soil Pb levels in the Twin Cities area. Various spatial modeling methods (i.e. general linear model, random forest, and support vector machine) will be tested for mapping soil Pb levels from samples collected in the community engagement and citizen science projects (2015-2016). A set of legacy soil Pb data for the city of St. Paul (1997-1998) will also be modeled with these methods. The predictor variables for soil Pb models will consist of urban environmental parameters related to Pb contamination sources (e.g. traffic volume, building density and housing age). The modeling results from different methods will be compared and reported. We will also georeference and digitize an old soil Pb map from mid-1980s in the Twin Cities area (Mielke et al. 1989). Our intention is to know whether the three sets of samples collected in different scales and time show matching results, and whether urban environmental parameters related to Pb contamination can be used to predict the soil Pb levels in the Twin Cities. The results will help house siting and land use planning for protecting human health in the urban environment.

C4.2.2 - Soil quality and food security in the tropics

(1948 - 2427) Accumulation and translocation of cadmium in cacao production systems of the Colombian central Andean region

Martha Cecilia Henao-Toro[1]; John Fernando Soler-Arias[1]
Universidad Nacional de Colombia[1]

Cadmium is a toxic heavy metal that is not essential for plants, but can be absorbed by them, through soils. A preliminary study showed high levels of Cd in cocoa beans in some areas of Colombian central Andean region, in crops seeded in stony soils developed from sedimentary rocks with relatively high levels of Cd. In order to determine the potential Cd accumulation in different tissues of cacao plants, 95 crops were selected and in each one a plant with mature fruits was sampled. The Cd in leaf and fruit tissues (shell, bean and pod husk) was analyzed by AAS after sample calcination and dissolution in HCl-HNO_3. Cd in soil and cacao leaf litter around trees was also determined. Bioaccumulation factor (BF) was calculated as the ratio of Cd in leaf or bean to that in soil, and Translocation factor (TF) as the ratio of Cd in leaf to that in fruit tissues. It was found statistical differences between Cd levels in leaf and fruit tissues, Cd in leaf being higher ($P<0.01$). Among the other fruit tissues there were no statistical differences. Cd means levels found were 7.18, 4.42, 3.36 and 2.88 mg/kg in leaf, bean, pod and shell respectively. Except for pod, levels in other tissues showed a high correlation with each other ($r> 0.6$, $P<0.01$), Cd in leaf was an acceptable estimator of Cd in bean ($r=0.67$, $P<0.01$). FB indicated that plant can be considered as accumulator since all values were higher than 1, and 10% even were higher than 50. FT suggests that mobility of Cd between leaves and fruits is low, with values generally lower than 1, which would exclude cacao as hyperaccumulator plant. Cacao leaf litter had the highest levels of Cd in all types of plant tissue evaluated ($P<0.01$), with a ratio Litter/Leaf of 2.3 on average. The risk of Cd cycling in crops of the study area can be high, as litter is a direct product of foliar abscission of cacao during all year, and leaf is the organ with the highest concentration of Cd. An estimate of maximum possible addition to soil of Cd by litter was of 1 kg/ha/year, calculated with the highest Cd concentration found in litter in this study and a dry biomass production of 21 Mg/ha/year of litter, reported for similar production systems. The cycling could also occur due to use of pod husk in compost production for cacao fertilization, since, along with FT, pod can accumulate 58% of Cd present in the leaf. A strategy of litter and crop residues management should be applied for reducing Cd recycling in cocoa production systems.

(2325 - 927) Achievements and Challenges of the Regional Soil Partnership for Central America, Mexico and The Caribbean

Olegario Muñiz[1]
Soil Institute. Autopista Costa Costa y carretera de Vento. Boyeros. CP. 10800. La Habana, Cuba. Email: olemuni7@gmail.com[1]

In 2012, FAO members approved the establishment of the Global Soil Partnership (GSP), an initiative aimed for improving the governance of natural resource soil and raising awareness of its importance on a global scale. The GSP is directed to stop and reversing the soil degradation process through the establishment of regional strategies based on Sustainable Soil Management. In October 2013, it was launched in Havana for the region of Central America, Mexico and the Caribbean with the participation of soil officials from 15 of the countries in the area; as well as international institutions and NGOs. Thus, it was established the Regional Soil Partnership (RSP), in front of which was an Steering Committee conformed by specialists of seven of the countries present. An Implementation Plan of activities for the region was approved for the following 5 years, as a contribution to the Food Security, the adaptation

and mitigation to the Climate Change and the provision of ecosystem services. Recently, the Third Workshop of our RSP was carried out at Panama City. In present paper, the achievements, shortcomings and challenges are discussed.

(6207 - 1148) Agronomic fortification of Zinc and Iron nutrition on productivity and quality of wheat

Sudha T[1]; Pallavi V[1]
University of agricultural sciences Dharwad[1]

field experiment was carried out during *rabi* season of 2015-16 and 2016-17 to study the effect of agronomic fortification of Zinc (Zn) and Iron (Fe) nutrition in irrigated wheat at Main gricultural Research Station, Dharwad, Karnataka, India. The experiment was laid out in a Randomized complete block design (RCBD) having 15 treatments and replicated thrice. A common dose of 100 N : 75P_2 : 50 kg K_2O kg/ha was applied to all the treatments. $ZnSO_4$ and $FeSO_4$ was applied to the soil alone and in combination with foliar application (0.5%) at the rate of 20 kg/ha each. Foliar application of $ZnSO_4$ and $FeSO_4$ each were made at heading and milky stage @ 0.5%. The higher number of earhead / m^2 (277), grain yield (41.3 q/ha) and biomass yield (106 q/ha) were recorded with combined soil (20 kg/ha) and foliar (0.5%) application of $ZnSO_4.7H_2O$ during heading and milky stage as compared to all other treatments and found on par with soil and foliar application of $ZnSO_4.7H_2O$ heading stage. Soil and foliar application of $ZnSO_4.7H_2O$ at heading and milky stage recorded higher gross returns (Rs. 74 x 10^3), net returns (Rs. 37 x 10^3) and B:C ratio (2.02) and found on par with soil and foliar application of $ZnSO_4.7H_2O$ at heading stage. Quality parameters like protein (14.2%), sedimentation value (37.6 ml) was significantly higher with soil and foliar application of $ZnSO_4.7H_2O$ at heading and milky stages compared to all other treatments and found on par with soil and foliar application of $ZnSO_4$, $7H_2O$ at heading stage. The soil of the experimental site showed high in Iron (Fe) content (3.56 ppm) the response of $FeSO_4.7H_2O$ is not noticed in the grain concentration.

(9958 - 2123) Assessment of chemical quality of soils of horticultural areas of the Federal District

Lucas Soares Mendes[1]; Rafaella Russolyne Marques Silva[1]; Carlos Eduardo Pacheco Lima[2]; Juscimar Silva[3]
ICESP Promove[1]; Embrapa Vegetables[2]; Embrapa Vegetables, BR 060, km 09, Brasília/Anapolis, 70275-970 (juscimar.silva@embrapa.br)[3]

The cultivation of vegetables requires intensive soil management, in particular regarding the addition of high doses of fertilizers. Such doses when applied without proper guidance may lead to loss of chemical quality of soils with direct effects on crop yield. The objective of this work was to evaluate the chemical quality of soils from vegetables areas of the Federal District, Brazil. It was analyzed 160 samples of top soils (0 – 20 cm depth) collected from the major administrative regions. Chemical quality was defined as function of fertility level of the soils, content of soil organic matter (SOM) and trace elements. The results showed that, in average, the levels of soil nutrients presented different behaviors. Phosphorus and potassium were below the critical level (nutrient status that correlates with maximum yield) in 51.8% and 59.2.7% of the samples, respectively. Potential acidity (56.1%) and CEC (60%) presented same pattern. The content of SOM was adequate for most of the soils and ranged from 10.6 up to 79.8 g/kg with the highest values observed on soils from organic farming. Available micronutrients were excessively high, reaching up to 10 folds the content considered adequate for vegetable growth especially for Fe, Mn, and Zn. Total content of Ag (< 44,18 µg/L), Cd (< 7.67 µg/L), and Pb (< 205.5 µg/L) were below de detection limit. Some samples presented the content of Cr (79%), Cu (10%), Ni (17.5%), and Mo (28.1%) above the Quality Reference Values (VRQ) for soils according to Brazilian regulation (CONAMA, 2009) and their monitoring are needed.

(4206 - 291) Biological indicators and soil quality indices for red soils under subtropical rainforest and under *Pinus sp.* plantation

Toledo Diana Marcela[1]; Arzuaga Silvia Amanda[1]; Galantini Juan Alberto[2]; Vazquez Sara[1]
Universidad Nacional Del Nordeste[1]; Universidad Nacional Del SUR-CERZOS-CONICET[2]

Over the last decade, massive forest-clearing, coupled with agricultural and forestry expansion in the province of Misiones (northeast of Argentina), has resulted in the loss of 500,000 hectares of subtropical rainforest, accounting for the highest annual deforestation rate in the country (1.3%, i.e. 60,000 ha $year^{-1}$). Rainforest areas are becoming smaller as a consequence of land-use changes for planting fast-growing exotic trees such as *Pinus sp.* (83% of forest area). The objective of this research was to assess the changes induced by subtropical rainforest-clearing and the subsequent plantation of *Pinus sp.* through biological indicators and functional indices of soil quality. The assay was carried out in Oxisols in the department of Oberá (Misiones). A completely randomized design was used and two treatments were included: rainforest (S) and 20-year-old *Pinus sp* (Pi) plantations. The soil was sampled from 12 plots under Pi and from 12 under S. Composite samples were collected from each plot to the 0 - 0.10; 0.10 - 0.20 and 0.20 - 0.30 m depths. The following soil properties were determined: total organic matter (MO), particulate organic matter (MOP), total nitrogen (Nt), potentially mineralizable nitrogen (NMP) and soil respiration (RES). The NPM/Nt, NPM/MOP, MOP/MO, MOP/RES and NPM/RES indices were calculated. The results were analyzed through an ANOVA, an LSD test ($P \leq 0.05$) and a Pearson's correlation test ($P \leq 0.05$). Clearing subtropical rainforests and the subsequent forest plantations resulted in lower MO (37%), MOP (41%), Nt (52%) and NPM (70%). The correlation of NPM with MO, MOP and Nt, as well as with the NPM/Nt, NPM/MOP, MOP/RES and NPM/RES indices, were shown to be positive and significant across the three depth levels. Land-use changes resulted in a negative organic balance and affected MO dynamics, as shown by the MOP/RES and NPM/RES indices, indicating a lower turnover rate for soils under forestry.

(2400 - 2611) Comprehensive study of soil physical and chemical properties under no-tillage systems in Brazil

Rhuanito Soranz Ferrarezi[1]; Ondino Cleante Bataglia[2]; Camilo Lázaro Medina[2]; Pedro Roberto Furlani[2]; Fernando Penteado Cardoso[3]
University of Florida[1]; Conplant Consultoria, Treinamento Pesquisa e Desenvolvimento Agrícola[2]; Fundação Agrisus Agricultura Sustentável[3]

The 2009 Brazilian Crop Tour (known as Rally da Safra) visited the main row crop producing regions in Brazil to determine the state of the art of intensive farming in Brazil. During this endeavor across the country, soil samples were taken to perform a comprehensive study of soil physical and chemical properties of no-tillage systems in soybean and corn summer crops. 1,171 soil samples were collected in two layers (0-5 and 5-10 cm), totaling 2,342 samples. We determined soil texture, soil cover, cation exchange capacity, pH, base saturation, P and total exchangeable

bases (Ca, Mg, K, Na). In addition, soybean and corn crop yield were estimated. Data were grouped into climatic regions and states: Region 1) cold and humid winter, wheat and oat cultivation (RS, SC, PR); Region 2) mild and wet winter, unpredictable weather changes, and wheat, oat, sorghum and winter corn production (MS, PR, SP); Region 3) warm and humid winter, corn and sorghum cultivation (MT, RO, SP, MG, GO); and Region 4) warm and dry winter, with corn, soybean and cotton production (MA, PI, TO, BA, GO). The sampled soils presented variable texture, soil cover and cation exchange capacity, and were predominantly formed by clay soils in the southernmost regions of the country – which presented the longest time under no-tillage cultivation. Sandy soils prevailed in the northeastern regions, where no-tillage systems are more recent. The surface lime addition was adopted by most corn and soybean producers in Brazil, as pH >5 in 74% of soils and base saturation >50% in 82% soils. We developed an interpretation range based on P levels and soil depth, which revealed the predominance of samples with high P levels for corn and medium for soybean in the 0-5 and 5-10 cm layers. The P concentration, extracted using ion exchange resin method from the Agronomic Institute of Campinas, indicated the presence of high P levels in 41% of 0-5 cm samples and in 36% of 5-10 cm samples. When considering the two sampling layers pooled, results showed the existence of high P in 51% of the samples. Clay soils had more samples with higher P, which coincides to regions with older, consolidated no-tillage systems. Cornfields tended to present higher soil fertility compared to soils cultivated with soybean. In regions 1 and 2, high levels of K prevailed, as opposed to regions 3 and 4. K increased with soil cover due to higher nutrient recycling by cover crops, with greater soil surface organic matter accumulation.

(2092 - 2578) Fertility and metal concentrations in soils of tropical *Eucalyptus* plantations under residual application of sewage sludge: indication of soil quality

Cassio Hamilton Abreu-Junior[1]; Antonio Leite Florentino[2]; Alexandre V. Ferraz[2]; Josè Leonardo M. Gonçalves[2]; Fábio Poggiani[2]; Verónica Asensio[2]; Takashi Muraoka[1]

USP/CENA[1]; USP/ESALQ[2]

The management of sewage sludge (SS) in agricultural areas increase soil fertility, nutrient cycling and crop yield. However, soil and plant contamination with metals is a great concern. In the case of São Paulo state, Brazil, the Environmental Company of São Paulo State (CETESB) defines three key values: quality reference values (QRV), prevention values (PV) and intervention values (IV) for soils as function of the concentration of metals. In this study, the objectives were: to assess the concentration of As, Ba, Cd, Co, Cr, Cu, Mo, Ni, Pb, Se and Zn in soils; to evaluate the soil fertility status; and to investigate the quality standards of tropical soils for *Eucalyptus* plantations as affected by residual application of SS. The study was carried out in four experimental sites at São Paulo state, Brazil: 3 experiments at Itatinga city (3 Typic Hapludox soils, TH, with texture varying from sand to loamy) and 1 at Angatuba city (TH, sand texture). The SS came from the sewage treatment plants of Jundiaí, Barueri and São Paulo cities. The sludges were applied only once at 10-17 years ago (before soil sampling for this study). For each site, treatments were SS doses (from 8 to 40 t ha^{-1}, dry base), conventional mineral fertilization (MF) and control (without sludge and mineral fertilizer). The experimental designs were randomized block, with 5 treatments and 4 replicates for three sites, and 3 replicates for one site. Analytical determinations were performed by ICP-OES after sample acid digestion (HNO_3+HCl), USEPA method 3050b. There was a residual effect of SS on the concentration of metals and soil fertility, in comparison with the MF, especially in the treatments with the highest doses (i.e., 30 t ha^{-1} and/or 40 t ha^{-1}). Notwithstanding, the metal concentrations in the soil were generally lower than the prevention values, except for Se. There was a relationship between the dose of sludge and the concentration of metals and soil fertility, i.e., the higher the effect of the doses, the higher the increase in the sandy texture soils. We concluded that there is a residual effect of the application of SS in comparison with the mineral fertilizer application, with an increase in the metal concentrations as soil fertility was improved. There is no soil contamination by metals as a residual effect of the application of sewage sludge. Conversely, the soil fertility and quality were improved for fast growing *Eucalyptus* plantations under tropical climate.

(4072 - 1230) Fertilizer application alters temporal dynamics of soil inorganic nitrogen and its availability to maize in two soil types in the Tanzanian highlands

Jinsen Zheng[1]; William N. Mmari[2]; Tomohiro Nishigaki[3]; Method M. Kilasara[4]; Shinya Funakawa[1]

Kyoto University[1]; Uyole Research Institute, Mbeya, Tanzania[2]; Japan International Research Center for Agricultural Sciences[3]; Sokoine University of Agriculture[4]

Regional and national efforts are underway to increase fertilizer use (especially nitrogen, N) in Sub-Saharan Africa (SSA), yet the fate of added N and the crop response are poorly understood. For two consecutive cropping seasons (2013–2015), we monitored the fluctuation of soil inorganic N and its availability to maize in the Tanzanian highlands. Four urea-N rates (0, 50, 100, and 150 kg N ha^{-1}) were applied to two types of soils (TZi, sandy Alfisols; and TZm, clayey Andisols). Seasonal variations in soil inorganic N availability coupled with plant N uptake revealed that, regardless of soil type, soil mineralized N at the early growing season were largely exposed to the risk of leaching due to small crop N demand. Shortly (10–12 days) after urea application, soil inorganic N availability (0–30) increased significantly with urea-N rate at TZm ($P < 0.001$) but not at TZi ($P = 0.17$), indicating that higher rate of urea-N applied at TZi was accompanied by more N loss. Fast depletion of applied urea-N at TZi, especially at higher N rate, was likely a result of substantial N loss through ammonia volatilization, as supported by the poorly pH-buffered soil with low cation exchange capacity at TZi. By contrast, a large fraction of applied urea-N was retained available to crop at TZm. Accordingly, yield at TZi was low (up to 2.6 Mg ha^{-1}) compared to TZm (up to 4.4 Mg ha^{-1}) under the same N rate. The best-fitted linear-plateau model indicated that the soil inorganic N availability in the top 30 cm at the tasseling stage (i.e., 68–71 days after planting) largely determined maize yield. Further, yields at TZi were still limited by N availability at the tasseling stage due to fast depletion of applied-N, whereas yields plateaued at TZm once N availability was above 67 kg N ha^{-1}. Our results provided a valuable reference for N management to increase yield, while minimizing the potentially adverse losses of N to the environment, in different agro-ecological zones in SSA, where N application is poised to increase.

(5485 - 1452) High resolution soil functional maps for Central America and Oaxaca using Digital Soil Mapping

Phillip R. Owens[1]; Axel Schmidt[2]; Zamir Libohova[3]; Minerva Dorantes[4]

USDA ARS[1]; Catholic Relief Services[2]; USDA NRCS[3]; ORISE Research Scientist[4]

Some of the current problems related to food security, drought and ecosystem degradation are rooted in the lack of information on soil function and soil resource linkages within landscapes. Additionally, the problem is coupled with (i) lack of detailed soil information; (ii) access to existing soil data; and (iii) investment in detailed soil surveys. As a result, a paradoxical situation has been created with soil being an overlooked national infrastructure resource, yet constituting the biggest freshwater reservoir. More than 70% of the agriculture in Central America is rain fed thus its dependence on the amount and distribution of water is critical. Recent government investments on subsidizing seed and fertilizer for the farmers in some of the countries while ignoring proper soil conservation and management has led to further degradation of soils and crop failures. Climate change and associated uncertainties have led to persistent and prolonged droughts in Central America especially in the so called "dry corridor". As part of the Water-Smart Agriculture project, sponsored by the Howard G. Buffett Foundation to improve food security in Central America, Catholic Relief Services (CRS), and United States Department of Agriculture (USDA), Dale Bumpers Small Farm Research Center - Agriculture Research Service (ARS) and Soil Science Division - Natural Resources Conservation Service (NRCS) have launched a Soil Mapping Initiative project aimed at creating detailed soil property maps by combining legacy data, local tacit knowledge, and new digital soil mapping (DSM) techniques as well as building capacity for sustainable future soil surveys efforts. The Soil Mapping Initiative project is focusing on generating detailed soil maps of properties that are directly related to soil water dynamics such as soil depth, texture, permeability and available water capacity. The property maps and interpretative maps will also be made freely available to users to help their management decisions from the field to watershed scale. We highlight some of the achievements and challenges of the DSM efforts.

(1206 - 2526) Influence of soils and micro-environment on the biomass and bioactive concentration of plantation grown E*urycoma longifolia*

Wan Rasidah Kadir[1]; Mohamad Fakhri Ishak[1]; Rosnani Abdul Ghani[2]

Forest Research Institute Malaysia[1]; Malaysian Agriculture Research and Development Board[2]

Differences in environmental parameters can significantly influence growth performance and quality of plants growing on such sites. This study examined the influence of soils, micro-climate and stand management on the growth, biomass production and the quantity of bioactive compounds that can be extracted from tongkat ali (*Eurycoma longifolia*) plants. Data collection and sampling were carried out for the Peninsular Malaysia, separated into five zones assumed to differ in micro-climate and environments, rainfall distribution as well as soil quality. Our discussion with plantation owners revealed that there was no standard or uniform plantation management regime and it differs for each organization. Thus we have to resolve with *E. longifolia* plantations of age range between 8-13 years for data collection and biomass sampling. Out of five sampling zones, two sites gave high biomass yield, one in the Northern zone (Perlis) and the other in the Southern zone (Johor). However, eurycomanone concentrations in plant sample collected from Perlis were rather inconsistent and not as much of identifiable pattern. Plants at open area have the highest eurycomanone concentration for the leaves part, probably due to the influence from soil and micro-environment. From the six plants harvested, only two plants have detectable eurycomanone in stem, and no eurycomanone was traceable in leaf stalk. For samples taken from Southern zone, the presence of eurycomanone was comparatively higher especially in roots and leaves. The other two zones i.e. the Eastern and Middle zones, eurycomanone were detected in roots, stem and leaves with concentration higher than those samples from shaded site in the Northern zone even though their biomass yields were much lower. On the whole, for all samples chemical analysis showed that eurycomanone was present in roots and leaves. We are not able to conclude on plantation management such as management during planting, fertilization and stand management due to scarcity of information. Nevertheless, from field observation we can roughly presume that stands management practiced by MARDI Kluang could be the option as three out of the four sites gave the highest biomass and eurycomanone yields. The site with low yield was planted on shallow soil. There is no issue with heavy metals content as the concentrations for all sites were below the permissible levels

(7240 - 2693) Influences of culturing eels in paddy fields on soil nutrients and rice's resistance to pests and diseases

Guo-jun Lan[1]; Xue-feng Hu[1]; Jing-long Zhao[1]; Si-wen Lu[1]; Fan Luo[1]

Shanghai University[1]

Excessive applications of chemical fertilizers and pesticides under the conventional rice farming system have already caused many environmental problems in China. In recent years, artificially ecological agricultural systems, called ecological planting-breeding coupling models, are introduced and gradually implemented in Shanghai and other areas in China. Rice-eel integrated farming is one of the important ecological coupling models, which means culturing eels in paddy fields during the rice growing season. The fields provide natural food, sufficient water and habitats for eels, and, on the other hand, eels improve rice growth through loosening soils, preying on rice pests and raising soil fertility. Our field experiments indicated that the rice pants for the eels treatment was 6.6% higher than the control, and the content of aliki-hydrolyzable N in the soil for the eels treatment was 3.1% higher than the control. Moreover, the incidences of rice leaf rollers, plant hoppers and blast for the eels treatment during the rice growing season were reduced by 46.6%, 39.5% and 33.4% on average, respectively. In short, the culture of eels in the fields can improve soil aeration, nutrients and biodiversity, thus stimulating rice growth and reducing the incidences of rice pests and diseases. The promotion of the rice-eel integrated farming system is beneficial to lessening the amounts of application of chemical fertilizers and pesticides during the rice growing season and reducing agricultural diffuse pollution effectively.

(6990 - 696) Knowledge management and technology transfer by the use of scrap farm for soil improvement via mushroom cultivation and inducing mushroom growing in the nature

Dr.Orathai Sukreeyapongse[1]; Dr.Thaworn Vinitsanan[2]; Dr.Weerasak Saksirirat[3]; Mr.Surachet Narabhat[1]; Ms.Prapatsorn Polwong[1]

Office of Science for Land Development[1]; Mahidol University[2]; Khon Kaen University[3]

In Thailand, some farmer in the northeast rural area, have free time after harvesting rice but they cannot grow any plant. They still need to expend for their family living. They want to do something but cannot due to lack of knowledge and experience. Therefore 3 objectives had been set to solve these problems. 1) To survey the need of the community and gathering knowledge for them. 2) To do knowledge management for soil improvement via mushroom cultivation by the use of scrap farm. 3) To transfer technology by the use of scrap farm for soil improvement via mushroom cultivation and induce mushroom growing in the nature. The results show that soil at the studied sites were low fertile, the pH were in the range of severe acid to medium. Plant nutrient of N, P and K were low. Soil properties need to be improved. The farmer want to learn

about mushroom cultivation which they can use scrap farm as a growing media. The trainees learned to grow mushroom in complete steps. They can separate mushroom pure culture, they can grow mushroom in PDA and in whole grains. They can produce mushroom bag and growing and harvest it in farmhouse. They can make compost from used growing media to amend and improve soil fertility. Average soil pH increased from 4.8 to 6.3, OM increased from 1.1 % to 1.6%, avail.P and extr.K increased from 4.3 and 65 to 27 and 163 mg/kg, respectively. They can induce Barometer Earthstars (*Astraeus hygrometricus*), Bolete (*Thaeogyroporus porentosus* (berk. ET. Broome) and Mouthpiece (*Tricholoma crissum*, Macrocybe Crassa (Beak)) to occur in the nature. They grew 700 Barometer Earthstars, 500 Boletes and 500 Mouthpieces in the studied area. 94.39% of the trainee was most satisfied the course, all of them (100%) will use the knowledge to improve their soil quality, to create job and produce mushroom as a community enterprise product. Soil quality in the studied area have been improved and the poverty of the farmers have been eradicated by this project.

(4875 - 1813) Large-area soil assessments for agriculture development in tropical Northern Australia

Mark Thomas[1]; Elisabeth Bui[1]; Seonaid Philip[1]; Ross Searle[1]; Ian Watson[1]; Peter Wilson[1]
CSIRO[1]

There is a need to develop new land to meet the world's rising demand for food. As the population grows, conflicts arise for precious land and water resources while the quality of much farm land (and yields) declines from poor management (e.g. nutrient imbalances, erosion, salinisation, etc.). Furthermore, many countries recognise the strategic importance of hedging against climate uncertainty for food security, and the desire to boost exports. Australia's pattern of soil and land evaluation - the precursor to agricultural expansion - since European colonisation in 1788 was initially *ad hoc* and centred on the settled hinterlands. Since World War 2 it has been more strategic supported by government investments, which in cases extended to the sparsely populated remote areas and producing coarse scale soil and land assessments (i.e. 1:250,000 – 1:2M scale mapping products). The sentiment to expand Australia's agricultural land persists, and there has been renewed interest in assessing opportunities in remote tropical Northern Australia where land and water are considered abundant. This paper describes experience in mounting large-area soil survey and mapping campaigns in the region under substantial operational constraints. Experience is drawn from two projects, each simultaneously assessing soils from multiple catchments, including the Flinders and Gilbert Agricultural Resource Assessment (155,000 km^2) and the Northern Australia Water Resource Assessment (196,000 km^2). Constraints include: short and fixed project timelines, each three years and catering for field access determined by unreliable but distinct wet/dry season breaks; a scarcity of suitable legacy data to draw upon, including soil survey and mapping of appropriate scale and themes; shortage of national soil survey capacity (personnel, equipment), and; remoteness and difficult field access, including a sparse transport networks. The paper presents pragmatic adaptations to these constraints allowing project objectives to be fully met. Adaptations include: adoption of digital soil mapping (drawing on past investments in digital terrain and geophysics data), statistically-based survey design, and rapid soil analysis; use of legacy soil survey data (after robust data evaluation) from government databases, and; inter-government agency partnerships to address short-falls in field skills and equipment. The approach can be modified in other countries where similar circumstances occur.

(3421 - 866) Measurement of biological N_2 fixation in field-grown common bean cultivars in Brazilian Cerrado soil using ^{15}N natural abundance method

Rafael Sanches Pacheco[1]; Bruno José Rodrigues Alves[1]; Robert Michael Boddey[1]; Enderson Petrônio de Brito Ferreira[2]; Rosângela Straliotto[3]; Adelson Paulo Araújo[4]
Embrapa Agrobiologia[1]; Embrapa Arroz e Feijão[2]; Embrapa Solos[3]; Universidade Federal Rural do Rio de Janeiro[4]

The ^{15}N natural abundance method (NA) can be used for distinguishing among the N from soil and air in N_2-fixing plants and thus to estimate the contribution of biological nitrogen fixation (BNF). The aim of this study was to estimate the BNF contribution for plant N nutrition by NA method in eight common bean cultivars with different agronomical traits at field conditions. Two field experiments were carried out in an Oxisol at Brazilian Cerrado biome, with eight common bean cultivars inoculated with *Rhizobium*. The NA method was used to estimate BNF in plant shoots at mid-pod filling and in grains at physiological maturity. Three non-fixing plants were used as reference and the assumed B value was -1.2. The same bean cultivars grew under mineral N (90 kg ha^{-1} as urea) to estimate their yield potential without N limitations. Averaged grain yield was 1614 and 2942 kg ha^{-1} in the Experiment I, and 3284 and 3919 kg ha^{-1} in the Experiment II, respectively, under inoculation or mineral N. None cultivar under rhizobium inoculation surpassed the grain yield provided by mineral N in both experiments. The ^{15}N natural abundance ($\delta^{15}N$) in non-fixing reference plants was 5.49‰ in the Experiment I and 4.88‰ in the Experiment II. In Experiment I, the contribution of N derived from atmosphere (%Ndfa) reached a maximum of 25% in shoots at mid-pod filling, while varied from 18 to 35% in grains at maturity. In Experiment II, the %Ndfa ranged from 7 and to 50% in shoots and 29 to 51% in grains. In Experiment I, the N_2 fixation was estimated as 6.7 kg ha^{-1} in shoots, averaged across all cultivars, and ranged from 6.42 to 17.89 kg ha^{-1} in grains. In Experiment II, the lowest amount of N_2 fixed in shoots was 2.5 kg ha^{-1} and the highest 31.3 kg ha^{-1}. The cultivar that accumulated less N from BNF in shoots was also the same that accumulated less N in grains, whereas the greatest accumulation of N derived from BNF in grains was 69.7 kg ha^{-1}. In Experiment II, the average grain yield of the inoculated cultivars was double of Experiment I and the average of the amount of N_2 fixed was 3 to 4 times higher in shoots and grains, respectively, indicating that a higher contribution of N from symbiosis occurred when the bean crop achieved its optimum yield potential. The ^{15}N natural abundance method allowed to detect phenotypic capability to acquire N from BNF among field-grown common bean cultivars.

Keywords: *Phaseolus vulgaris*; rhizobia inoculation; $\delta^{15}N$; biological N fixation.

(1884 - 1443) Pineapple mineral nutrition profile and diagnosis of nutritional status

Marco V. Gutiérrez-Soto[1]; Esteban Loría-Solano[2]
University of Costa Rica, Dept Agronomy, Fabio Baudrit Exptl. Stn.[1]; Agrocontrol, Guápiles[2]

Pineapple nutritional requirements, particularly K and N, are superior than most tropical crops, but only a small fraction is retained in the fleshy fruits. In the field, most of the uptake occurs during vegetative development, when nutrients are applied mostly to the foliage. It is important to know the content and distribution of nutrients in the whole plant to improve fertilizer use and to produce well-nourished plants

capable of sustaining higher fruit yields. Here we present the content and distribution of essential nutrients in all organs of whole vegetative and reproductive MD-2 pineapple plants grown in a greenhouse in Costa Rica (10^{o}N, 840 m elev.), under optimal nutrient and water supply. We also characterized the mineral profile of different leaf strata and leaf segments, with emphasis on the utility of the D leaf as a diagnosis organ. Our results revealed that substantial amounts of nutrients are removed by a pineapple crop especially after 4 months, and point to stems and roots, in addition to leaves, as major sinks of Ca and P, and micronutrients respectively. Large amounts of K and N were contained in succulent leaves, but substantial nutrient uptake was observed during fruit and crown development. Nutrient content of fruit peel and pulp was quite low compared to vegetative organs, and do not support the application of copious amounts of K and Ca during fruit development. The root system was extensive, fragile, with abundant root hairs, and was the main route for mineral uptake. Plants fed *via* the root were larger, heavier, greener, and produced higher yields in shorter periods than plants growing in the field. The number and quality of slips was also superior. K and N use efficiency and nutrient content and balances increased significantly. Several young, fully expanded leaves exposed to full solar radiation could be used for diagnosis purposes, and no support for the use of basal leaf segments was obtained; instead, we recommend to periodically sample and nutritionally analyze whole plants for fertilizer needs determination, and conclude with suggestions regarding the routes for mineral uptake in pineapples, the role of the root system and the stem in nutrient budgets, and the intervention of on-farm biogeochemical cycles to improve fertilizer and water use efficiency using soils covers, timely irrigation and incorporation of crop residues, and to fine-tune protocols for sampling and diagnosis of the pineapple plant nutritional status

(9990 - 616) Soil analysis and use of the calcary as an efficient public management in family agriculture in the municipality of Jeceaba, Minas Gerais

Leandro Marciano Marra[1]; Marcelo Zózimo da Silva[2]; Lindayane Cardoso Chaves Marra[3]; José Silva Soares[4]; Wilton Fernandes Monteiro da Mata[5]; Selene Cristina de Pierre Castilho[1]; Jean Sérgio Rosset[1]; Gledson Martins[6]
Universidade Estadual de Mato Grosso do Sul - Unidade de Mundo Novo[1]; IFET-MG[2]; Escola Adventista - Mundo Novo - MS[3]; Deputado Federal / Emater - MG[4]; Produtor Rural / Jeceaba - MG[5]; Graduating UEMS[6]

Jeceaba - MG has an area of 236 km^{2} located in the region of Alto Paraopeba, an average altitude of 850 m. The rural area is composed of 22 localities with 2,417 inhabitants (44.79%). The number of agricultural establishments reaches 345 that employ 756 men and 266 women. By the year 2013, a family agricultural era exercised very empirically and semi-technical support. Only 8% knew what a soil test was and 3% used limestone. Thus, as a form of support and promotion of rural development were implemented in 2013, Pro-Analysis and Pro-Calcary projects with the aim of enabling, encouraging and introducing a chemical and physical soil analysis and a correction of soil acidity. A partnership was signed with IFET-Campus Barbacena-MG for a soil analysis and created the Municipal Law of Family Agriculture that allows the subsidization of agricultural inputs to family farmers. As results, 150 soil analyzes were performed for 78 establishments. Of these, 65% had high acidity. Regarding phosphorus, 94% of the areas sampled had very low and low levels. As for potassium, sulfur, calcium and magnesium, in general, presented low levels. The organic matter content showed that 99% is not an ideal for soil conservation. As for the micronutrients copper, iron, manganese and zinc as samples presented medium to high level, exception was found at low lows. A textural analysis evidenced that 98% of the known areas of the medium or clay texture. 285 tons of dolomitic limestone were subsidized for the crop year 2013/2014, which resulted in an investment of R$ 38,990.00, which represents 0.15% of the municipal collection in the year 2013. In addition, a public management practice granted the award for the best public project developed in Minas Gerais. As well as its application as a management practice that is the project, there is not a technological innovation, but rather in its application as a management practice that is the odd project, when articulating partnerships with research centers and public power, promoting an approximation of science with the rural man and the greater contribution of resources to family agriculture.

(2888 - 1077) Soil quality under no-till: challenges and opportunities for food security in the tropics

Abhas Sinha[1]; Arunava Ghosh[1]; Tapamay Dhar[1]; Prateek Bhattacharya[1]; Kulanand Mishra[2]; Prakash Paneru[2]; Bedanand Choudhary[2]; Shurra Raj Shrestha[2]; Sarita Manandhar[2]; Neal Menzies[3]
Uttar Banga Krishi Viswavidyalaya[1]; Nepal Agricultural Research Council[2]; University of Queensland[3]

No-till (NT) is an essential component of conservation agriculture, which includes crop residue retention and crop rotation as other components. No-till and crop residue retention practices were initiated in the 1960's for soil erosion control. Besides water and resource conservation, these practices may improve soil quality over time, for example by increasing soil organic matter, which provides physical, chemical and biological functions in soil, and hence contributes to long-term food security from agricultural soils. To ensure food security in the tropical environment of the Eastern Gangetic Alluvial Plains (Bangladesh, India and Nepal), a project was initiated in 2014 on sustainable and resilient farming systems intensification. We monitored soil quality in 2016-17 period to assess the changes in soil organic carbon and soil pH in the top <15 cm depth, and partial nutrient balance in either rice-maize or rice-wheat systems grown under NT versus tillage systems in the 1000 -2500 mm annual rainfall region. The alluvial soils of the region vary in texture from sandy loam to clay loam and are mostly classified as Inceptisols and Entisols. Soil organic carbon varied from 0.35 % to 1.65 % and generally followed rainfall gradient; as the annual rainfall increased organic C concentration increased. At all sites the soil under NT had higher organic C than under conventional till. Soil pH_{H2O} varied from 5.8-7.1 across the region. At all sites, soil pH decreased under NT compared to under conventional till at some sites up to pH 0.4 units, the lower the initial soil pH the higher the decrease in pH under NT practice. Partial nutrient balance for N, P and K in rice-wheat and rice-maize systems was positive for P (>50 kg ha^{-1}) but negative for K (->100 kg ha^{-1}) under both tillage practices. Soil quality changes under NT and farming systems intensification in the tropics have provided the opportunity to increase soil organic C benefits. However, NT and intensification also presents challenges including acidification through increased product removal and as a result of increased application of urea-N fertilizer, and of imbalances in nutrients applied as fertilizer relative to crop removal resulting in soil nutrient exhaustion. Legumes in rotation should reduce N requirement but increasing acidification may be an ongoing constraint to sustainable and resilient farming systems in the tropics unless remediation measures are included in the farming practice.

(2815 - 2293) Use of effluent from a pharmaceutical industry as fertilizer for seedlings of a native tree species

Carina Aline Prado[1]; Mariana Paiva Batagini Giron[1]; Fernanda Gonçalves Mendes[1]; Marco Aurélio Kondracki de Alcântara[1]; Hélcio Izário Filho[1]
EEL-USP[1]

Sustainability involves many aspects. Among them, the utilization of nutrients present in effluents generated by antropic activities. A destination that has been studied is the application of these materials to the soil for agricultural purposes. In recent years, some environmental damage has been detected resulting from the incorrect dumping of effluents from the pharmaceutical industry. The pharmaceutical industry generates a large number of residues with high organic content. Residues resulting from the production of antibiotics are an example of such compounds, which may contain high recalcitrant and high molecular weight components. In order to reduce this kind of environmental damage, a fertilizer was developed from the chemical precipitation (pretreatment) of an effluent generated by a pharmaceutical industry. This fertilizer was tested for Schinus molle, popularly known as aroeira-salsa. This species has been used in reforestation activities and in some other agroforestry systems. The plants were grown in an Ultisol, medium-textured, with high aluminum contents, under a greenhouse experiment. The occurrence of this soil is common in the region of the Vale do Paraíba, São Paulo State, Brazil ($22^{o}47'26"S$; $45^{o}66'11"W$). The application of the fertilizer to the soil improved its characteristics in relation to the contents of C, N, P, K, Mg, Ca, base saturation, pH, Al and density. Also, nutrient absorption and plant growth benefited from this fertilizer application.
Keywords: Tropical Soil; Pharmaceutical industry effluent; Fertilizer; *Schinus molle*

(6888 - 1020) Vegetation tillering of Brachiaria ruzizienses in response to different doses of phosphorus

Ramaiany Lohanny Sousa Cremer[1]; Lucas Vinícius Albuquerque de Oliveira[1]; Pablo Rogério Ciechorski[1]; Renan Marré Biazatti[1]; Rogério Gonçalves Teixeira[1]
Federal University of Rondônia Foundation[1]

Grassland is the basis of animal feed, the choice of forage and the correct fertilization in pasture formation, are the main ways to maintain high productivity livestock. In this context, the *Brachiaria ruziziensis*, has gained great space in Brazilian livestock, because it has a characteristic to be quite palatable and well accepted by the animals. Its nutritional requirement and something limiting the productivity, especially in poor phosphorus soils. For several reasons the tillering of forages has been considered fundamental to maintain the high productivity of the plants, with this, the research identified the best dose of phosphate fertilizer that increases the greater tillering of the forage studied. There were five different dose treatments (0, 100, 200, 400 and 800 $Kg.ha^{-1}$) with five replicates each, conducted in polyethylene pots of 8 dm^{-3}, in a greenhouse and distributed in a completely randomized design. The till number was counted at 30 and 60 DAE. At 30 (thirty) and 60 (sixty) days, the fertilization efficiency was linearly increased, where the highest tillering was 800 $Kg.ha^{-1}$. The results were justified by phosphorus being a determinant in the energy production, and a helper in the initial start of the plants, limiting the growth of the plant in its absence, as demonstrated in the experiment, the increasing dose allowed an increase of up to 800% in the number of grassy tillers so greater number of leaf area and fresh mass available to the animals. It is concluded that the phosphorus is fundamental in the establishment of *Brachiaria ruziziensis* and with this, it reduces the use of phosphate minerals for animal feed without losing quality and that the absence of this hinders the management of a high production livestock.
Keywords: forage; phosphate fertilizer; productivity.

C4.2.3 - Soil quality to secure human and environmental health

(5814 - 1461) Are protected areas a source of quality of life?

Laiz Coutelle Honscha[1]; Roberto Martins Baisch[1]; Manoel Rodrigues da Silva Júnior[1]
Universidade Federal do Rio Grande, FURG, Rio Grande, CEP: 96203-900, Brasil.[1]

The interaction of water, soil and air compartments through physical, chemical and biological characteristics directly influence the quality of life of organisms. An ecosystem is healthy where all its members are in balance generates a favorable environment for life. Environmental changes through anthropic actions imply environmental contamination, being these actions coming from industrial areas, agropastoral, mining, etc. The soil is considered a geochemical deposit of chemical substances, which are capable of altering its natural composition, which can lead to damage to living beings. Exposure of populations to contaminated soil may pose a risk to human health. Environmental Protection Areas are legally envisaged by law to protect the natural environment, having the function of preserving water resources, landscape, geological stability, biodiversity, the genetic flow of fauna and flora, protecting the soil and ensuring the well-being of human populations. Based on the assumption that legally protected areas were created to maintain environmental quality and that this is indispensable for life quality, the aim of this study was to evaluate the soil conditions of Protected Areas located near urban areas using ecotoxicological assays and chemical analysis. The study was carried out with surface soil samples from seven protected areas collected in southern Brazil. For the protected area to be considered "clean" the results of the ecotoxicological tests should be within the criteria accepted for the negative control according to standardized protocols, while the concentration of the chemical elements should be below the maximum levels allowed in the Brazilian laws. Based on the criteria adopted for ecotoxicological assays and chemical analysis, only 3 of the 7 protected areas (43%) met the criteria for being considered "clean" soils. This probably reflects the influence of anthropic activities within protected areas, showing fragility in delimitation and management. The strategy used in this study should be used in other parts of the world to assess the anthropic impact in protected areas.
Keywords: soil contamination, soil quality, ecotoxicity, metals.

(9644 - 514) Assessment of Heavy Metal(loid)s Pollution Status in Agricultural Land near Industrial Complex in Korea

Hyun Uk Kim[1]; Byeong Hwan Seo[1]; Kwon Rae Kim[1]
Department of Agronomy & Medicinal Plant Resources, Gyeongnam National University of Science and Technology, Jinju 52725, Republic of Korea[1]

Some soil and water near industrial complexes are polluted due to rapid industrialization and it has drawn much attention to environmental pollution issues. Consequently, various projects and studies have been conducted to evaluate the current status of environmental pollution. As of 2014, there are 1,009 industrial complexes in South Korea and 447 of them are operated as agricultural industrial complexes. Since the agricultural land near an industrial complex has a potential to be contaminated by pollutants such as heavy metals, which can be discharged from the industrial complex, it is necessary to manage the hazardous materials of the agricultural land and conduct a safety assessment for the area. This study was conducted to evaluate the heavy metal contamination level of agricultural lands near industrial complexes located in Gyeonsangbuk-do province, Korea. Fifteen industrial complexes were selected and the concentrations of heavy

metals in soil were measured in nearby agricultural lands. Ten land lots were selected for each industrial complex: five within 500 m from the boundary line of the industrial complex and five between 500 m and 1,000 m from the boundary line of the industrial complex. Three samples were taken at regular interval from each lot by using auger and these samples were composited and mixed. The collected samples were air-dried and sieved with a 2 mm sieve. These samples were acid-digested by using aqua regia and the concentrations of As, Cd, Cu, Ni, Pb, and Zn were analyzed by ICP-OES (8300DV, Perkin Elmer, USA) and that of Hg was analyzed by a Hg analyzer (DMA80, Milestone&T CI, Ltd). The results of analysis showed that only one sample exceeded the concern level of arsenic (25 mg kg^{-1}) among the determined seven heavy metal(loid)s (i.e., As, Cd, Cu, Hg, Ni, Pb, and Zn) and the seven heavy metal(loid)s in all other samples were below the concern level. This study used the integrated pollution index (IPI), which is one of the methods for evaluating heavy metal pollution in soil. The reference concentration was the heavy metal(loid) mean content proposed by the soil measurement network of the Ministry of Environment in 2014. IPI of 15 industrial complexes ranged from 0.07 to 2.86 and the results indicated that only three of them were polluted.

(8489 - 2748) Brazilian Family Agriculture: a small guide family from farmers to researchers

Carlos Victor Dourado Batista[1]; Júlio Iglesias Guerreiro[2]; Fábio Branco da Cruz[3]; Mônica Santana Vianna[2]; Joao Paulo Machado Torres[2]
UFRJRadioisotope Laboratory Eduardo Penna Franca, Institute of Biophysics, Federal University of Rio de Janeiro (UFRJ), Brazil[1]; Radioisotope Laboratory Eduardo Penna Franca, Institute of Biophysics, Federal University of Rio de Janeiro (UFRJ), Brazil[2]; Company of Agricultural Research of the State of Rio de Janeiro (PESAGRO-RIO)[3]

Brazilian Family Agriculture has been recognized as a force economic and social. Because of this, several academic works in different areas (mainly in health and environmental sciences). Therefore, the State Center for Research in Vegetables is reactivating its experimental field, laboratory and extension actions. This region has priority for the concentration of teaching and research agencies and the target of numerous researches of a decade of 1990. However, as local micro-basins as a target of scientific and international speculation. This situation shows the violation of ethical issues that weaken the strategies of implementation of agroecological transition systems or of Good Agricultural Practices. They are strategic as effective partnerships between scientific research and family farmers for the strengthening and efficiency of activities constructive relations. This work presents the preparation of a guide for researchers, through the experience and perspectives of the producers. This guide intends to support professionals, especially research, with an interest in developing studies in a participatory way in these communities. Purpose of this extension activity is to support the training of young professionals on the problems of family farming and their complexities. Results are intended to guide the preparation of research proposals in an effective partnership with rural communities. In this first stage we are making visits to the rural property to follow the routine of the producers in their activities in the fields, such as commercial transactions, such as meetings of associations of farmers. In the sequence, we have interviewed extension workers, health agents and doctors. Surveys of the scientific and technical publications related to the studies developed in the region. It is observed that the theme most discussed by the researchers is related to the use of pesticides and health. Tomatoes, zucchini, coriander, parsley and chives are the most grown by farmers. Biodiversity is longer because the investment focuses on foods that are more profitable. It is evident the absence of an appropriated support for property management and pesticide use. However, farmers know about the poor management of the soil and about the risk of their health and pockets. This information represents a challenge to achieve a sustainable environment and soil health.

(7084 - 2659) Cadmium, copper and chromium, pseudo-total concentration and available to soil in long-term experiment

Iolanda Maria Soares Reis[1]; Suelen Cristina Nunes Alves[2]; Wanderley José de Melo[2]; Eliandra de Freitas Sia[1]; Ianna Bizerra Barros[3]
Universidade Federal do Oeste do Pará[1]; Universidade Estadual Paulista Júlio de Mesquita Filho/Faculdade de Ciências Agrarias e Veterinária[2]; Universidade Federal de Viçosa[3]

Knowing the distribution of heavy metals in the soil as its pseudototal and available contents is of paramount importance for the evaluation of environmental impacts, as well as knowing the contents associated with soil particles. The objective of this work was to evaluate the pseudototal and available soil content of the cadmium, copper and chromium metals in eutrophic Red Latosol fertilized with sewage sludge for fifteen consecutive years at three depths. The experiment was installed in field conditions, in randomized blocks, in a Red Latosol eutroferric submitted to four treatments with different dosages of sewage sludge (dry base) in five blocks. Soil samples were collected from the superficial layer, 0.00-0.05; 0.05-0.10 and 0.10-0.20 m, and the pseudo-determinations were made and available for determination of the cadmium, copper and chromium contents. The analyzed cadmium, copper and chromium contents did not present variations in the analyzed depths. The concentration of cadmium was higher in the treatment with mineral fertilization when compared to the treatment fertilized with different doses of sewage sludge, this can be attributed to the chemical constitution of the minerals. On the other hand, copper and chromium metals presented higher levels in the treatments with 10 and 20 Mg ha, at depths 0 to 5 and 10 to 20 m, it is important to note that the sewage sludge used in the 15th year experiment did not have high concentrations of these metals , this shows that the contents presented may be associated with the quantity of metals remaining from another year, that is, residual quantity.

Keywords: Availability, determination, heavy metals
Financial support: CAPES

(3623 - 2712) Can the Quick Diagnosis of Soil Structure (DRES) method describes the soil quality of Brazilian pastures?

Thamires Rodrigues de Sá Valle[1]; Renato de Aragão Ribeiro Rodrigues[2]; Fabiano de Carvalho Balieiro[2]; Ademir Fontana[2]; Marcella Leal Santos[1]; Guilherme Kangussú Donagemma[2]
Universidade Federal Fluminense[1]; Embrapa Solos[2]

Soil structure is related to many soil ecosystem services and has been used as manageable property in evaluating soil quality in agricultural areas. From this perspective, Quick Diagnosis of Soil Structure (DRES) shows up as an efficient soil structure assessment in field. It was first developed to no-tillage crop systems but it may be well fit to others productive systems such as pasturelands. Brazilian cattle herd is one of the largest in the world, occupying around 159 million hectares. However, about 50% of this area is estimated being under some degradation level. Hence, strategies to pasture recovery demand previous diagnosis to stablish appropriated rehabilitation technics and pasture management. This work intends to distinguish pastures degradation levels by visual evaluation of soil structure (DRES), soil surface cover (forage and weed vegetation characteristics) and the following soil attributes: mean weight diameter, soil C concentration and stocks. The experimental area are rural farms, in Valença Municipality, Rio de Janeiro State, Brazil. The region is known as “Mar de Morros” due

its rugged relief, and the local soil is classified as Cambisols. A previous visual classification of degradation levels reaches four treatments defined as N1-light, N2-moderate, N3-severe, and N4-very severe degradation. Three areas of each level were selected and soil samples were collected in 0.0-0.2 meters depth. The Spearman correlation was applied ($p < 10\%$). Previous results confirmed pastures degradation levels since worse soil structure described by lower DRES grades (N3= 2.4; N4= 2.7) were associated to lower soil C concentration and C stocks, smaller aggregates and higher occurrence of exposed soil. The opposite occurs to N1 and N2 (N1= N2= 3.9). Results show positive correlations between the DRES index and soil C stocks (r= 53.1%, p= 0.079) and concentration (r= 40.6%, p= 0.193), mean weight diameter (r= 56.6%, p= 0.0059) and soil cover percentage during rainy season (r= 79.0%, p= 0.004). Negative correlation between DRES index to exposed soil percentage during rainy season (r= -79.0%, p= 0.004) were estimated. Thus, results reveal the DRES as a feasible assessment method to soil quality in pasture, able to distinguish degradation levels. Well manageable pastures got higher DRES grades and better soil quality, due to higher biomass production (above and belowground) and soil protection.

Keywords: Soil structure, DRES, pastures degradation.

(1295 - 1087) Changes of soil chemical quality index in according to time in paddy soils by long-term application of soil amendments

Myungsook Kim[1]; Seokcheol Kim[1]; Seongjin Park[1]; Changhoon Lee[1]
NAS[1]

The changes of soil chemical quality index in paddy soils applied of soil amendments were assessed from data of long-term experiment plots which were operated from 1969 to 2016 by the National Academy of Agricultural Science, Suwon, Korea. The treatments were inorganic fertilization (NPK), inorganic fertilizer plus soil amendments(rice straw compost, NPK+C; silicate fertilizer, NPK+S; lime, NPK+L; mixing rice straw compost and silicate fertilizer, NPK+CS). The quality index of soil for chemical properties was analysed by method suggested by Yoon et al.(2004), and divided into by 4 periods(Period Ⅰ: 1969 ~ 1978, Period Ⅱ: 1979 ~ 1985, Period Ⅲ: 1986 ~ 2001, Period Ⅳ: 2002 ~ 2016). The order of magnitude of soil chemical quality index was NPK+CS > NPK+S > NPK+L > NPK+C > NPK. The quality index of soil chemical properties of NPK, NPK+C and NPK+S treatments ranged from 70 to 74 in period , from 64 to 71 in period Ⅱ, and to 75 to 82 in period Ⅲ and Ⅳ. Especially, the decrease of the chemical quality index value of NPK, NPK+C and NPK+S treatments in Period Ⅱ was attributed to the decrease of the soil pH value below the optimum range of rice growth due to irrigation water. NPK+L treatment increased from 71 ~ 72 to 76 during the period Ⅰ, Ⅱ and Ⅲ due to the increase of pH by the lime application. The NPK + CS treatment increased to the highest value from 82 to 82 in period, but tended to decrease at period Ⅲ and Ⅳ. It showed that this was caused by the accumulation of silicate fertilizer, resulting in a decrease of the chemical quality index value of the soil. When a constant amount of soil amendments was continuously applied for 48 years, the soil chemical quality indexes were improved. But after that period, the soil chemical quality index was decreased because of excess accumulation of soil amendments. In order to determine the quality of paddy soils that meet the agricultural environment conditions in Korea, the soil quality including physical and microbial properties as well as chemical characteristics should be evaluated at a later stage.

Keywords: Long-term application, paddy soil, soil chemical quality index, rice straw compost, silicate fertilizer, lime

(7234 - 1796) Characterization and valuation of soils with potential investigative and productive in the Bogota's Savannah, Colombia.

Gabriela Sepúlveda Prieto[1]; Melissa Lis-Gutiérrez[1]
Universidad de Ciencias Aplicadas y Ambientales[1]

Latin America is considered one of the most diverse regions in relation to natural resources. This area offers 31% of the world's fresh water, and has approximately 23% of land considered high productive potential. Rapid population growth has increased the demand for ecosystem services offered by soil. This is causing greater anthropogenic intervention, reflected mainly in the conversion of natural ecosystems to agricultural soils, which affects their quality. In recent decades, productive activities have been directed towards sustainability, ratifying the need to guarantee food security at a global level. In this context, agriculture faces the challenge of producing food and raw materials in a sustainable manner, which favors the reduction of pollutant emissions, in order to maintain soil quality and face the threats posed by climate variability and change. In Colombia, a large percentage of agricultural activity takes place in the central zone of the country, where the department of Cundinamarca occupies the seventh place, producing vegetables, fruits, potatoes, flowers, among others. These crops, in many cases, are produced intensively, without considering the impact they can have on the productive capacity of the soil. Hence the importance of the participation of future professionals in the discipline in relation to sustainable production. The purpose of this work was to characterize and evaluate the current state of the soil at free exposure (1218 m^2), in the investigative and productive unit El Remanso, which is located at coordinates 4° 47'58.93''N and 74°2'48''W, in the savannah of Bogotá, Cundinamarca, Colombia. For this, we use quality indicators, following the standard USDA methodologies, such as apparent density, real density, porosity, texture, humidity and pH. The results obtained, led to establish that the evaluated soils have influence of volcanic ash, which improves some properties such as moisture retention, accumulation of organic matter, among others. Likewise, they have textures C, SiC, CL SCL, SiCL and SiL, pH between slightly acid and moderately alkaline (6.5-8.2), average apparent density of 0.73 g/cm^3. The surface horizon allowed identifying two activities that can influence the loss of soil quality. Otherwise, the loss of structure is associated with conventional tillage practices, a condition that makes compaction probable. On the other hand, the loss of nutrients, structure and humidity is related to intensive production.

(3712 - 1503) Chemical characterization of soils adjacent to a wastedump of the Stella Maris polymetallic mine Paso de Indios, Chubut. Argentina.

RacK, M.G.[1]; Valenzuela, M. F[2]; Nillni, A. M.[3]; Ferro, L. F.[4]
Universidad Nacional de la Patagonia San Juan Bosco (UNPSJB), Ruta Nº 1 Km 4, S/N, Comodoro Rivadavia, (9005), Argentina (monirack@yahoo.com.ar)-Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET)[1]; Universidad Nacional de la Patagonia San Juan Bosco (UNPSJB), Ruta Nº 1 Km 4, S/N, Comodoro Rivadavia, (9005), Argentina -Universidad Nacional de la Patagonia San Juan Bosco (UNPSJB). Ruta Nacional N° 259 km 16,41(9200), Esquel, Argentina[2]; Facultad de Ciencias Naturales. Universidad Nacional de la Patagonia San Juan Bosco (UNPSJB), Ruta Nº 1 Km 4, S/N, Comodoro Rivadavia, (9005), Argentina[3]; Universidad Nacional de la Patagonia San Juan Bosco (UNPSJB). Ruta Nacional N° 259 km 16,41(9200), Esquel, Argentina[4]

The main environmental problem associated with the exploitation of metallic deposits is related to the presence of polymetallic waste dumps. If they are not managed properly, once the exploitation is finished, they become environmental liabilities. Depending on the mineralogy of the exploted deposits and the climate of the region, they can produce acid drainage and as a result, they will affect the properties of the surrounding soils. The objective of this work is to characterize the chemical properties of the soils adjacent to a Stella Maris polymetallic

mine, located in an arid climate, such as the Paso de Indios area, Chubut. The mine stopped working approximately 30 years ago and consists of a group of vein-shaped structures hosted by a small intrusive and volcaniclastic rocks around it. The mineralogy of the dump consists of sphalerite, galena, pyrite, chalcopyrite and marcasite, with barite, calcite and quartz gangue. Its pH is moderately alkaline and the contents of Cu, Zn, As, and Pb exceed the guideline levels of soil quality established by National Law of Hazardous Waste N° 24,051 (Regulatory Decree N° 831/93 - Argentina). Two sites of interest were considered for the soils study: one of control (PI1), which was considered as an adjacent area not impacted by the exploitation, and another located at the base of the dumps (PI2), which has been impacted for the mentioned activity. The morphological properties of the soils were described and a sampling was made in each horizon to carry out chemical analysis and determination of Cu, Pb, As and Zn contents. Both studied soils, which have an eolic origen, were transported. They present a sequence of A-C horizons. The electrical conductivity, the content of organic matter, the cation exchange capacity and the bases contents (Ca, Mg, Na and K) are similar in both profiles. However, the PI2 profile shows an increase in pH in depth, being similar to the pH of the dump. On the other hand, there are higher Pb contents in the surface horizon than in the PI1 profile. Although the Pb exceeds the guideline levels of soil quality, the enrichment in this horizon is nine times less than that of the waste dump. The presence of calcite in the dump and the arid climate would not facilitate the mobilization of heavy metals and the generation of acid mine drainage in the deeper horizons of the PI2 profile. The Pb content of the surface horizon could be product of theeolic dispersion, which requires a more detailed study.

(5267 - 2047) Comet assay in *Eisenia andrei* coelomocytes as a tool for assessing the genotoxicity of urban soils

Ronan Adler Tavella[1]; Laiz Coutelle Honscha[1]; Caroline Lopes Feijo Fernandes[1]; Flávio Manoel Rodrigues Da Silva Júnior[1]

Universidade Federal do Rio Grande[1]

Urban soils quality is an indispensable condition for maintaining of well-being and life quality. On the other hand, studies have shown an increasing number of contaminated sites in urban clusters. This condition is aggravated when there are industrial zones adjacent to urban areas, exposing populations to the two types of contamination. Rio Grande is a city in the extreme south of Brazil with more than 200,000 inhabitants and located in the estuary of Lagoa dos Patos. It is a city with intense urban flow, allied to industrial complex and port activities. Lethal toxicity studies conducted in the study area in soil organisms have shown little sensitivity to detect this toxicity, with biomarkers being a promising alternative for detecting toxicity in an early manner. Thus, this study aimed to evaluate the use of the comet assay in *Eisenia andrei* coelomocytes as a sensitive tool for detecting genotoxins in soil samples from urban areas, using soil samples collected in environmental protection areas as a control. Soil samples from two sites were collected: one influenced mainly by the oil industry and the other influenced by the oil industry and a complex of fertilizer industries. As control, soil samples from two environmental protection areas of the same city were used. For chemical monitoring of these soils were measured concentrations of arsenic, cadmium, copper, lead and zinc. The exposure (14 days) of *Eisenia andrei* worms to the soil samples was performed according to ISO 11268-1: 2012 and subsequently, extraction of the worms' cells (coelomycetes) was performed using 10% alcohol solution, followed by centrifugation and addition of buffer. Aliquots of this solution were used to perform the comet assay on the coelomocytes and 100 nucleoids were counted per animal and ten animals per site. The results obtained showed a significant increase in the DNA damage of the cells of the organisms exposed to urban soils when compared to control soils. Urban soils presented a higher concentration of all analyzed elements compared to protected area soils, except for lead. Thus, it can be concluded that the presence of industrial activities in urban soil could compromise soil quality, causing the deposit of the soil genotoxins. Among these harmful genotoxins for soil organisms are arsenic and metals such as cadmium, copper and zinc.

(3150 - 1993) Competitive adsorption of Pb(II), Cu(II), and Zn(II) ions onto hydroxyapatite-biochar nanocomposite in aqueous solutions

Yu-Ying Wang[1]; Yu-Xue Liu[1]; Hao-Hao Lu[1]; Li-Li He[1]; Rui-Qin Yang[2]; Sheng-Mao Yang*[3]

Institute of Environment, Resource, Soil, and Fertilizer, Zhejiang Academy of Agricultural Sciences, Hangzhou, 310021, P. R. China[1]; Zhejiang Provincial Collaborative Innovation Center of Agricultural Biological Resources Biochemical Manufacturing, Zhejiang University of Science and Technology, Hangzhou, 310023, P. R. China[2]; Institute of Environment, Resource, Soil, and Fertilizer, Zhejiang Academy of Agricultural Sciences, Hangzhou, 310021, P. R. China 2 Engineering Research Center of Biochar of Zhejiang Province, Hangzhou, 310021, P. R. China[3]

A hydroxyapatite-biochar nanocomposite (HAP-BC) was successfully fabricated and its physicochemical properties characterized. The analyses showed that HAP nanoparticles were successfully loaded on biochar surface. The adsorption of Pb(II), Cu(II), and Zn(II) by HAP-BC was systematically studied in single and ternary metal systems. The results demonstrated that pH affects the adsorption of heavy metals onto HAP-BC. Regarding the adsorption kinetics, the pseudo-second-order model showed the best fit for all three heavy metal ions on HAP-BC. In both single and ternary metal ion systems, the adsorption isotherm of Pb(II) by HAP-BC followed Langmuir model, while those of Cu(II) and Zn(II) fitted well with Freundlich model. The maximum adsorption capacity for each of tested metals by HAP-BC was higher than that of pristine rice straw biochar (especially for Pb(II)), and also exceeded those of other reported adsorbents. Therefore, HAP-BC can be explored as a new material for future application in heavy metal removal.

(5936 - 2883) Effect of commercial insecticides used for the control of the western corn rootworm (*Diabrotica virgifera* ssp. *virgifera*) on the nematode community

Ludovit Cagan[1]; Andrea Cerevkova[2]; Dana Miklisova[2]

Slovak Agricultural University in Nitra, Slovakia[1]; Institute of Parasitology, Slovak Academy of Science, Košice[2]

Soil health and quality can be assessed through the investigation of physical and chemical soil properties and/or by studying the communities of living soil organisms, e.g., bacteria, springtails, or nematodes. The present study assessed the effect of commercial insecticides used for the control of the western corn rootworm (*Diabrotica virgifera* ssp. *virgifera*) on the nematode community. Three different insecticide variants were used in the experiment: a granular application of tefluthrin, seed treatment of clothianidin and granular application of clothianidin. This study concludes that soil nematode communities are very sensitive to climatic conditions or any environmental change. Within the same environmental conditions, it was found that nematode communities were also affected by the

chemical control of insects with clothianidin or tefluthrin. For many parameters of nematode communities, the effects of year and sampling date were more pronounced than the effects of insecticide application.

(9768 - 573) Effect of different immobilizing agents on soil quality and metal uptake by plant in heavy metal contaminated soilEffect of different immobilizing agents on soil quality and metal uptake by plant in heavy metal contaminated soil

Byoung Hwan Seo[1]; Hyun Uk Kim[1]; Kwon Rae Kim[1]
Department of Agronomy & Medicinal Plant Resources, Gyeongnam National University of Science and Technology, Jinju 52725, Republic of Korea[1]

This study examined the performance of different immobilizing agents on the quality of soil affected by heavy metals through determination of selected soil biological and physiochemical parameters together with metals availability to Chinese cabbage over long period of pot incubation. The immobilizing agents used in this experiment included: lime (L), gypsum (G), fly ash (F) and livestock manure based compost (C). All immobilizing agents were applied to the soil on the dry weight basis of soil at 3% for all agents while lime was treated at 1%. These immobilizing agents were either applied in isolation and complex mixtures as lime+ gypsum (LG), lime+ compost (LC) and gypsum+ fly ash (GF). As expected, all the immobilizing agents tested increased soil characteristics (i.e., organic matter content, cation exchange capacity, total nitrogen content, available P, soil porosity and stability of soil aggregates). The greatest increase on these soil quality parameters was obtained with compost treatment, followed by mixed treatment of LC. The organic immobilizing agent, compost was good in its capacity to supply essential macronutrients and organic matter content. With the exception of F, microbial biomass carbon and dehydrogenase enzyme activity (DHA) was also enhanced by all immobilizing agents in particular with LC treatment. All immobilizing agents used decreased phytoavailability of As, Cd, Cu, Pb and Zn as determined by the corresponding metal concentration in Chinese cabbage. Therefore, these immobilizing agents can be used successfully in the remediation of metal-contaminated mine soil. Over all, the result obtained in this study suggests that among immobilizing agents, compost was effective in both the *in situ* immobilization of metals, and improving soil properties leading to a large increase in plant biomass.

(6697 - 276) Genotypic variation of rice plants exposed to cadmium in tropical contaminated soil

Thiago Assis Rodrigues Nogueira[1]; Takashi Muraoka[2]; Zhenli He[3]; Jamille Santos da Silva[2]; Laís Karina Silveira[2]; Milena Emi Nishikawa[2]
São Paulo State University, Avenida Brasil 56, Ilha Solteira, 15385-000, Brazil[1]; University of São Paulo, Piracicaba, SP, Brazil[2]; Indian River Research and Education Center, Institute of Food and Agricultural Sciences, University of Florida, Fort Pierce, FL, USA[3]

The dry matter yield, Cd concentration and the daily intake of Cd from rice cultivars in a tropical contaminated soil was evaluated in order to identify Cd-tolerant genotypes that exhibit a lower potential for Cd accumulation in the grain. A greenhouse experiment was carried out in Piracicaba, Brazil. Three rice cultivars with characteristics of low (Cateto seda), medium (BRSMG Talento) and high (BRSMG Caravera) capacity of Cd uptake were used and cultivated in pots filled with 4 kg of Oxisol samples. Pots were arranged in a completely randomized block in a factorial scheme (6 x 3) with four replications. The cultivars were exposed to six levels of Cd (0.0, 0.65, 1.3, 3.9, 6.5, and 11.7 mg kg^{-1}, added as $CdCl_2.H_2O$), based on the guideline established by CETESB. Daily Cd intake from rice was calculated by the Cd content in rice grains (for the level of 1.3 mg Cd dm^{-3}) multiplied by the average of daily rice consumption in Brazil (160 g, fresh weight). Based on the WHO/FAO provisional tolerable weekly intake (PTWI) of 8 µg kg^{-1} of body weight, the daily intake of Cd considering the average human body weight (70 kg) of the Brazilian population was calculated. Dry matter yield of the shoot and grain of rice plants decreased with increasing Cd supply levels linearly. Cd concentrations in shoot and grain significantly increased with external Cd loading rate. Grain Cd concentrations ranging from 0.01 to 1.61 mg kg^{-1} in the cv. Cateto seda, from 0.01 to 1.70 mg kg^{-1} in the cv. BRSMG Talento, and from 0.02 to 4.45 mg kg^{-1} in the cv. RSMG Caravera. Grain Cd concentration for the cv. Cateto seda (0.35 mg Cd kg^{-1}) and the cv. BRSMG Talento (0.63 mg Cd kg^{-1}) did not exceed the critical levels of Cd (1.0 mg kg^{-1}) for human consumption (according to Brazilian legislation) when Cd was applied up to 1.3 mg kg^{-1} (alert value for Cd in Brazilian soils). However, grain Cd concentration for cv. BRSMG Talento was not in the acceptable range for human consumption (0.4 mg kg^{-1}) according to the Codex Alimentarius Commission of WHO. Daily intakes of Cd in rice cultivars were higher than the PTWI when the daily rice consumption was 160 g. The results suggest that human Cd intake can be reduced by selecting low-Cd rice cultivars. There is clear necessity for continuous monitoring so as to ensure that the food supply and diet of the Brazilian population is safe.

(5083 - 521) Heavy metal sorption indexes in urban soils

Francisco Bautista[1]; Elsy Campuzano[1]; Carmen Delgado[1]; Avto Gogichaichvili[1]
Universidad Nacional Autónoma de México[1]

The growth of populations in urban areas increases anthropic activities derived from industry, vehicular traffic and the generation of solid waste that releases into the environment large amounts of particulates containing heavy metals that when breathed or inhaled are of high risk for human health. Particulate materials are deposited on urban surfaces such as plants, streets and soils, thus contributing to the pollution of urban soils. Pollution in urban areas is increasing and has become a study of interest, however, the capacity of the soil to incorporate heavy metals has been little studied. The aim of this study was the evaluation and development of three heavy metal sorption indices and their mathematical validation using decision trees for classification purposes. The study started from the analysis of the Lehmann index that considers the pH and the predominant structure (type of aggregate). The investigation was carried out in the urban area of the city of Morelia, Michoacán, Mexico where a systematic sampling of 100 surface soil samples was carried out; the content of organic matter, pH, cation exchange capacity, percentage of clays, structure, stoniness and bulk density were determined. The Lehmann index was evaluated and two new indices were developed: the modified Lehmann index and the Bautista-Campuzano index. The mathematical validation of the three indexes was carried out by the elaboration of decision trees for classification with the WEKA software. In the Lehmann index the percentage of clays, structure and stoniness was mainly considered; in the modified Lehmann index the capacity of cation exchange, organic matter, stoniness and pH was used; and in the Bautista-Campuzano index, pH, organic matter, clays, stoniness and bulk density were considered of greater importance. The three indices showed congruence

between the soil properties and the heavy metal sorption classes with a Kappa coefficient> 0.7. However, the Bautista-Campuzano index showed greater theoretical congruence according to the decision tree for classification, which is why it is proposed to use this index in urban land management plans. This study reveals the importance of the mathematical and theoretical evaluation of the indices by means of decision trees for classification. The city center of Morelia, was the one that presented the low capacity class of adsorption of heavy metals, so it is considered urgent to make decisions and take actions to protect the population

(8069 - 1647) Heavy metals in soils impacted by the alluvial gold mining in the Peruvian Amazon

Velásquez Manuel[1]; Guerrero B. Juan[2]; Gamarra Alfredo[2]; Bazán Rubén[2]; Nazario Julio[2]; Tello Lily[2]

Instituto de Investigaciones de la Amazonía Peruana (IIAP)[1]; Universidad Nacional Agraria – La Molina (UNALM)[2]

Nowadays the Peruvian Amazon is being impacted by the alluvial gold mining which is the most important source of mercury pollution worldwide. Its main process consists in slash and burns trees, sediment extraction, goldy gravel pick up, amalgamation with mercury and gold recovery. According to Asnner (2016) every year 6,000 ha are deforested. Fish and hair of children sampled showed up to 1.5 and 2.1 ppm of mercury, were maximum limited established by USEPA are 0.3 ppm and 1 ppm respectively. Furthermore, approximately 3,000 t of mercury were thrown to the Amazonian rivers since 1980 up to 2000 year. A healthy soil is essential to warrant health for humans and for the environment so the main objective was to evaluate the degree of heavy metals pollution in soils to measure and value its quality and prevent environmental and human risk. Through multivariate and geostatistical analysis a research was carried out at an alluvial gold mining concession in the Peruvian region, Madre de Dios. In 13 ha it was determinate three types of areas: recently impacted, impacted (6 to7 years ago) and non-impacted; 93 topsoil samples (0-20 cm depth) were taken in order to characterize it and determinate heavy metal content. According to Peruvian and Canadian environmental quality standards, there was no pollution detected except for Cd. As, Ba, Pb, Cu, Cr, Ni, V and Zn mean concentration was 1.90, 29.80, 4.60, 12.68, 7.90, 7.93, 12.67, and 26.65 mg kg^{-1} DM respectively. Cadmium mean concentration in impacted areas was 2.22 mg kg^{-1} DM in contrast to environmental standards which maximum limit is 1.40 mg kg^{-1} and in non-impacted areas is 6.6 mg kg^{-1} DM; so its origin might be geochemical. There was no pollution caused by mercury in non-impacted areas and impacted areas; it was not detected because intense volatilization and leaching caused mainly by pluvial precipitation. According to multiple correlations, 82% of the variability of heavy metal was explained by soil pH (4.24 to 5.19), cation exchange capacity (7.82 to 19.43 cmol(+)kg^{-1}), clay particle (1.44 to 21.44%) and organic soil matter (0.03 to 0.24%). In spite there was no pollution registered, contaminated sites evaluation is important to warrant any ecological restoration management. According to Minamata convention on mercury, every country needs to assess its contaminated sites in order to prevent environmental and human risk, so this research provides a guideline to evaluate contaminated sites in the Amazonia.

(4112 - 761) Legal and ilegal deforestation actions in Ceará state in 2015 and 2016

Ana Leônia de Araújo Girão[1]; Rodrigo de Oliveira Girão[1]

SEMACE[1]

Deforestation is one of the actions related to economic development of a region, besides the environment impact of vegetation supress afects the soil functions, mainly in regions with dualistic climatic conditions, as Ceará state. The state environment agency (SEMACE) is responsible for licensing and supervising the deforestation actions performed in Ceará. Aiming to analyze the deforestation actions licensed, comparatively with the supervised areas related to deforestation, we observed the deforestation requisitions filed in SEMACE and the fines related to flora infractions in the years 2015 and 2016. It was observed also the soil classes in the areas deforestated and its environment fragility. In 2015 were requested 268 licences to deforestation, representing 9.500 ha. It was identified 35 fines representing 195 ha of irregular areas related to infractions against flora. In 2016 were requested 172 licences to deforestation, representing 3.000 ha. It was identified 23 fines representing 61 ha of irregular areas related to infractions against flora. Analyzing the spacial distribution of deforestated areas we identified that they are concentrated in the regions of Baturité, Sertão Central, Sobral-Ibiapaba, Litoral Oeste e Região Metropolitana de Fortaleza – RMF, confirming the relation with economic activity whereas these areas have high urban densities and agricultural production, partially with irrigation. The soil classes from these regions are mainly the Argissolos vermelho-amarelos that are characterized as deep soils with low obstruction due to a horizon with clay accumulation, and can be eutrophic or distrophic. Due to deforestation, the soil from these regions may be impacted from erosive processes, specially if they occur in sloping areas, reduction of natural fertility, surface sealing, moreover, other general impacts as biodiversity reduction. Comparatively, in a study promoted by the Environment Minister disclosed in 2011 informs that Ceará had 48% of the state area deforestated. According to the Forest inventory of Ceará, disclosed in 2016, the state has around 43% of areas without forest (including urban areas, rural and water bodies). The area identified in the present study represents 0,08% of the deforestated area of the state. We can conclude that the situation of deforestation in the state is threatening and actions of monitoring and supervising must be enlarged to assure the real situation of deforestation in the Ceará state.

(2578 - 2946) Mercury bioextraction using earthworm (E*isenia foetida)* in degraded soils by mining in the choco department (Colombia)

JUAN CARLOS MONTOYA SALAZAR[1]; John Fredy Betancur[2]; Tatiana Mosquera–Córdoba[3]

Caldas University[1]; Manizales University[2]; independent[3]

Among the less desirable effects of mining is the contamination of soils and subsoils by Mercury, the goal os studies being the search for different strategies and methods that could help to mitigate this problem. This investigation evaluated the bioremediation process through vermicomposting in a soil contaminated with mercury (Hg), from open-mining in the Union Panamericana municipality (Chocó-Colombia). Field work was carried out exsitu on a pilot scale, with a design of complete blocks at random with three repetitions. Treatments were: T1: Contaminated Soil with mercury (SC-Hg) + earthworm (Eisenia Foetida), T2 (50% SC-Hg-50% Compost + earthworm), T3 (Contaminated Compost with mercury + earthworm) and T4 (Compost + earthworm) established as a control. The soil samples were collected at 0-20cm depth, obtaining 15 subsamples. There were determined in all treatments: Hg, pH, organic carbon, CEC (Cation Exchange Capacity), Texture, Bulk Density and Soil Moisture. The population and size of the earthworms were also evaluated. The initial values of the parameters in the soil were: organic carbon of 1.63%, pH of 5.58, CEC 10.67 cmol(+)/kg, and 1980 ppm of Hg. The process showed mercury extraction by the earthworm, and highly significant differences in Hg contents were observed among treatments with respect to the initial values. T3

had the highest removal rate (65%), followed by T2 (43%) and T1 (28%). The values of pH, organic carbon, and CEC showed significant differences between treatments. The final population and the size of the earthworms were only affected in the T1 treatment, where they increased by 20% and 5% respectively. The other treatments had an increase in the population and size up to 50% more. The results show that the combined use of earthworms and compost is an efficient alternative for bioremediation of contaminated soils.

(5841 - 2038) Phyto-microbe remediation of heavy metal and organic pollutant co-contaminated farmland soils

Xiaoe Yang[1]; Zhenli He[2]
Zhejiang University[1]; University Of Florida[2]

Soil pollution has become a world-wide environmental issue for food safety and human health. In most cases soil co-contaminated with both heavy metals and organic pollutants like pesticides and persistent organic substances. How to remediate heavy metal and organic pollutant co-contaminated soils has become a hot research spot in recent years. This paper provided a brief review regarding the progress of phyto-microbe remediation of co-contaminated soils in the last decade. Systematic studies on the processes and effectiveness of phyto-microbe remediation of soils co-contaminated by cadmium (Cd), combined with DDT, PAHs, or nitrate in vegetable-producing farmlands. The results from our research showed that planting Cd hyperaccumulator *Sedum alfredii* with application of DDT degrading special microbe (DDT-1) for one year, soil Cd was removed by 26%, and DDT was degraded by 28% under subtropical climate conditions in Southeast China. For Cd-PAHS co-contaminated soils in Northeast China, planting Cd high accumulator combined with application PAHs degrading microbe (P-1) and metal extraction promoters for one year, soil Cd was reduced by 11%, and PAHs content decreased by 26%. The results showed that phytoremediation integrated with special microbes is effective for remediating complex contaminated soils. The mechanisms of phyto-microbe co-remediation for complex polluted soils are discussed.

(8558 - 1391) Potential of urban agriculture in Moscow and its effect on soil

Anna Buyvolova[1]; Alexandre Rappoport[2]; Tatiana Prokofieva[2]; Anna Rakhleeva[2]; Lyudmila Lysak[2]; Ekaterina Morachevskaya[2]; Marina Rozanova[2]; Alexey Kiriushin[2]
Lomonosov Moscow State University, the World Bank[1]; Lomonosov Moscow State University[2]

Urban farming has a positive effect on urban environment. Currently, over 800 million people around the world are engaged in urban agriculture. However in Russia neither urban farming nor roof gardening are common. Researchers have just started studying the potential of the development of urban farming in Russian cities. The present study aims to help fill the existing knowledge gap by analyzing how urban farming affects soil properties in Moscow and providing an estimate of the rooftop gardening potential in Moscow. Unfortunately, no research on soil in the context of urban agriculture is presently conducted. In this study, soils from three plots in Moscow gardens used for farming and gardening during different periods of time are analyzed. The authors conclude that urban farming has the most positive effect on urban soils: humus reach topsoil (Corg 2,2%), high biological activity (both micro- and macrofauna). The level of heavy metals exceeds Russian standards on two of the plots with a high level of total Pb (up to 192 mg/g) and Zn (up to 68.7 mg/g). Because urban farming has a positive impact on urban soil properties the potential for urban agriculture in Moscow is estimated as high, however the risk of food and soil pollution is also high. This should be taken into account when growing food in the city. An analysis of the production capacity of roof gardens reveals that 4000 ha are available for roof gardening. The potential of growing vegetables on rooftops is estimated as high: up to 30% of tomatoes consumed by Muscovites can be grown on the roofs using special technologies. However, before green roof technology can be applied to urban farming on a larger scale, necessary management practices have to be developed. This will ensure that the citizens will benefit from green roofs: rainwater will be disposed in a more cost-effective manner, the service life of roofs will increase and the thermal insulation of the upper floors will improve. The research provides evidence that urban farming can be developed in Moscow, and that it has significant environmental benefits for the city.

(4368 - 1189) Response of soil chemical and microbiological attributes to different ages of riparian forest restoration in Paraná River

Gabriela S. Machineski[1]; Andrea S. Scaramal[2]; Amanda C. Gil[2]; Karina L. Alves[2]; Gabriel E. Freitas[2]; Pablo H. N. Severino[2]; Breynner G. P. Bertagnoli[2]; Arnaldo Colozzi Filho[2]
State University of Londrina, Rod. Celso Garcia Cid, km 380, Zip code 86.057-970, Brazil[1]; Agronomic Institute of Paraná, Rod. Celso Garcia Cid, km 375, Zip code 86047-902, Brazil.[2]

The riparian forest plays an important role in soil and water protection and it is of utmost importance to maintaining the ecological balance. The objective of this study was to evaluate the effect of different ages of riparian forest restoration in soil chemical attributes and microbial biomass and activity. We selected six areas around the Paraná River: 1. an undisturbed riparian forest; 2. a restored riparian forest of 30 years of age; 3. a restored riparian forest of 19 years of age; 4. a restored riparian forest of 3 years of age; 5. an initial riparian forest restoration and 6. an agricultural crop area. At each area, soil samples were collected in five points, one central point and four points directed at north, south, east and west. In each point, five subsamples were collected from 0-0.1 m topsoil layer to compose one sample. Soil chemical attributes determined were: carbon (C), phosphorus (P), potassium (K^+), calcium (Ca_2^+), magnesium (Mg_2^+), aluminum (Al_3^+), pH and organic matter. Microbial biomass was estimated by microbial carbon biomass and the enzymes: acid and alkaline phosphatase, arylsulfatase and β-glucosidase were measured to estimate microbial activity. The P content was higher in agricultural crop area, which was expected due to annual fertilizations. However, that was no pattern to other chemical attributes. Microbial carbon biomass was higher in the undisturbed riparian forest and in restored riparian forest of 3 years of age and acid and alkaline phosphatase and arylsulfatase were greater in undisturbed and restored areas than agricultural crop area. Agricultural crop area and initial riparian forest restoration presented higher β-glucosidase activity. In several chemical and microbiological attributes, only the samples of restored riparian forest of 30 and 19 years of age were similar to undisturbed riparian forest, which shows that restoration of riparian forest can be a slow process and lead to ecological restoration.

(3007 - 2603) Soil enzymatic activity as soil quality indicator of metal(loid) contaminated soils: a meta-analysis

Humberto Aponte[1]; Pablo Cornejo[1]
UFRO[1]

Enzymatic activities (EAs) are good indicators of soil quality due to their sensitivity and fast response under changes and perturbations. They can response in several ways depending on the chemical form and concentration of metal(loid)s, and some soil factors such as pH and total organic matter. Therefore, an assessment of which EAs are the potentially better indicators of soil quality under metal(loid) contamination is required. The aim of this work was to determine if EAs are good indicators in metal(loid) contaminated soils. Additionally, we evaluated which EAs are the most negatively affected under metal(loid) contamination through a meta-analysis. A bibliographic search was performed through the Thomas Reuters Web of Science using keywords such as “soil enzymes”, “enzymatic activities”, and “heavy metal”. The search was limited to the last ten years. A total of 115 articles were obtained, among which 15 showed the needed data for the meta-analysis. Values of means, number of replicates, and standard deviations of EAs were manually extracted from text, tables, and figures. These values were classified in observations of EAs for: 1) metal(loid) contaminated soils, and 2) non-metal(loid) contaminated soils. Data whose physic-chemical characteristic were not different were taken per study. This resulted in 195 observations partitioned in seven EAs, which were used to quantify the magnitude of the effect of metal(loid) contamination on these biochemical properties as the response-ratios. The meta-analysis was made with the package “meta” of R version 3.4.1. The result was a significant less activity in metal(loid) contaminated soils for the enzymes dehydrogenase, urease, acid and alkaline phosphatase, catalase, and arylsulfatase. Dehydrogenase was the most negatively affected. This can support the idea that intracellular oxidoreductases can be more vulnerable to metal(loid) contamination, due to extracellular enzymes might be stabilized in clays or humus-clay-enzyme complexes, which give them more tolerance against soil changes.
Keywords: Soil enzymes, heavy metals, response-ratios

(8953 - 2311) sSil structural quality in pasturelands in the city of buritis (RO), Brazil

Carlos Henrique dos Santos Zebalos[1]; Vanessa Gretzler Monteiro[1]; Luis Gustavo Lima Fogaça[1]; Ana Paula Duarte de Lima[1]; Everton Gonçalves Leite[1]; Edimar Rodrigues Soares[1]; Adriana Ema Nogueira[1]
Faculdade de Educação e Meio Ambiente - FAEMA[1]

Localized within the Amazonian Region, the state of Rondônia ranks eighth for cattle herd in Brazil. Livestock production in that state takes large portions of land with low technologic level. As a result, a considerable part of the pasturelands has become deteriorated. This study aims to evaluate the soil structural quality of pasturelands in the city of Buritis (RO), Brazil. The analysis took place at Boa Esperança and Boa Sorte farms, in November 2017. Three areas at Boa Esperança were evaluated: 1 – cultivation of *Panicum maximum* cv. Mombaça planted for 19 years; 2 – cultivation of *Panicum maximum* cv. Mombaça planted for two years; and 3 – cultivation of *Brachiaria brizantha* cv. Xaraés planted for a year and a half. The area 4 was evaluated at Boa Sorte, having *Brachiaria decumbens* cultivated for two years. For structural evaluation purposes, the visual examination method was deployed and grades from 1 to 6 for Soil Structural Quality Index were attributed. The average of indexes in each area was: area 1 – 4,87 (good structural quality); area 2 – 3,64 (regular structural quality); area 3 – 4,67 (good structural quality); and area 4 – 3,36 (regular structural quality). The obtained grades for areas 2 and 4 show that land use in such areas should be treated with conservationist techniques to improve overall soil structural quality over time. The good quality shown in area 1 points out that keeping fodder plants for large periods of time does not compromise overall structural quality. In this scenario, for better production results, it is only needed to improve chemical factors by fertilizing and correcting soil acid levels. The evaluation of soil structural quality is proven to be useful to help producers enhance their methods of land use, also contributing to a sustainable livestock production.

(6455 - 3084) Strategies for phytoremediation in soils contaminated with As, Cd, Pb, and Zn by slag disposal

William Ramos da Silva[1]; Clístenes Williams Araújo do Nascimento[1]; Fernando Bruno Vieira da Silva[1]
Universidade Federal Rural de Pernambuco[1]

The generation of waste through mining poses a potential risk of contamination of soil, water resources, plants and animals. For decades, the municipality of Santo Amaro da Purification - BA has suffered the impacts caused by improper and inadequate release of thousands of tons of steel slag, contaminated mainly by Cd and Pb, and by the exposure of these contaminants to the population through the distribution of this material for landfills in squares, streets and residences. The city today is known to present the highest human contamination per Pb in the world. The objective of this study was to evaluate the use of corn (Zea mays) and castor bean (Ricinus communis) for phytoextraction induced by chelating agents or phytostabilization. For this, a greenhouse experiment was carried out with the use of both plant species and phytoextraction inducers (citric acid and NTA). After the cultivation period, the contents of As, Cd, Pb and Zn were evaluated in soil and plant to evaluate the potential of the remediation technique. The data demonstrated that the environmentally available concentrations of As, Cd, Pb and Zn in the soils surrounding the Pb smelting plant are among the highest that have been reported. The application of the chelating agents citric acid and NTA increased the absorption of heavy metals by corn and castor bean. Although the removal of the metals with citric acid application is lower, it is more indicated because it presents greater degradability and helps in the inhibition of the phytotoxicity of the metals. Corn showed better phytoextractive capacity for As, Cd, Pb and Zn in the soil under study. The castor bean, although it did not translocate high concentrations of the metals, presented accumulation in the roots, being able to be used as phytostabilizing plant and generating economic benefits for the production of inedible vegetable oil. The mean estimated time for remediation of the area using phytoextraction was *high*, ranging from 76 to 259 years; therefore, this is not a viable alternative for remediating soils in the studied area. However, good development in the contaminated soil along with restriction of the metal(oid) translocation to shoots enables castor bean to phytostabilize metal(oid)s. Additionally, castor bean cultivation may be an alternative for an economic return because of biofuel production.

(6862 - 903) Structural quality of the soil according to management in an integrated system of livestock and agricultural production

Matheus Henrique Martins Silva[1]; Raiane Maiara Gonzalez Frantz[1]; Eliza Fernanda Oliveira dos Santos[1]; Augusto Vicente Fortes Júnior[2]; Karen Andressa Ribeiro Artner[1]; Edimar Rodrigues Soares[1]; Adriana Ema Nogueira[1]
Faculdade de Educação e Meio Ambiente[1]; Universidade Federal de Pelotas[2]

The present essay evaluates the structural quality of soils according to their management in an integrated system of livestock and agricultural production in the city of Rio Crespo (RO), Brazil. This study took place at Esperança farm in September 2017. The following managements were analyzed: area 1: crop-corn-grain/winter crop-soy (2015/2016); crop-

soy/*Bracharia ruziziense*s/pasture – 60 days – 3,87 UA/ha (2015/2016); crop-soy/winter crop-corn-silage/*Bracharia ruziziense*s/pasture – 60 days – 3,39 UA/ha (2016/2017); area 2: crop-corn-grain/winter crop-soy (2015/2016); crop-soy/*Bracharia ruziziense*s/pasture – 60 days – 3,39 UA/ha (2015/2016); crop-soy/winter crop-corn-sillage/*Bracharia ruziziense*s/pasture – 60 days – 4,22 UA/ha (2016/2017); area 3: *Crotalaria*/crop-corn-grain/*Bracharia ruziziense*s without pasture; area 4: *Crotalaria*/crop-corn-grain/winter crop-soy (2015/2016); crop-soy/winter crop-corn-grain/*Bracharia ruziziense*s/pasture – 60 days – 3,20 UA/ha (2015/2016); crop-soy/winter crop-corn-grain/*Bracharia ruziziense*s/pasture – 60 days – 4,22 UA/ha (2016/2017); and area 5: native wilderness. The evaluation of the soil quality was made visually through the Rapid Soil Structure Diagnosis method, with grades for Soil Structural Quality Index ranging from 1 to 6. The indexes for each area were: area 1 – 5,67 (great structural quality); areas 1 and 4 with indexes of 4,12 and 4,05 respectively (good structural quality). Areas 2 and 5 were ranked with index values of 2,77 and 2,54 respectively (poor structural quality). The deployment of integrated systems improves the overall soil structure quality. The best structure is achieved when no animal pasture is used. In areas with animal population over 4,0 UA/ha, there is the need to constantly monitor the soil structure quality, and to observe the homogenic distribution of animals throughout the area.

(1196 - 2487) Structural quality of the soil in an integrated system of livestock and agricultural production in the city of ariquemes (RO), Brazil

Lucas Pedro Cipriani[1]; Julyana Corrêa de Ávila[1]; Rogério Carlos de Souza[1]; Edneia Maria Sobrinho Rodrigues[1]; Edimar Rodrigues Soares[1]; Adriana Ema Nogueira[1]
Faculdade de Educação e Meio Ambiente[1]

This study evaluates the structural quality of the soil in an integrated system of livestock and agricultural production at Esperança farm, in Ariquemes (RO), Brazil, in August 2017. Three areas belonging to the integrated system and one single area of extensive pasture were analyzed. Area 1 has a history of previous successive cultures of corn/*Brachariaruziziense*s (no pasture) in the agricultural year of 2015/2016 and soy crop in 2016/2017. Area 2 was previously cropped with soy/corn/*Brachariaruziziense*s (with pasture) in the agricultural year of 2014/2015, with one crop of soy in 2015/2015 and once more with soy in 2016/2017. Area 3 experienced crops of *Brachariaruziziense*s/soy (no pasture) in the agricultural year of 2014/2015, followed by one single culture of soy in 2015/2016 and once again soy/*Brachariaruziziense*s in 2016/2017. Area 4 was essentially formed by deteriorated pasture. The structural quality of the soil was evaluated visually through the Rapid Soil Structure Diagnosis method, with grades for Soil Structural Quality Indexes ranging from 1 to 6. The management used in areas 1, 2 and 3 had better structural quality compared to area 4 (deteriorated pasture), with indexes equal to 4,87; 4,67; 5,67 and 2,57 respectively. The succession of *Brachariaruziziense*s/soy (no pasture), soy and soy/*Brachariaruziziense*s showed the best structural quality, whereas the area with deteriorated pasture had poor quality.

(6425 - 2327) Which pesticides are contaminating Brazilian soils?

Caroline Lopes Feijo Fernandes[1]; Lisiane Volcão[1]; Flávio Manoel Rodrigues Da Silva Júnior[1]
Universidade Federal Do Rio Grande[1]

Soil is an indispensable natural resource for the maintenance of life on the planet, however, agricultural production techniques have introduced a variety of synthetic substances in this compartment, with pesticides being the main example of these xenobiotics. Brazil is the world leader in the pesticide consumption market. However, these agrochemicals are recognized as an environmental, social and public health risk and constitute the main class of pollutants in agricultural soils. These factors motivate a need to monitor and control soil contamination by pesticides in Brazil. Thus, the objective of this work was to verify in the literature the diversity of pesticides found in soil samples within the Brazilian territory. The literature review was done in a systematic way, using the keywords pesticide, pesticide residues, soil, Brazil and Brazilian. The databases used were PUBMED, Web Of Science, TOXINET, SCIELO and Google Scholar (to grey literature). The sum of articles obtained in the search in all databases was 2.769 articles, but only 13 were included because they were related to the research theme (pesticides in Brazilian soils). In the 13 articles that were included in this review, 38 types of pesticides were found. Of these, 80% comprise the class of organochlorines, 5% the class of pyrethroids and the remaining 15% are equally divided into the classes imidazoles, imidazolylcarboxamide, triazoles, dinitroaniline and organophosphates. Organochlorine pesticides were reported in 12 articles, while the other classes were in only 1 study. However, the number of pesticides found is extremely small compared to the 504 marketed in Brazil. From this, it is possible to conclude that there is a need for new studies that contemplate chemical analyzes of real soil samples, with or without agricultural history, so that environmental risk can be predicted, diagnosed and reversed.

C4.3 - Soils and land use change

C4.3.1 - Ecological soil management systems and soil quality

(6043 - 1990) Acute toxicity in earthworms by the use of forest pesticides

Isabela Aparecida Giordani[1]; Carolina Riviera Duarte Maluche Baretta[1]; André Junior Ogliari[1]; Elizeu Moizés Bonfim[1]; Patrícia de Oliveira[1]
Universidade Comunitária da Região de Chapecó[1]

Pesticides are used indiscriminately throughout the world and the true impact of these products on the terrestrial biota is unknown. It is estimated that 0.1% are of specific action, reaching only the target pest, and the others reach other organisms too (CARRIGER et al., 2006), including species that play important roles in soil quality such as earthworms, which are important in maintaining the structure and decomposition of organic matter (GILL & GARG, 2014). The present study aimed to evaluate the toxicological potential of a pesticide used in forest system on the survival of *Eisenia andrei*. The experiment was conducted in a completely randomized design, with six replicates for each concentration of the Comet^{TM} herbicide (pyraclostrobin), based on the application recommendations for forest species (0, 58, 140, 350, 525 and 875 µL). For the tests, earthworms of *Eisenia andrei* species were used, following the recommendations of ISO 11268-2 (1998). Tropical Artificial Soil (TAS) was used for the tests, a standard soil for ecotoxicological testing, composed of sand, coconut fiber and kaolin. Each experimental unit received 500 g of contaminated soil and ten adult individuals with clitellum, weighing between 250-600 mg. The tests were maintained at 20±2 °C temperature and 12:12h photoperiod (light/dark). Survival evaluation was performed at 28 days. The results were subjected to analysis of variance (One-way ANOVA), followed by the Dunnett test ($p<0.05$). The test met the validation criteria in accordance with the respective ISO guideline. The mortality rate in the control did not exceed 10% of the total of individuals (average of 100% survival), with a coefficient of variation lower than 30%. The mortality of organisms of *E. andrei* species was not significantly affected by the

application of the Comet™ concentrations tested. There are currently no studies testing the toxicity of pyraclostrobin to terrestrial organisms. Toxicological assays with *Danio rerio* fish indicate a highly toxic potential of this fungicide for the species (ZHANG et al., 2017). We suggest further studies evaluating the toxicological potential of the substance pyraclostrobin. It is concluded that the Comet™ product, based on pyraclostrobin, was not able to cause toxicological effects on the lethality of *E. andrei* species at the concentrations tested

Keywords: Terrestrial ecotoxicology; *Eisenia andrei*; pesticides.

(4500 - 1604) Baby corn and biomass production for green manure in organic production system

Ana Amélia dos Santos Cordeiro[1]; José Guilherme Marinho Guerra[2]; Ednaldo da Silva Araújo[2]
Post-Graduation Student - Soil Science, UFRRJ[1]; Researcher, Embrapa Agrobiology[2]

The baby corn exports small amounts of nutrients from the system and when grown in consortium with other species of green manure has the possibility to pay the investment of the planting and still guarantee an extra gain with its commercialization. The objective of this study was to evaluate baby corn productivity and amount of aerial phytomass produced by green mucuna (*Mucuna pruriens* (L.) DC. Var. Utilis (Wall ex Wight) Baker ex Burck) and corn,). The experiment was installed in Fazendinha Agroecológica Km 47 (Embrapa Agrobiologia, Seropédica, RJ). A randomized complete block design was used, with three treatments and eight replications: a) corn at the density of 100,000 ha^{-1} plants; b) green mucuna at the density of 100,000 ha^{-1} plants and c) maize and green mucuna consortium at densities of 100,000 and 50,000 ha^{-1} plants, respectively. In the monocultures, sowing was carried out on the same date and, in the consortium, the corn was sown 20 days after planting the corn. The baby corn harvest was started at 57 days after sowing, being performed three days after emergence of the stigmas and repeated every three days, totaling five harvests. The cut of the aerial part of the species had as reference the flowering of the green mucuna in monoculture, at 156 days after sowing. The results were submitted to statistical analysis using the F-test, with the help of the SAEG Program and the means were compared by the Scott-Knott test at the significance level of 5% probability. No differences were observed in relation baby corn productivity when it was compared to corn monoculture and intercropped with green mucuna. The amount of aerial phytomass produced differed among the treatments, being the highest value observed in intercropping, which shows that this consortium strategy, with a view to green fertilization, has a high capacity of soil cover and phytomass production "*in situ*", Associating species with different C/N ratios, in addition to replacing the system with N derived from the atmosphere, and allowing the farmer to generate monetary income with the production of mint.

(7586 - 2846) Carbon and nitrogen soil in different management of long term pastures in the region of Mata Atlantica - Brazil

Mirelly Mioranza[1]; Renato Campello Cordeiro[1]; Renato de Aragão Ribeiro Rodrigues[2]; Fabiano de Carvalho Balieiro[2]; Ademir Fontana[2]; Guilherme Kangussu Donagemma[2]; Marcella Leal Santos[3]; Thamires Rodrigues de Sá Valle[4]; Pedro Augusto Dias de Oliveira[5]
Universidade Federal Fluminense, Outeiro de Joao Batista s/nº, Niterói – RJ, Brasil[1]; Embrapa Solos, Rua Jardim Botânico, Rio de Janeiro – RJ, Brasil[2]; Universidade Federal Fluminense, Rua Passos da Pátria, Niterói – RJ, Brasil[3]; niversidade Federal Fluminense, Rua Passos da Pátria, Niterói – RJ, Brasil[4]; Universidade Federal Fluminense[5]

Changes in land use can result in an important source or sink of carbon (C) from the atmosphere, depending on the management applied. The most important examples of land use changes in Brazil are the conversion of native vegetation to pasture and agriculture, and more recently the conversion to integrated systems. The objective of this work was to determine the carbon and nitrogen content and soil content in pasture areas under different managements. Samples were collected in the experimental field of Embrapa Cattle of Milk, in the municipality of Coronel Pacheco - MG, in pasture areas under Silvopastoral System (SSP) – composed of *brachiaria decumbens*, *Eucalyptus grandis* e *Acacia mangium*; Monoculture of Managed Pasture (PM); Degraded Pasture (PD) and Native Forest (NF) established for 20 years on a clayey red-yellow latosol in mountain topography. The samples for determination of total and labile C and N contents and stock were collected at depths of 0-100 cm and 0-30 cm respectively. The total and labile C content was influenced by the handling in the 0-10 cm layer, in the following order: PM (34.37 and 2.04 $g.kg^{-1}$), SSP (25.77 and 1.94 $g.kg^{-1}$), MN (21.90 and 1.49 $g.kg^{-1}$) and PD (19.20 and 1.37 $g.kg^{-1}$), in which the PM presented the same tendency of accumulation of carbon in depth. In this way, the largest stock was obtained in PM (121 $Mg.ha^{-1}$), SSP (108 $Mg.ha^{-1}$), NF (99 $Mg.ha^{-1}$) and PD (98 $Mg.ha^{-1}$). As for N, the total contents were similar in the different managements, whereas the labile N in the first layer was higher in the SSP (0.13 $g.kg^{-1}$), decreasing the depth content. This result is probably due to the presence of legumes (*Acacia mangium*) in the SSP that may have influenced the lower nitrogen availability, due to the higher uptake by the roots. The obtained stock was: PM (9.7 $Mg.ha^{-1}$), SSP (7.9 $Mg.ha^{-1}$), NF (8.5 $Mg.ha^{-1}$) and PD (8 $Mg.ha^{-1}$). It is remarkable the contribution of carbon by the well managed pasture in relation to degraded pasture and forest. These results can be attributed to the more developed, voluminous and well distributed root system of the grasses, which favors the high deposition of C to the soil in the form of roots. The apparent efficiency of the root system in contributing organic C to the soil probably results from the fact that they are not exposed to climatic factors and are in direct contact with the soil.

(1171 - 1763) Carbon stock in a sandy soil of the southwestern Amazonia

Falberni de Souza Costa[1]; Marcelo André Klein[1]; Erbesson de Souza Brito[2]; Manoel Delson Campos Filho[1]; Daniel Moreira Lambertucci[1]; Deborah Pinheiro Dick[3]; Itauane Oliveira de Aquino[3]; Leonardo Barreto Tavella[2]
Embrapa[1]; Ufac[2]; UFRGS[3]

Soil conservation management (SCM) system with no-till (NT), cover crops and cash crops in rotation and/or succession, limestone and fertilizers can recover and/or maintain soil quality in terms of its carbon (C) stock in comparison to the slash-burn system with or without conventional tillage (CT). The objective of this study was to determine the effect of SCM system on temporal variation of soil carbon stocks in its natural state (native forest – NF) and under different tillage/cropping systems. The experiment was conducted in an Acrisol of the smallholder property, Mâncio Lima municipality, Acre state, Brazil, in split-plot design in a randomized complete block design with three repetitions, for NT and CT (main parcels), and the succession manioc (*Manihot esculenta*)/cover crops (green manure)/maize (*Zea mays*). The sub parcels were: (1) control: slash and burn (C); (2) cover crops (*Mucuna aterrima* or *Canavalia ensiformes* or *Sorghum bicolor*) among cash crops (CC); (3) CC with addition of P-fertilizer (CCP); (4) CC with addition of

limestone (CCL); and (5) CC with addition of P-fertilizer and limestone (CCPL). Disturbed and undisturbed soil samples were collected (0-1.0 m) in the Amazonian summer of 2006 (beginning of the experiment), 2012, 2016, and analyzed for total organic carbon (Walkley-Black), and physical and chemical properties. In this study are presented only soil C stocks in NF, C and CCPL both under CT and NT. The C stock is presented for the 0-0.3 m because more than 50 % of the total C stock are located in this layer. The greatest C stock was observed under NF (46 Mg ha^{-1}) that ranged from 18.3 Mg ha^{-1} (0-0.05 m) to 14.2 Mg ha^{-1} (0.20-0.30 m). The others land use reduces an average of 26 % of the C stock under NF. C stocks did not differ among land uses investigated in this study.

(8060 - 2705) Chemical composition differences of mountain soil at natural regeneration areas (Nova Friburgo-RJ)

Matheus Dias Nideck[1]; Pedro Longo Guerra[1]; Thalita de Lima Adame[1]; Monica Santana Vianna[2]; João Paulo Machado Torres[2]; Ricardo Finotti Leite[1]
UNESA[1]; UFRJ[2]

Nova Friburgo (Rio de Janeiro State) was affected by extreme climatic events on January 2011. These events resulted in many landslides in mountain slopes that created many degraded areas where all the plant cover and superficial soil layers were removed. Many of these areas are under natural regeneration but plant growth still incipient. Evaluate and monitor soil characteristics and changes through space and time can furnish important insights about the successional pathways of soil regeneration and it constrains, furnishing insights for restoration projects. We sampled three degraded slopes surrounded by agricultural properties and a forest fragment on Barracão dos Mendes (Nova Friburgo – RJ). We collected eighteen soil samples along each degraded hill declivity and adjacent forest portions, making 54 samples for degraded areas and 54 samples for forest areas and 18 samples at each slope segment: 20 to 70 m, 70 to 140 m and upper portion 140 to 210 m. The concentrations of expressive elements for the soil fertility profile Al^{3+} and Ca^{2+} and pH was initially considered. These parameters were compared between the areas and between the different slope segments. Comparisons were made using Mann-Whitney (U test) with Bonferroni correction. Degraded areas presented significant lower Ca^{2+} concentrations (0,53 $cmol.dcm^{3}$) and lower pH (4,54) compared with forest areas (1,33 $cmol.dcm^{3}$) and (5,13) (U=3,55, p=0,0003 and U=2,54, p=0,01, respectively). Inversely, degraded areas presented significant lower Al^{3+} concentrations (than forest areas (0,73$cmol.dcm^{3}$) than forest areas (0,49$cmol.dcm^{3}$) (U=2,39, p=0,01). Slope portions did not differed in relation to all parameters at forest areas (U=0,39, p=0,65 for all comparisons) and at degraded areas (U=0,25, p=0,76 for all comparisons). Preliminary results indicates that soil of degraded slopes under natural regeneration are nutritionally poorer and more acid than the forest areas what can explain the difficult of plant settlement at these areas. However, values did not differed between slope segments indicating that differences found for plant settlement between slope portions are not being influenced by these parameters. The results indicate that restoration actions should consider the soil fertility pattern to evaluate the natural regeneration process. Subsequently, we intend to correlate soil fertility to the nutritional requirements of the species and the levels of pesticides found in the soil and organic matter.
Keywords: natural regeneration, soil conservation, restoration.

(1020 - 3067) Comparison of soil carbon stock in conventional and organic palm plantation in northeast Amazon

Arianne Flexa de Castro[1]; Manoela Sena Avelar[1]; Richardson Sandro dos Santos Freitas[1]; Fabio Alexandre Oliveira Teixeira Filho[1]; Sílvia Fernanda Mardegan[1]
Federal University of Para[1]

Amazon is target of degradation and deforestation. Land use changes after deforestation cause several effects in ecosystems processes. In this context, oil palm (*Elaeis guineensis* Jacq., Araceae) plantation is in expansion process and its effects on nutrient cycling and storage, as well as carbon stock in Amazon soil are so far misunderstood. Here we investigated how land use change affects soil physical-chemical properties and organic carbon (C) stocks in northeast Amazon. The study was carried out at Agropalma agroindustry complex, Tailândia-PA, Brazil, in a typic dystrophic Yellow Argisol. We sampled in organic (OP) and conventional (CP) oil palm plantation, which we separated into frond piles, inter rows and oil palm rows. At each site, we collected three depth intervals (0-10,10-20, and 20-30 cm) to quantify soil C content and stock, as well as to determine its physical-chemical properties. A terra firme forest (TF) nearby was collected as reference. Soils from forest and oil palm plantations are highly sandy (60% sand; 27% clay) and have low fertility. TF had lower fertility than oil palm plantations. Among plantation types, fertility at OP is higher than at CP, while among treatments, frond piles are more fertile than inter rows. Soil acidity was high (pH around 4) and similar among sites. Soil C:N ratio was low and variable, with no differences among plantation types and depth. Soil C content and stock in TF were lower than in both OP and CP plantations. Soil C content in oil palm row at OP was 7% higher than at CP. Comparisons within palm plantations indicated that soil C stock in frond piles was higher at both OP and CP (17.41, and 16.93 Mg C ha^{-1}, respectively) than at inter rows and oil palm rows. The higher soil C stocks in frond piles and oil palm rows are likely related to the presence of oil palm roots, and to higher inputs of organic matter. Conversely, the lower C stocks at inter row soils are likely to be related to poor drainage system and soil compaction. Our previous results suggest the enhanced potential of organic oil palm plantations to storage C in soil. This is probably due to the use of oil palm empty fruit bunch as fertilizer, rising soil organic matter content. Altogether, our results point that the conservative management of oil palm plantation has the ability to enhance organic C sequestration in Amazon soils.

(2766 - 894) Ecological farming - soil awareness in praxis

Houšková Beata[1]; Makovníková Jarmila[1]; Šlinský Ján[2]
National Agricultural and Food Centre – Soil Conservation and Research Institute, Gagarinova 10, 827 13 Bratislava, Slovakia[1]; EKOplod, Pavlovce nad Uhom, Slovakia[2]

Soil, alongside with air and water is the basis for life on the Earth. For many years, the function of soil has been understood only as a mean for production. Nowadays the soil is perceived as an integral part of environment which must be preserved for future generations. This shift in human thinking is also due to the increase in soil awareness. We cannot be satisfied with present situation as it still needs a lot of work in soil issues promotion in the society, but because soil is considered as non-renewable resource according to several soil protection documents, soil awareness is becoming stronger. One, very effective way, how to contribute to soil protection is ecological farming. Soil is subjected to several external factors which can influence its properties. The cause of soil degradation directly lies in the way of soil use, which affects its ecological functions and consequently the stability of the land. Sustainable soil use must keep equilibrium with the other parts of environment and ecological farming is also the way to realize it. Example can be soil cultivation in spirals where individual fields have circle shape. Such cultivation is based on low soil surface disintegration without

turning the soil layers and without heavy machinery and fertilizers. It is realized by a rotating arm fixed in the middle of the field. Soil cultivating tool is mounted on a chain and is guided along the arm. It is possible to fix interchangeable tools that can serve as a spade, rotary tiller, and seeder or for drip irrigation. The circular fields are located side by side and one working arm can be easily moved to an adjacent field. In these fields it is already possible to see the change of soil properties. This is noticeable in the amount of stable soil aggregates proportion in comparison with fields cultivated in traditional way. Due to low soil disturbance also amount of earthworms is higher in circle fields. Improvement in soil structure tends to grow from the fields with 1 year to the fields with 5 years of ecological cultivation, thus with years the effects are more and more visible. Ecological farming is soil awareness in praxis and can significantly contribute to soil protection and sustainable use according to A2030 SDG's, especially goal 15 which aims to: protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss.

Keywords: soil awareness, ecological farming, field's shape, soil structure, SDG's

(2139 - 732) Effect of rangland management on soil properties in South Africa

Elmarie Kotzé[1]; Hennie Snyman[1]; Chris Du Preez[1]

University of the Free State[1]

Rangeland management can affect soil in various ways. Direct effects are related to animal trampling and excretion, while indirect effects are involved with changes in vegetation structure and function, like defoliation, burning and drought. Both beneficial and detrimental effects of rangeland management on soil properties have been found in several studies in South Africa. Livestock grazing are known to significantly change almost every aspect of soil structure and function, including soil porosity, chemistry, microbiology, nutrient cycles, productivity, and erosion rates. It has been reported that high grazing intensity increases soil compaction and erosion, while reducing soil aggregate stability, and decreasing soil nutrient and organic matter levels. Drought and fire in arid and semi-arid rangelands in South Africa, generally reduce soil organic matter content and the soil seed bank which can lead to reduced porosity and increased bulk density, causing further soil compaction. However, the decrease in root mass due to drought can also add organic matter to the soil. These effects, especially when combined, leads to rangeland degradation in the form of compaction or erosion. Soil degradation (erosion and compaction) due to rangeland management in South Africa is substantially higher in communal than in commercial rangelands, with areas mostly affected in steep sloping land in the eastern parts of South Africa primarily used for grazing, with KwaZulu-Natal, Northern and Eastern Cape Provinces being badly affected by soil degradation. Rangeland degradation seems to be highest in KwaZulu-Natal and the Northern Province of South Africa. Whereas the eastern Karoo is no longer seen to be severely degraded by agricultural experts, as it appears to have benefitted considerably from rangeland management strategies. The rate of rangeland degradation is decreasing in commercial areas, largely due to state intervention, strategies and schemes, while it is perceived to be increasing in communal districts. Rangeland management should include strong, effective, and specific measures to prevent degradative effects or to repair soil damage where it has already occurred. Changes in rangeland management, especially applying long enough resting periods, can be very effective in controlling soil compaction, infiltration and erosion.

(8603 - 1231) Epiedafic fauna in a long-term integrated crop-livestock system at different grazing intensity

Daiane Dalla Nora[1]; Ângela Denise Hübert Neufeld Vieira[1]; Hazael Soranzo de Almeida[2]; Juliane Schmitt[1]; Paulo César de Faccio Carvalho[2]; Rodrigo Josemar Seminoti Jacques[1]

Universidade Federal de Santa Maria[1]; Universidade Federal do Rio Grande do Sul[2]

The integrated crop-livestock system representing a production model that seeks sustainability of agricultural systems and increase the productivity, reconciling animal and agricultural production. This system has a direct and indirect effect on soil fauna, which undergoes rapid changes by changing the management. Evaluating these effects is essential, because edaphic invertebrates are directly related to soil quality. This work aimed to determine the frequency of epiedafica soil fauna at different intensities of grazing in a long-term integrated crop-livestock system, conducted with different grazing intensities. The study was carried out in an area of 22 hectares located in the municipality of São Miguel das Missões / RS / Brazil, cultivated under tillage system. The soil is classified as typical Rhodic Hapludox. In winter, the consortium black oats plus ryegrass is used for animal grazing and in the summer the soybean crop for grain production. The area was divided into 14 plots and the treatments are the four grass heights 10, 20, 30 and 40 cm and control without grazing. The experimental design was complete randomized blocks with three replications, and areas between blocks without grazing. Sampling was carried out in 2014-2016, using traps in two seasons: after grazing of the animals (October / November) and post harvest of the soybean (April / May). Nine traps were installed in each plot, totaling 27 per treatment. The traps were installed with 70% (v / v) ethanol solution for preservation of organisms, since they stayed in the area for 7 days. The captured organisms were identified at the level of order and the frequency of the taxon was calculated. Among the 13 orders collected, Araneae, Coleoptera and Heminoptera presented higher frequency and lower variation among different pasture heights after animal grazing. After the soybean harvest, these organisms were also the most expressive; however, they behaved in different ways among the grazing intensities. The orders Araneae and Coleoptera presented higher frequency in the plots without grazing. This behavior indicates that the different intensities of grazing affect the frequency of the organisms in the soybean crop, however, this influence was not expressive after animal grazing.

(1612 - 1290) Evaluation of Microbial Activity in Soil under Different Management Methods, with Addition of Organic Material with Deep or Conventional Amendment

Juliana Zucolotto[1]; Roberto Stefani Takahashi[1]; Paulo Cesar Tavares de Melo[1]; Elke Jurandy Bran Nogueira Cardoso[1]; Gustavo Scardazzi Lago[1]; Renato Manzini Bonfim[2]

Escola Superior de Agricultura Luiz de Queiroz[1]; EMBRAPA[2]

The conventional system of potato production has proven to be unsustainable due to the high inputs and the high incidence of pathogens that prevent consecutive crops in the same area. The deep tillage system for potato, developed by the study group PACES (Designing Sustained Agriculture in Sustainability) located at Escola Superior de Agricultura "Luiz de Queiroz" (ESALQ/USP) in Piracicaba (São Paulo – Brazil) , aims to improve the chemical, physical and biological soil properties, making it appropriate for cultivation in tropical conditions. The soil microbial activity is an indicator of the intensity of microbiological processes, which are essential for the maintenance of

soil biological quality. This work evaluated the microbial activity of soil under different forms of soil management. The five treatments were: 1. Deep Tillage and amendment of Panicum maximum 2. Deep tillage and amendment of Brachiaria brizantha 3. Deep Tillage and amendment of Zea mays; 4. Conventional tillage and amendment of Zea mays; 5. Control - conventional tillage with no amendment. The samples were collected at the depths of 0-20 cm and 20-40 cm and at 5 periods within the potato (Solanum tuberosum L. cv. Atlantic) cycle, being : twenty-three days before planting (T0), 1 day before planting (T1), 24 days after planting (T2), 45 days after planting (T3) and 80 days after planting (T4) and the samples were sent to the Soil Microbiology Laboratory of the Department of Soil Science of ESALQ, where they were submitted to respirometry analysis by the method of Alef (1995).For statistical analysis a randomized block design with five treatments and six replications was randomized. For respirometry, the analysis of the variables of time and treatments were submitted to analysis of variance and for the comparison of means, the Tukey test (P <0.05) was used for each depth (0 to 20 and 20 to 40 cm). All analyzes were performed using software R version 2.15.3. The conventional tillage productivity of potato was shown to be lower than in the deep tillage treatments, and this difference could be an effect of soil tillage that was done differently for both systems. The treatment with deep tillage and amendment with Panicum maximum presented the best potential to keep the microbial activity high during the whole potato cycle, but there was no significant difference between the amendment with Panicum and Brachiaria

(5962 - 2586) Evaluation of substrates and temperatures for germination of *Dalbergia nigra* (Vell.) Fr. All.

Ana Paula Braido Pinheiro[1]; Adriele dos Santos Jardim[1]; João Vitor Garcia Silva[1]; Adriano Alves Fernandes[1]; Fábio Ribeiro Pires[1]; Sara Dousseau Arantes[2]; Luis Fernando Tavares de Menezes[1]
UFES[1]; INCAPER[2]

Known locally as the *jacaranda-da-bahia*, *Dalbergia nigra* is native species of the Atlantic Forest with characteristics of late secondary to climax. It is a tough species to regenerate in nature and threatened of extinction, but has a great potential for the recovery of degraded areas as it adapts well to soils with low fertility. There are few studies about germination of this species, so it is fundamental to define the optimum conditions for the evaluation of the physiological quality of the seeds, mainly regarding temperature and substrate. The objective of this work was to evaluate the influence of different temperatures and substrates on the germination and vigor of *jacarandá-da-bahia* seeds, aiming at the establishment of a protocol for the evaluation of their physiological quality. The experiment was carried out at the Universidade Federal do Espírito Santo (UFES/CEUNES), the experimental design was completely randomized with four replicates of 25 seeds, in factorial scheme with three temperatures and four substrates. The sowing was done between sand, vermiculite and commercial organic (Tropstrato®), and on the paper, placed in gerbox boxes, and the test was conducted in Biochemical Oxigen Demand (BOD) germination chambers for 14 days at constant temperatures of 25 °C, 30 °C and 35 °C and 12 h photoperiod. The percentage of germination and the rate of germination were evaluated through daily evaluations of root protrusion. After the formation of the normal plant, the lengths of the root system and of the aerial part were evaluated. There was no interaction between the factors studied, therefore, they were independent. Means were compared by Scott-Knott test at 5% probability. The percentage of germination was statistically equal in the three temperatures. The temperature of 25 °C showed a higher rate of germination. The highest root length was observed at temperatures of 25 °C and 30 °C, and shoot growth was favored at 30 °C. Regarding the substrates used, the paper and the commercial organic showed a higher percentage of germination and a higher rate of germination. For the root growth the vermiculite and commercial organic substrates stood out, and as for the length of the aerial part all the substrates were statistically equal. For *Dalbergia nigra* it is recommended to evaluate the percentage of germination at 14 days, but a maximum value of 34% was observed. This low percentage may be related to the low physiological quality of the seeds.

(5082 - 2650) Litterfall production and nutrient cycling on Caatinga woody leguminous.

Anacláudia Alves Primo[1]; Maria Diana Melo[2]; Graziella de Andrade Carvalho Pereira[2]; Ivanderlete Marques de Souza[2]; Henrique Antunes de Souza[3]
Universidade Federal do Ceará[1]; Universidade Estadual Vale do Acaraú[2]; Embrapa Meio-Norte[3]

The knowledge on nutrient cycling through litter is important for the management of the species in agroforestry systems (SAFs), since the litter is an important way of making plant nutrients available to soil. The aim of this work was to evaluate the litterfall production and nutrient cycling of woody species in an agroforestry system of Caatinga. The study was developed in SAF belonging to Embrapa Goats and Sheep, located in the county of Sobral-CE, Brazil. The evaluated species were four native leguminous from Caatinga: *Mimosa caesalpiniifolia* (sabiá), *Mimosa tenuiflora* (jurema-preta), *Libidibia férrea* (jucá) and *Poncianella piramydalis* (catingueira). To collect the litter, collectors were installed under the tree canopy, using six replicates for each species evaluated. The samples were collected monthly during the year 2015. After each collection, the materials were oven dried at 60 °C with circulation, to quantify the total litter production of each species, followed by macro and micronutrients analyzes of the residues of each collection. The period of greatest litter production occurred at the end of the rainy season and at the beginning of the dry period, between June and August. Thus showing an influence of rainfall regime on the production of litterfall. The jucá species presented higher production, followed by catingueira, sabiá and jurema-preta, with 925.8, 332.2, 259.3 and 221.9 g m^{-2} of dried mass. Calcium (Ca) presented greater accumulation of litter in the sabiá and catingueira species: nitrogen (N) was higher in the jurema-preta and jucá species; iron (Fe) was the micronutrient with the greatest accumulation in the litter in all species evaluated. It was observed that not all leguminous plants were Ca element superior to N as generraly occurs. In this study two out of five species showed higher N compared to Ca. This predominance of Ca in the residues can be due to the fact that it is a structural component of the cells of the vegetal tissue, thus tending to be one of the last to be released to the soil via litter decomposition. Overall, the elements P, K, Mg and S presented low accumulation during the one-year period evaluated. The leguminous on Caatinga greatly contribute with the soil residues accumulation. The adoption of SAFs in Caatinga as a soil conservation system maintain the recycling of nutrients within the agroecossystem, as well as in natural ecosystems, thus avoiding the expansion of areas in the process of degradation.

(9111 - 684) Measuring changes in soil carbon stocks in western Japan as influenced by land conversions from forest land to cropland

Nobuhisa Koga[1]; Takashi Kusaba[1]; Hiroshi Niimi[1]; Takeo Shima[1]; Tsuyoshi Yamane[1]
Kyushu Okinawa Agricultural Research Center, NARO[1]

In National Greenhouse Gas Inventory Report, CO_2 emissions from soil carbon stock changes resulting from land use conversions are the object of the report. However, those emissions from land use conversions between forest land and cropland are not fully investigated in Japan. In

this context, we measured changes in soil carbon stocks resulting from past land use conversions from forest land to cropland in western Japan. In the present study, we selected 8 sites from western Japan, and soil carbon stocks at both forest land and cropland (including grassland) converted from the forest land were measured at each site. The croplands at the 8 sites included 4 upland fields, 3 grazed meadow lands and 1 citrus orchard. The soil types were Andosols (volcanic ash-derived soil) for 4 of the croplands and Red-Yellow soils for the reminder. Elapsed times after land conversion from forest land to cropland ranged from 23 to 76 years (mean of 43 years). At both forest land and cropland, 3 soil profiles were created each land, and soil sampling was duplicated at each soil profile (six-replicated soil samples were taken from each land). For forest land soil (0-50cm) and cropland soil (0-30cm), soils were divided into several layers, based on the color and hardness of the soil. Then, soil samples for determining dry bulk density and carbon content of the soil were taken layer by layer. The comparison between forest land and cropland in terms of soil carbon stocks was made on an equivalent soil mass basis; namely, the soil depth considered for forest land was adjusted in order that the soil mass considered for forest land equaled that for 0-30cm in croplands. The soil masses were calculated by subtracting soil organic matter weight (carbon content x 1.724) from dry soil weight. Of the study sites, analyses of samples from 5 sites (3 Andosol sites and 2 Red-Yellow soils sites) were completed. For 4 of the 5 sites, soil carbon stock in forest land was greater than that in cropland. The mean ratio of soil carbon stock in cropland to that in forest land for the 5 sites was 0.80 (range: 0.36 to 1.09). It seemed that the ratios of soil carbon stock in cropland to that in forest land decreased with elapsed times after land conversion from forest land to cropland. We are still accumulating further data to derive the country-specific soil carbon stock change factor for land conversions from forest land to cropland.

(2084 - 2140) Monitoring restoration success of soil's quality in forested ecosystems: A global meta-analysis

Adriana Allek Litaiff[1]; Agnieszka Latawiec[2]; Renato Crouzeilles[1]

Programa de Pós Graduação em Ecologia, Departamento de Ecologia (UFRJ); Centro de Ciências para Conservação e Sustentabilidade do Rio; Instituto Internacional para Sustentabilidade[1]; Centro de Ciências para Conservação e Sustentabilidade do Rio; Instituto Internacional para Sustentabilidade[2]

The ecological restoration process and its success depend to a large extent on the soil's integrity and functionality. Recent global meta-analysis have been carried out to understand the effects of restoration success for biodiversity and vegetation structure, yet understanding restoration success of soil's quality in forested ecosystems remains unclear. Aiming to quantify how does restoration success varies for different soil's quality indicators (soil organic matter, biological, chemical and physical), we conducted a global meta-analysis encompassing 432 quantitative comparisons between restored and reference (e.g. old-growth forests) forest systems. As expected, we found that all indicators were more depleted in restored than in reference systems. Using the response ratio's metrics we found that biological indicators (-0.55) were more depleted than soil organic matter (-0.38), physical (-0.19), and chemical (-0.02) indicators. Our study shows that restoration practitioners should focus more effort on restoring biological soil fauna since it showed the most contrasting difference between restored and reference systems. This global meta-analysis provides insights not only in the trends of restoration success of soil quality, but also into which indicators are more critical to be restored and monitored in order to achieve more cost-effective restoration of soil's quality.

(9150 - 2122) Review of existing knowledge on soil crusting in South Africa with an appraisal of some specific case studies and possible solutions

G.P. Nortje[1]; M.C. Laker[2]

University of South Africa[1]; University of Pretoria[2]

Review of existing knowledge on soil crusting in South Africa with an appraisal of some specific case studies and possible solutions M.C. Laker[1]; G.P. Nortjé[2] [1]Professor Emeritus of Soil Science, University of Pretoria, Pretoria, South Africa; [2]Senior Lecturer of Environmental Soil Science, University of South Africa, South Africa (nortjgp@unisa.ac.za) Soil crusting (surface sealing) is a widespread and serious problem throughout all nine provinces of South Africa and in neighbouring countries, like Botswana, Namibia, Swaziland, Zimbabwe, Malawi and Tanzania. Unlike subsurface soil compaction, human-induced soil crusting is not confined to cultivated or irrigated areas (rainfed and irrigated), but it is also a widespread problem in overgrazed rangelands and overgrazed areas in game parks and National Parks. Both mineral and biological soil crusts are problems. Extreme crusting is found on soils where sub-tropical fruit crops i.e. avocado and macadamia nuts are grown in three of South Africa's main production areas namely, KwaZulu-Natal, Limpopo and Mpumalanga. Various research methodologies are used to study soil crusting. Soil factors determining the susceptibility of a soil to crusting include soil organic matter, sesquioxides, particle size distribution, exchangeable sodium percentage, magnesium:calcium ratio and parent material. Negative impacts of soil crusting include the reducing of water infiltration, leading to increased runoff and erosion and induced drought; inhibiting soil aeration; inhibiting germination and seedling emergence; inhibiting root functioning and development. Management practices that lead to the development of bare areas on crusted soils or are aimed at deliberately maintaining bare areas, e.g. under drip and micro irrigation, or off-road driving in game parks, aggravate soil crusting and its negative impacts. Crusted soils often do not recover even after several decades. In this paper the existing knowledge on soil crusting (surface sealing) in South Africa is reviewed, as well as viable practical solutions to prevent and alleviate soil crusts for example: changes in management practices, and amelioration by means of mulching, the application of gypsum (or phosphogypsum) or organic soil conditioners, such as polyacrylamide (PAM).

(3191 - 1541) Sand encroachment and land degradation in an agropastoral area restored in the southern region of Sétif (Algeria)

Salah Belghemmaz[1]; Mohammed Fenni[1]; Yacine Louadj[2]; Afrasinei Gabriela M.[3]

UFA Sétif-1, Laboratory of Valorization of Biological and Natural Resources, Faculty of Life and Natural Sciences, Ferhat Abbas University, Sétif-1, 19000 Algeria[1]; UFAS Sétif-1, department of agronomic sciences, Faculty of Life and Natural Sciences, Ferhat Abbas University, Sétif-1, 19000 Algeria[2]; Remote Sensing and GIS TeleGIS Laboratory, Department of Chemical and Geological Sciences, University of Cagliari, Italy[3]

This study allowed us to establish a preliminary assessment of the state of degradation of the steppe ecosystem in the southern region of higher plain of Sétif (Hammam Sokhna). Soil sampling was done on the southern boundary of the sebkha and headed west to the north east a distance of about 15 km. The pedological evaluation had allowed us to complete our field observation. The high soil salinity, and high pH, low

soil organic matter, and low vegetation density, are all the sign of the predisposition of the soil to sand encroachment. Bad tillage management and overgrazing weaken the soil, make it susceptible to deflation. The Wind is the driving force behind sand encroachment. The accumulation of sand increases from the upstream to downstream of the toposequence. The presence of dune landscape testifies the sand encroachment phenomena. In summary, the degradation of this steppic environment due to sand encroachment is a reality. The agropastoral vocation of this region is threatened by the sand dynamic. The fight against this phenomenon must be included in a rehabilitation project. Dune fixation by atriplex must be revived and also, the restriction or controlled agricultural activity where the areas are more sensitive to degradation must be taking into account in the rehabilitation project of this steppic ecosystem.

Keywords: Steppic- Ecosystem, sand encroachment, degradation, Hammam Sokhna

(7424 - 3168) Soil CO_2 efflux in conventional and agroforestry-based oil palm production systems

Alessa Nayhara Mendanha Costa[1]; Steel Silva Vasconcelos[1]; Saime Rodrigues[2]; Helen Ramos[3]; Lilianne Cunha[4]; Osvaldo Kato[1]; Débora Castellan[5]

Embrapa Eastern Amazon[1]; Federal Rural University of Amazon[2]; World Agroforestry Centre[3]; Federal University of Para[4]; Natura Inovação e Tecnologia de Produtos Ltda[5]

The oil palm is an oilseed of great economic importance. In Brazil, the state of Pará is the biggest producer of this crop. Oil palm cultivation in agroforestry systems (AFS) is considered an alternative more sustainable of expansion of this crop. However, spite of its carbon accumulation potential, there are still many gaps in research on CO_2 production from soil respiration in these systems. The efflux of carbon dioxide (CO2) from the soil, a result of autotrophic and heterotrophic respiration, is a sensitive indicator of the crop impact on soil carbon cycling. From March 2016 to March 2017 in the region of Tomé-Açu, Pará, eastern Amazon, three systems were evaluated: (a) an eight-year-old agroforestry-based oil palm system (AFS P); (b) an eight-year-old conventional- based oil palm system (oil palm monoculture); and (c) a 40-year-old secondary forest. Soil CO_2 efflux was monthly determined with a portable photosynthesis measurement system (model LI-6400, LI-COR, Lincoln, NE, USA), connected to a soil breathing chamber (LI-6400-09). The experimental design was completely randomized. The effect of the systems on soil CO_2 efflux was tested with ANOVA; Tukey at 5% was used to compare the averages. The soil CO_2 efflux was significantly higher in the 40-year-old secondary forest (secondary forest = 5.89 ± 0.10 µmol CO2 m^{-2} s^{-1}) than in oil palm systems (AFS P = 3 , 75 ± 0.05 µmol CO2 m^{-2} s^{-1}, oil palm monoculture = 2.22 ± 0.04 µmol CO2 m^{-2}, s^{-1}). The litter stock of these systems and annual carbon efflux (data not shown) follow the same pattern of CO_2 efflux (secondary forest > AFS P > oil palm monoculture).The greater diversity and density of species present in the secondary forest and in the agroforestry-based oil palm system, associated to the higher litter stock of these systems, favors the accumulation of organic matter and microclimatic conditions, which can stimulate the root development and rate of decomposition, contributing to the autotrophic and heterotrophic respiration, and consequently, for the greater soil CO_2 efflux in these systems. Although "soil metabolism" in AFS is not the same as forest metabolism, the more diversified oil palm cropping system (AFS P) is, more akin to a more ecologically integrated system (secondary forest).

Keywords: Keywords: Oil palm, soil CO2 efflux, agroforestry

(7872 - 312) Soil compaction by livestock in selected communally grazed semi-arid savanna rangelands of South Africa

Simeon Materechera[1]
Faculty of Natural & Agricultural Sciences, North-West University, p/b X2046 Mmabatho, 2735, South Africa[1]

Although soil compaction from livestock traffic is known to be a serious problem, its extent in communally-grazed semi-arid rangelands of South Africa has not been well assessed. This study quantified the impact of grazing animals (Cattle, goat, sheep) on soil compaction in three communal grazing rangelands located within the vicinity of the city Mafikeng in the North West Province. The rangelands represented the major grazing practices employed by smallholder farmers (uncontrolled annual stocking densities of over 300 AU ha^{-1}). A controlled grazing plot (20 AU ha^{-1}) at the North-West University Research Farm was used a control. Livestock in communal lands are herded to graze during the day but are confined in kraals overnight. Measurements were made in summer (July to October) of 2015. The profiles of all grazing lands displayed a compacted surface (1-5 cm) layer with an average penetrometer resistance of 2.35 vs 1.61 MPa (communal vs controlled) grazed lands. The average soil bulk density was significantly higher ($p<0.05$) in the communal than controlled grazed lands (1.51 vs 1.28 Mg m^{-3}). The former lands had consistently lower gravimetric water contents than the latter at all depths. Soil compaction significantly reduced ($p<0.05$) the infiltration rate of water in the surface soil of communally grazed lands compared to the control (0.93 vs 2.45 mm h^{-05}) implying a reduction in large soil pores. This could explain the localised ponding widely observed in these rangelands during rainy seasons. In sloppy areas, the waterlogging contributed to water erosion which could lead to transfer and redistribution of soil sediments and nutrients into nearby surface water sources thereby posing the risk of siltation and eutrophication. Loss of vegetative grass cover due to overgrazing in the communal lands was visible and could increase the compaction. There was less variation in soil properties across communal lands. Soil compaction in the grazing lands could also be exacerbated by the predominantly sandy soils which are poorly aggregated due to low clay and organic matter contents. The study concluded that both the uncontrolled number of animals and time of exposure to grazing in communal lands contributed to soil compaction. It was recommended that rotational grazing schemes need to be improvised and hoof traffic needs to be kept off the land as much as possible especially when the soils are wet in order to reduce the susceptibility of the soil to compaction.

(7911 - 2100) Soil organic carbon labile fractions as indicator to manage tropical soils with different land use systems of the Peruvian Amazon

Ceila Lao[1]; Julio Alegre[1]; Sady García[1]; Eddie Shrevens[2]
Universidad Nacional Agraria La Molina[1]; Leuven University[2]

Soil organic matter is a very complex and important indicator to improve soil fertility and soil physical properties in the tropical regions, but will depend of many factors to keep it available and efficient in nutrient cycling and soil stability. Actually the physical and chemical analysis of organic soil fractions matter (OSFM) has become more relevant because of their different mineralization rates and their contribution of carbon to the soil. The OSFM become the most important indicator of soil quality especially at the Peruvian Amazon where we have a diversity of land uses and very few information exist about this fractions. In this

study we have evaluated the effect of soil management on OSFM under 10 different production systems in the Peruvian Amazon based in forest and secondary forest, pastures, woody trees, fruit trees and mix of woody and fruit trees. It was evaluated the content of dissolved organic carbon (DOC), particulate organic matter (POM), microbial biomass (MBS) and oxidizable carbon in permanganate (POXC) in the 10 different land uses systems. Soil samples were taken at two depths (0 - 15 cm. and 10 - 30cm.) during the dry season. The results showed that the carbon contained in the soil microbial biomass was higher in the multistrata system (221.2 mg C kg^{-1}). The higher oxidizable carbon content in soil permanganate resulted in the peach palm (*Bactris gasipaes*) system associated with *Pueraria phaseoloides* (417.5 mg C kg^{-1}) and the primary forest system had the highest content of dissolved organic carbon (12.46 mg C kg^{-1}) as well as the content of particles of organic matter (11891.7 mg C kg^{-1}). At the same time with the hierarchical analysis by clusters, we obtain 4 groups formed by A: Peach palm, improved pasture, degraded pasture, heart palm (*Bactris gasipaes*) and oil palm *(Elaeis guineensis*); B: Multistrata sytem 2 (10% clay) with *Cedrelinga catenaeformis* and other timber and fruit species, Brazilian nut (*Bertholletia excelsa*) and secondary forest; C: Multistrata 1 (5 % clay) and D: Primary forest. It is concluded that efficient soil management with different land use systems in tropical regions contributes to the preservation of fractions of soil-labile organic carbon.

Keywords: Microbial biomass, oxidizable permanganate carbon, dissolved organic carbon and particulate organic matter.

(6855 - 2554) Soil quality index, a tool for monitoring and conservation of Chilean sclerophyll forest

Martínez-Herrera, E.[1]; Magni, C.[1]; Grez, I.[1]; Rubio, R.[1]; García-Chevesich, P.[1]; Romero, F.[2]; Morales L.[3]; Soto G.[3]; Neira, J.[3]
Universidad de Chile, Facultad de Ciencias Forestales y Conservación de la Naturaleza, Casilla 9206, Santiago, Chile[1]; Reserva Natural Altos de Cantillana, Paine, Chile[2]; Universidad de Chile, Facultad de Ciencias Agronómicas, Departamento de Recursos Naturales, Santiago, Chile[3]

Soil quality must be expressed through a function such as the productive capacity of the soil or environmental protection. Soil quality is dynamic and can change in short term, according use and management practices. The aim of this work was to evaluate a SQ index to support growth and sustainability of sclerophyll forest of central Chile. Three sites (A, B and C) located in the foothills of the Andes mountain range, all with sclerophyll forest in a conservation - degradation gradient, were selected. Cattle activity and litter removal is practiced on site A, occasional cattle on site B, and site C is maintained for more than 20 years without any production activity. A SQ function was computed as a linear combination of hierarchically organized indicators. The indicators used were physical properties (cone index, shear strength), chemical properties (pH, N, P and K available, B, Fe, Mn, Zn and Cu, exchangeable cations and cation exchange capacity) and biological properties (litter depth and soil organic carbon). A score for each of these properties was computed using measurements (indicators) that were normalized (0-1) with one of the three (more is better, optimum, or worse) scoring functions, according to their relative importance. The SQ index obtained was 0.19 in site A, 0.36 in B and 0.55 in C, indicating that the site with the highest anthropogenic activity had the lowest soil quality, while the site with 20 years of exclusion reach the highest soil quality.

Keywords: Soil health, Mediterranean forest, forest sustainability.

Financial support: Project Propuesta de protocolo para la definición de créditos por ganancias en biodiversidad en ecosistemas mediterráneos de Chile central, 2015. PROYECTO GEF Nº 59602.

(1720 - 1617) Soil quality index: evaluating reclamation of bauxite mined-soils under coffee cultivation

Rafael Silva Santos[1]; Silvano Rodrigues Borges[1]; Dener Márcio Silva de Oliveira[1]; Ivan Francisco Souza[1]; Ernst Eduard Jan Verburg[1]; Laisa Gouveia Pimentel[1]; Rogério Santana da Cruz[1]; Ivo Ribeiro da Silva[1]
Universidade Federal de Viçosa[1]

Mining activities cause severe impacts to the soil, and reclamation requires monitoring and proper evaluation of the processes involved. In this study, our objective was to develop a soil quality index (SQI) for monitoring the reclamation of bauxite-mined lands for coffee production. Fertilizer treatments (no fertilizer, poultry litter, chemical fertilizer, chemical fertilizer + poultry litter) and intercrops (no intercrop, grass [*U. brizantha*], legume [*S. capitata + S. macrocephala*], and grass + legume) planted between the coffee plants (*Coffea arabica*) were used as rehabilitation techniques. Soil attributes grouped into organic, chemical, physical, and microbiological properties were evaluated at pre-mining (native forest and 10-year-old coffee plantation), post-mining (reference sites), and at 19 months after the start of the experiment. Labile organic carbon, total exchangeable basis, bulk density, and acid phosphomonoesterase activity were selected for calculation of the SQI. Mining reduced the SQI by approximately 65% compared to the undisturbed site under coffee cultivation (pre-mining). However, reclamation involving intercrops fertilized with poultry litter—alone or in combination with chemical fertilizer—resulted in a 23% increase in the SQI after only 19 months. Whereas fertilization alone produced a modest increase in the SQI, intercropping alone (i.e., without fertilization) resulted in no improvement of the SQI. The proposed SQI had a high sensitivity to reclamation practices and can provide a useful tool for monitoring the reclamation of bauxite-mined sites.

Keywords: Poultry litter; Land restoration; Coffee cultivation; Cover crops; Soil organic matter.

(1579 - 2696) Solubility of different residue from the benefit of marble and agricultural liming materials

Luis Paulo Patente Tanure[1]; Maria Maiara Cazotti[2]; Liovando Marciano da Costa[2]; Paulo Roberto Cecon[2]
Produquimica[1]; Universidade Federal de Viçosa[2]

Brazil stands out among the world's largest producers and exporters of ornamental stones. Advice on natural resources, such as soil degradation, water contamination, atmospheric and visual pollution, besides the generation of fine residues, mainly in the beneficiation process. In this context, the objective was to evaluate the solubility of cutting (RS) and polishing (RP) of the marble and compared to the agricultural liming (CC). After a granulometric standardization of the 0.053 mm sieve samples, 1 g of sample was added to 50 mL of HCl at concentrations of 0.01; 0.10; 0.50; 1.00 and 2.00 mol L^{-1}, with four replicates. The reaction time was 12 hours, as samples were shaken hourly for 15 minutes at 200 rpm. After a reaction, as solutions containing as limestone samples, they were filtered on slow filtering quantitative filter paper. In the filtrate the contents of Ca and Mg were determined by atomic absorption spectroscopy. After filtering, the filter papers containing the residues were brought to the muffle at 500 ° C for one hour. By mass difference before acid attack and post muffle was found to determine the limestone residue. Data were submitted to analysis of variance and as means compared by the Turkey test ($p < 0.05$). It was observed that the RP presented higher solubility along the increase of the HCl concentration, following the RS and later the CC. Possibly due to the specific RP surface of 2.68 $m^2 g^{-1}$ in relation to 1.53 of the CC and 1.68 of the RS, which confirms the importance of the granulometry in the solubility of the agricultural liming materials. The residuals generated with the solubilization of the limestones were

adjusted as a function of the HCl concentration, it was observed that the carbonate consumption present in the RP occurred until the concentration of 0.36 mol L^{-1} HCl, RS up to 0.39 and CC up to 0.29. The higher consumption of the carbonates in the CC is related to the lower concentration of Ca and Mg oxides present in the sample. The materials CC, RP and RS presented 26, 33, 33% of oxides of Ca and Mg, respectively. Besides the granulometry, the chemical composition of the residues was also important in the solubility of the evaluated materials. The residues present great potential agricultural liming materials, mainly in the regions close to the production of ornamental rocks, reducing costs with freight, solving an environmental embarassment and improving the conditions of the soils.

Keywords: agricultural liming materials; residue management; ornamental rocks

(3644 - 3049) Technique of Restoration of Degraded Soils by Extractive Activities in the Peruvian Jungle

Gladys López[1]

Forestsoil Consultoria Ambiental[1]

The present research tackles the technique used in the recovery of areas deteriorated due to the impact caused by the exploration and exploitation of hydrocarbons in the tropical forests of the Peruvian jungle. These generate loss of vegetation cover, erosion, compaction, loss of fertility, pollution, modification of the water regime and alteration of biodiversity. The restoration of these areas has traditionally been carried out through woody forest plantations, without taking into account soil management and the adequate selection of plant species, thus extending the time and effectiveness of the restoration procedure. The objective of the study was to recover a degraded area of 9.30 ha with the appropriate technique in a shorter time to comply with the environmental commitment of the Total Abandonment Plan (TAP) according to the Peruvian regulatory framework for these activities. The technique used for the restoration of the area consisted of applying an adequate soil management (decompaction, incorporation of organic amendments fertilization and improvement of drainage) and an assisted reforestation prioritizing the use of native legume species and nitrogen fixers of the genus *Inga sp, Ochroma sp* and *Guazuma crinita* with appropriate characteristics for their development under these conditions. Likewise, maintenance and monitoring of the area by evaluating parameters of soil quality, composition, structure and diversity of the vegetation with the modified Whittaker method was carried out. As a resulting effect, there was an increase in soil pH from 3.8 to 4.72, organic matter from 0.68 % to 4.60%, potassium levels from 22 to 188 ppm, and phosphorus levels from 0.9 to 4.1 ppm. Forest species, as well, presented a growth in average height of 9.5 m, with an average basal area DCH of 132.70 cm and a better coverage and vigor of the revegetated plants which favored the increase of natural regeneration achieving 100% of plant coverage in a period of 24 months. The results of this technique's design show that the development of vegetation, water and nutrients retention, soil loss reduction, natural regeneration and biodiversity recovery can meet the environmental commitments in a short period of time, thus providing an alternative technique to the traditional method used to restore areas impacted by extractive activities in tropical forest areas.

C4.3.2 - Assessment and inventory of land use change under the SDG´s perspective

(1090 - 725) Carbon storage dynamics in sugarcane, pastures, eucalyptus, coffee and citrus in the mogi guaçu and pardo watersheds, Southern Brazil

Carlos Cesar Ronquim[1]; ivan André Alvarez[1]

Embrapa[1]

In the context of climatic changes, the observation of land use change scenarios is important to inform land use policies and also to evaluate the contribution of fitomass in carbon storage. However, information about the importance and potential for carbon sequestration by agrosystems is still scarce. Thus, assessments such as those proposed by this research are important for the scientific progress in this area. This study presents the evaluation of carbon storage dynamics in sugarcane, pastures, eucalyptus, coffee and citrus agroecosystems. The land use change and occupation was based on satellite images interpretation in the Mogi Guaçu and Pardo watershed of São Paulo state, southern Brazil and carried in two different times: 1988 and 2016. The results revealed that the sugarcane is on average capable of accumulating nine times more carbon in $t.ha^{-1}.yr^{-1}$ than other agrosystems. Sugarcane, pastures, eucalyptus, coffee and citrus has a potential to store 107.2; 11.7; 11.1; 10.3; 8.5 t CO_2 $ha^{-1}.yr^{-1}$ into biomass respectably. The expansion of the cultivated area with sugarcane, with efficient accumulation of CO_2 for area unit and time possibilited to remove of the atmosphere 128.7 million t. CO_2 in twenty six years. The results obtained can be relevant for the generation of environmental indicators and producing positive impacts on the environmental valuation of the production agrosystems.

Keywords: agrosystems, environmental valuation, fitomass, land use change.

(4845 - 976) Land use change in the farm settlement umari, lábrea, in the period of 1996 to 2011

Mariano Vieira dos Santos[1]; Heron Salazar Costa[2]; Miqueias Lima Duarte[3]

Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, Humaitá, 786, Brasil (mariano_vieira@hotmail.com)[1]; Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, Humaitá, 786, Brasil (hescosta@ufam.edu.br)[2]; Universidade Federal do Amazonas - Grupo de Pesquisa Agricultura & Ambiente, Humaitá, 786, Brasil (miqueiaseng@hotmail.com)[3]

Deforestation in the southern region of Amazonas was been increasing expansion over the past few years. This is mainly due to the expansion of agricultural projects and deployed by improper occupation areas located in the vicinity of farm settlements and roads. This study aimed to characterize the soil use change in Farm Settlement (FS) Umari, on 1996 at 2011 period. It is a farm settlement located in the municipality of Lábrea (Purus Amazonas-South Middle), created by the National Institute of Agrarian Reform-INCRA, having currently 46 family units settled, which develop traditional agricultural activity and also act in extractive production. To characterize the dynamics of land use were used pictures Landsat 4 and 5, obtained from the database of the National Institute for Space Research (INPE). The images were processed with the aid of the QGIS 2.8 software, from the supervised classification using the Semi-Automatic Classification Plugin-SCP. Also was to do a statistical analysis for the estimation of accuracy and Kappa index of classification. Than quality of the data, it was found an average of 93.56% for accuracy and 0.80 for the Kappa index. Taking the total area of the farmer settlement (9,730.80 ha), at intervals of three years, it was found the following percentage of deforested area: 14.2% (1996-1999); 15% (1999-2002); 19.7% (2002-2005); 21.4% (2005 – 2008); 24.5% (2008 – 2011); 31.4% (2011-2014). Over the period of 15 years analyzed, the increase was of 221%, being that this increase was not linear, having the following variation: 0.8%; 4.7%; 1.7%; 3.1%; 6.9%. It was not possible to correlate the deforested area increase with the increase in production, however, on the basis of March 2017, provided by the Institute of agricultural and Forestry Sustainable Development State of Amazonas-IDAM found low productivity in relation to secondary vegetation

(18.01%). Despite the FS Umari have most of your areas still covered by original vegetation; it was observed an increase in acceleration of deforestation over the last six years. Such acceleration is attributed to the opening of highways, local roads associated with the economic moment of each period. The small agricultural productivity observed does not seem to justify the increased deforestation occurred.

(1635 - 3176) Soil, Agricultural Suitability and Use at Rural Properties in the State of Mato Grosso.

Angelo Mansur Mendes[1]; Gisele Freitas Vilela[1]; Osvaldo Tadatomo Oshiro[1]
Embrapa Territorial[1]

Agriculture is the main source of welfare in Brazil. The state of Mato Grosso is probably the best example for it, with its 903 thousand km^2 covered by 3 biomes. The New Brazilian Forest Code (Brazilian Federal Law nº 12.651 - May 25, 2012) created a *Cadastro Ambiental Rural* (CAR) hosted at *Sistema Nacional de Cadastro Ambiental Rural* (SICAR), with the aim of creating a database for controlling, monitoring, environmental and economic planning, and for fighting against deforestation. The aim of this work is to identify, using a geographic information system (GIS), the soil and agricultural suitability and the land use at rural properties larger than ten 'rural modules' in the State of Mato Grosso accross its different biomes. We used ArcGIS 10.5 to geoprocess the databases on: soil and agricultural suitability by the Planning Department of the State of Mato Grosso; biomes by the Brazilian Ministry for Environment; soil use by the Brazilian National Institute for Space Research; and CAR, made available by SICAR. We considered only the properties larger than 10 fiscal modules, i.e. 16,669 rural properties registered under SICAR. The largest biome portion, Amazônia, occupies approximately 53% of the state's territory, and has 8,065 properties. The predominant soil classes in this part of the state are Oxisols and Ultisols, the main agricultural suitability classes in the management level C for agriculture use were good (23.3%), regular (39.7%), and land not recommended (20.6%), and the main land uses in 2014 were forestry (44.8%) and planted pasture (22.6%). The Cerrado biome portion occupies almost 40% of the state of Mato Grosso, has 7,910 properties where the predominant soil classes are Oxisols and Entisols, the agricultural suitability classes in the management level C for agriculture use were good (21.6%), regular (25.5%) and land not recommended (51.5%), and the main land uses were not forestry (78.2%). Whereas at the Pantanal biome portion occupies nearly 7% of the state and has 817 registered properties where the predominant soil classes were Plinthic subgoups and Alfisols, agricultura suitability were regular for native pasture and silviculture (43.3%) and good for planted pasture (19.6%), and the main land uses were not forestry (86.7%). The GIS tool enables the characterization of the large properties and may additionally serve to direct the farmers towards the best choices for areas based on the soil and agricultural of their farms.
Keywords: Biome; Geographic Information System (GIS); rural environmental registry (CAR).

C4.4 - Soil education and public awareness

C4.4.1 - Soil science education in the 21st century

(5195 - 986) An Ecuadorian case study on the relationship between student's learning styles and academic performance in soil science

Pablo Quichimbo[1]; A. Javier Aguirre[2]; Michelle Chérrez[3]; Ute Hamer[4]; Leticia Jiménez[5]
Carrera de Ingeniería Agronómica, Facultad de Ciencias Agropecuarias, Universidad de Cuenca, Av. 12 de Octubre y Diego de Tapia, Cuenca, 0101168, Ecuador; Institute of Landscape Ecology, University of Münster, Heisenbergstraße 2, Münster , 48149, Germany.[1]; Proyecto PROMETEO, Secretaría de Educación Superior, Ciencia, Tecnología e Innovación (SENESCYT), 9 de Octubre y Gil Ramírez Dávalos, Quito, 170526, Ecuador.[2]; Carrera de Ingeniería Agronómica, Facultad de Ciencias Agropecuarias, Universidad de Cuenca, Av. 12 de Octubre y Diego de Tapia, Cuenca, 0101168, Ecuador[3]; Institute of Landscape Ecology, University of Münster, Heisenbergstraße 2, Münster , 48149, Germany[4]; Departamento de Ciencias Biológicas, Universidad Técnica Particular de Loja, San Cayetano Alto s/n, Loja, 1101608, Ecuador[5]

Nowadays, there is a challenging debate about the soil science's future in education. However, several studies have only paid attention in teaching aspects of this science, while the student's learning aspects have been neglected. Under this context, if learning can be defined as a relative permanent change in the behavior resultant from the experience, then learning styles can be referred as the ways that people learn and it is a part of the broader concept of personality of each individual. Thus, having an audience of learners with a range of different learning styles and characteristics, learning tools should be designed considering the diversity of knowledge, gender, age and development of individuals. Regarding research on learning styles applied to specific sciences in institutions of higher education, there are several studies but there is no information for soil science. Consequently, this study aimed to know the differences in preferences in learning styles of students who receive introductory courses of soil science in an Ecuadorian university and to study the effect of learning styles on students' academic performance. Thus, this work can contribute to know about learning's aspects under the typical environment of Ecuadorian students, this in turn can contribute to plan future strategies to reach the best development and achievements of students and teachers. For this purpose a study based on the application of the Honey-Alonso Learning Styles (CHAEA) questionnaire was carried out to identify and relate the learning styles with the academic scores in a group of students who received introductory courses of soil science at the Faculty of Agricultural Science in the University of Cuenca from March 2015 to February, 2016. The results of this study showed that there is a general preference in students towards pragmatic and activist styles. Furthermore, there are marked differences by gender, being men more pragmatic than women, while women are more active than men, and also women showed a tendency to be more theoretical and reflective than men. Academic performance was not influenced by the learning styles, however in students who showed multimodal preferences in learning styles the academic performance was increased. These results highlight that teaching plans of soil science have to take into account the diversity of students based on their learning style preferences.

(5891 - 2354) Digital 3d elevation model and augmented reality in the study of the soil/landscape relationship in Roraima, northern Amazonia.

Marcelle A. Urquiza[1]; Valdinar F. Melo[1]; Márcio R. Francelino[2]; Luciana S. Barros[1]; Ariecha V. R. Tibiriçá[2]; Marcelo M. Santiago[2]
Federal University of Roraima[1]; Federal University of Viçosa[2]

Challenges for teaching in the classroom, in the field and in research laboratories that address the relationship between soils/landscape and their representations are a constant, due to the complex nature that permeates the environmental relations, which have spatial expression and can be modeled according to their territorial distribution. The scale in which a landscape is organized is much superior to the field of vision and perception of humans, which hinders the mental and visual conception of the observed environment, and in areas with great

territorial extension more detailed observations and nuances are naturally diminished , due to the complexity of terrain and difficulties of access, like in the Amazon environments. The aim of this work was the creation of a 3D model and the integrated use of Augmented Reality (AR) resources, in order to foster the development of teaching practices with geotechnological tools that allow the view of environmental scenarios with a different approach, specifically in the spatial distribution of land use in the area of Tepequém settlement, State of Roraima, extreme north of Amazonia. As a result, a 3D model was built in ABS-M30 material representing 370 km², in the planimetric dimensions (48x50) cm with an altimetric difference of 2.65 cm in the elevations represented by the Digital Elevation Model (DEM) processed. The Land Use and Coverage Map (LUCM) and the MDE were recreated as Virtual Objects (VO) in the ArcScene software, and then animated. These materials were associated to graphic codes (QRcodes) that provided the experience of AR, virtually overlapping the VO generated on the prototype of the printed model. The QRcodes associated with the videos allowed a virtual tour of the features generated by the MDE and LUCM, and the integrated effect of other morphometric variables and hydrography, recovering the character of innovation to the visualization of these information plans, and the incentive to teaching practices that integrate the technological bias in everyday academic life. The changes in the learning process enriched by the use of AR that allow observations with different perspectives can establish a different understanding level of the soils relation and their uses in the landscape, in a technological and playful way.

Keywords: Virtual objects; land use; environmental education; qrcodes.

(1040 - 1684) Digital game in soil education

Josiane Pacheco Menezes[1]; Fabrício de Araújo Pedron[1]; Fábio Franciscatto[1]; Rafaela Toaldo Happke[1]; Viviane Sebalhos Dal Molin[1]; Rosamari Piaia[1]
UFSM[1]

Educational software, including digital games, are important tools in education, since they present different pedagogical aspects, enhancing the learning of concepts, contents and skills, as well as promoting the development of reasoning and learning for the target audience. This research aimed to create and evaluate the performance of a computer application (digital game) on soils designed to the undergraduate and graduate students. Students of the course Integrated in Computer Science for Internet of the Industrial Technical College of Santa Maria (CTISM) and the Soil Museum of Rio Grande do Sul, both from UFSM, developed the digital game in the program Netbeans, using the language PHP, the database SQL and CSS styling. The game database has more than 250 questions in the areas of morphology/genesis, classification, mineralogy, fertility/chemistry, physics and soil biology/microbiology. The game was evaluated by undergraduate and graduate students and some teachers in the area of soil science. After this evaluation, the results indicated that the game helped the learning process, receiving a grade 8 in the importance for the professional formation of this public. In order to improve the quality of the game as well as its applicability, the public suggested the inclusion of images, score, explanations for the wrong answers as well as enabling the game for android system. The next step will be the improvement of the game for the launch of the first official release to the target audience.

Keywords: educational software; transdisciplinarity; education

(6136 - 3066) Knowledge building in undergraduate soil course: alternative methodologies during the teaching-learning process

Caroline Jardim da Silva Lisboa[1]; Aline dos Passos Silva[2]; Clécia Cristina Barbosa Guimarães[2]; Antônio Carlos de Azevedo[2]
Universidade Estadual do Maranhão[1]; Escola Superior de Agricultura Luiz de Queiroz[2]

The debate about the undergraduate teaching usually address the need of rethinking pedagogic methodologies as part of the path to better learning. The present study evaluated alternative strategies to the traditional soil science teaching method (lecturing) in undergraduate level, from a qualitative perspective. Four parallel classes, 23 to 28 students each, in Agronomy and Forest courses (freshman, 2o. semester), in Luiz de Queiroz College of Agriculture (ESALQ), at the University of São Paulo (USP), participate in classes in which seven teaching strategies: diagnostic evaluation, dialogued lecture, neighborhood exploration, concept mapping, two workshops (identification of minerals in sand fraction, and Cation Exchange Capacity with dies) and guided study. The students and the professor evaluate and were evaluated regarding the potential of such methodologies in the teaching-learning process. Among the strategies, the conceptual map was highlighted by the students as the one in which they became aware of the how fragile their understanding of basic concepts that they should mastered by that step of the course, mainly regarding sedimentary and metamorphic rocks. After a few classes, they were allowed to review the first version of their maps, and draw a new version, and this time the maps were much more detailed and richer in connections among the subjects. The study showed the need to better address and qualify the teaching learning process, both by the professor and students, and take advantage of the great variety of teaching methodologies available. In this sense, the professor should act at the interface student-science-knowledge and the student be proactive in constructing and transforming his/her knowledge.

(9377 - 1308) Learning to learn the soils: existentialist phenomenology as the foundation of a libertarian and innovative teaching.

Débora Jurado Ramos[1]; Jeani Delgado Paschoal Moura[1]; Douglas Vitto[1]; Estevão Conceição Gomes Junior[1]; Clarissa Gaspar Massi[1]
State University of Londrina[1]

In modern society, man's familiarization with the environment is done vertically, in order to enjoy it for the maintenance of unprecedented human life, denying that we, Homo sapiens, are part of nature. Unfortunately, regular education has little progress in encouraging a harmonious relationship between man and natural resources. In this sense, it was sought, in the activities described in this study, a methodology that would meet the construction of an individual who is active in his own learning, aware of his inalienable freedom and responsible for his choices. For this, the existentialist philosophical current is evoked through Sartre (1987, 2002), to understand human freedom, which according to this philosopher is a natural and inseparable attribute of men. Phenomenology complements existentialist thinking by providing us with an understanding of the lived world, showing us that harmonious living in a place, socially, ecologically and even spiritually, is intrinsic in its habitation. Thus, phenomenology allows individuals to approximate a supportive cycle by situating them in their space-times and showing them how their individual choices influence the world, and, moreover, snuggles humans back to the place. An educational model inspired these practices, the Escola da Ponte, created in Portugal, widely discussed by Pacheco (2015), which allows the student to command his learning, the organization of his educational space and the freedom to think and act. As part of the pedagogical practice, facing the structuring content Beginning, location and exploitation of natural resources, the Geography teacher asks the students: What natural resources do we enjoy? The lack of reference to the natural resource alone led to the elaboration of this study. There was no class in the conventional format, there was no adult rule, no content imposition. Gathered in groups determined by the affinity of interests about the soils, the students established their calendars of studies,

contents approached, activities, that is, they were free. The results were impressive, autonomous students, involved in the learning process, concentrated and applied. His scientific and human acquisitions have been immeasurable, which proves that it is time for a revolution in teaching towards learning to learn.
Keywords: Escola da Ponte; Bridge's School; libertarian education; soil education.

(3332 - 1107) Project-based learning and soil judging: approaches to teaching the "hidden skills" in Soil Science

Carol Smith[1]; Henry Chau[1]; Helen Gilmore[1]; Judith Van Dijk[1]; Sam Carrick[2]
Lincoln University[1]; Landcare Research[2]

Soil scientists are increasingly working in a multidisciplinary world where they interact with professionals from different disciplines; stakeholders and diverse end user groups. Successful professional interactions and positive outcomes require more than an academic knowledge of soil science. The ability to communicate; critically appraise; problem solve; and to be an effective team player are all important skills. Allied to this are the practical field skills, unique to soil science such as the ability to describe soil profiles. For the latter, the kinaesthetic approach embodied in soil judging allows the student to also connect with pedological theory; we posit that it is a pedagogically-aligned style of learning. At Lincoln University, we have adopted two approaches to address these issues. Firstly, we have developed a 300 level course which utilises a project-based learning approach. This course is based on advanced field research, whereby the students form multidisciplinary groups who choose a real world environmental "problem", and design a research project to answer the problem. Group work involves experimental design, data collection and analysis, through to communication of their findings. The groups "learn by doing". Students are assessed using a range of approaches from practical skills testing, report writing, reflective journal and presentation / communication skills. Students reported an increase in a diverse skill set: communication, critical reflection, teamwork and problem-solving skills. Secondly, soil judging has become part of the wider soil science skills which students have been encouraged to acquire at Lincoln University. While soil judging in New Zealand is in its infancy compared to other countries, the undergraduate student soil science society and academic staff members have been enthusiastic in practicing soil description skills and have participated at a range of soil judging contests. Students report that they have become more confident in soil description and that it has stimulated their interest in learning about soil science. It may also be an effective recruitment pipeline into the discipline: offering students with a practical and kinaesthetic aptitude who perform well at soil judging an insight into the academic side of the soil science discipline. Both project based learning and soil judging are effective tools for students to acquire a valuable range of skills to a professional career in soil science.

(4049 - 1143) Soil Expert Systems need On Ground Extension Experience

Packer I J[1]; Lawrie J[1]; Chapman G A[1]; Lawrie R A[1]
Soil Knowledge Network NSW[1]

The New South Wales (NSW) Soil Knowledge Network (SKN) is a small group of retired and semi-retired soil conservationists, scientists, soil surveyors and soil extension officers. The broad aims of SKN are to improve soil management and reduce or eliminate land degradation. We work as an independent partner with government and industry, largely on a voluntary basis. Among our other activities we provide soil training and workshops, produce soil videos, help formulate soil policy and support the use of legacy soil data and historical soil information. To help meet our objectives we support NSW government action on soil mapping and recording soil descriptions and data in databases. Widespread feedback from our training courses and field days indicates strong demand for practical and independent soil management advice. Despite soil electronic data/information being freely available, many land managers as well as government and professional advisors often have difficulties translating existing soil data into relevant land management decisions to meet landholder circumstances. Experienced persons in the soil extension network are growing older and few new soils staff, either in private or government agencies, are arriving to bridge the gap between often complex but essential data and useful knowledge. In these circumstances we propose that it is an ideal time to apply the knowledge of experienced extension workers to the development of expert soil management and extension systems. Given both the fundamental importance and the essentially non-renewable nature of the soil, should society continue to expand the investment in expert electronic systems, or should extension service capacity and training just be permanently increased? We argue both are synergistic and both are urgently needed.
Keywords: Soil Knowledge Network, soil expert systems, training courses, soil extension.

(7913 - 2567) Soil sampling and spatial statistics - a multi-level education experience

Guido Lorenz[1]; María Eugenia Figueroa[1]; Marcia Mabel Acosta[1]; Cecilia Zurita[1]
Facultad de Ciencias Forestales, Universidad Nacional de Santiago del Estero, Argentina[1]

Spatial variation of soils and its relevance for sampling designs are fundamental aspects for soil-related investigation or monitoring programs. Sophistication of statistical procedures during the last decades allows today for a very detailed and concise description of spatio-temporal variation of natural phenomena. In order to address these aspects in higher education, an educational project was created with the objective to get insights in concepts of spatial variation and to acquire capacities to deal with it, at under-, postgraduate and teacher level. The methodology consisted in (i) a systematic sampling of surface soil under sparse vegetation, in a 10 m x 10 m square with grid resolutions of 1 and 0.2 m, executed by undergraduate courses in Soil Science and Experimental Statistics; (ii) obtaining of fine-scale aerial photographs of the study unit, by means of a drone (Phantom 4, camera DJI FC330); (iii) analyzing of soil pH and electric conductivity in laboratory, as undergraduate activity, (iv) processing of soil and image data by means of spatial statistics, using R statistical environment; (v) training of the group of teachers in theory and techniques under R, and generation of educational material, using R markdown and the Moodle platform; (vi) continuing the undergraduate activities with class projects about soil sampling and basic concepts of geostatistics and finally, (vii) creating a postgraduate course, to be implemented in the first semester of 2018. Based on a real field experience, the undergraduate students could learn about sampling strategies and its execution, complemented by laboratory analysis of soils and interpretation of soil data. Respect to statistics, the following aspects were addressed: normality of data, treatment of non-normal data, spatial trends, spatial dependency and semivariogram, kriging procedure and causal modeling. The postgraduate course encompasses a detailed treatment of the mentioned concepts, with instruction in data processing with R statistics environment, accompanied by the reading of papers on essential topics. Due to its openness and the multi-level focus, this educational project has to be understand as a continuous, reciprocal teaching-learning process, allowing for adaption and broadening in the future.
Keywords: spatial variation, soil maps, R statistics

(9364 - 341) Soil Science education in the 21st century to generate conscience and to accomplish the sustainable development goals, and arrive to the XXII century.

Reyes-Sánchez Laura Bertha[1]

Universidad Nacional Autónoma de México.[1]

The educational projects and the Education itself depend on the public policies generated by the governments as well as on the amount of money that the governments and societies destine to educate. Nevertheless, the possibility of having public policies and investment for the preservation of the natural resources and of the life on Earth, does not depend of the government; such possibility depends on a type of education that allows the citizens to understand the need to build, boost and request that their governments create preservation policies and invest on it. Due to these facts, an education which main value is the accumulation of concepts doesn't generate governments capable of creating preservation policies, nor citizens able to boost, demand, or invest on them. Teaching doesn't mean to educate, instruction is only a part of the education, but it is not the same. Educating involves forcibly the explicit formation of values that ingrain emotionally and cognitively all the information transmitted; in this way it is possible to progressively form consciousness that will build a preservation culture in the medium and long term. When we teach sciences we transmit basic and specialized information in various levels, we teach how to use that knowledge in theory and in the practice and we teach how to use that information to do interpretations, corrections, and projections; unfortunately this doesn't create an environmental consciousness nor builds a preservation culture that supports sustainability for our planet. If we want to create a knowledge that has a citizen culture within and that reflects in a culture of preservation of the natural resources as a building block for development, we do not need to instruct the citizens on the science of natural resources; what we need is to educate them to preserve those natural resources as indispensable elements for life itself. The really important is to explain to each citizen why the natural resources are important for them and why its loss affects us all without importance of the social class where we belong. The main idea is then that the knowledge that is taught has the purpose of PRESERVATION for the achievement of the SDGs. The Education is, as explained, the most important public policy in order to preserve the soil and all the natural resources and thus the life on Earth. The question of how we pretend to educate with this purpose and through what strategies? will be addressed during the presentation.

Keywords: Soil; sustainability; education.

(5988 - 1923) Trump Cards: Super Soil – a tool for teaching about the classification and use capacity of soils

Larissa Pinto Seiberti[1]; Amanda Duim Ferreira[1]; Fábio Ribeiro Pires[1]; Graziela Evencio de Oliveira[1]; Kerwin Araújo Costa[1]

Universidade Federal do Espirito Santo[1]

Soils are an essential component of the biosphere, performing key ecosystem functions and providing the foundation and nourishment for terrestrial food, fiber, and biofuel production. The challenge of the soil education in the soil science is create tools that promote children's interest in the type of soil on their feet and also create awareness that each type of soil has adequate capacity for use and management. Our objective with the cards game Super Soil is exactly it: to promote the capacity of discern which soil attributes result in soils suitable for each use. The trump card game model is perfect for this use as it encourages comparison and has the potential to transmit ground science concepts in a simplified way, which makes learning intuitive. Top Trumps® is a card game traditionally played between two or more people. Each card lists numerical data that players compare with the aim of 'trumping' their opponent by having a greater value. The winner gains the opponents card(s) with the game continuing until only one player holds all the cards. The trump card game has already been used for educational purposes with various themes: trumps game "Plants, drugs and medicines" was produced as a result of a Science and Plants for Schools (SAPS) award; "Bacteria, virus and cell trump cards" was produced by Centre of the Cell and "Micro Trumps", a microbial card game, by the Chilled Food Association. In Brazil, the authors of this abstract found little use of the trump card for educational purposes, an example being the adaptation of Grow's Super Trunfo® game, developed by Gonzaga et al (2017), that compares chemical elements based on the periodic table. The game Super Soil was developed for the 1st Soil Education Week, held in 2015 at the São Mateus Campus of the Federal University of Espírito Santo, where 353 students from the municipal school system attended. Our game has 30 cards and shows all 13 class of soil that occur in Brazil, according to the third edition Brazilian System of Classification of Soils (SiBCS, 2013). We chose to present the soils up to the second level (order) in the classification to show that even within a single class the soils are different and leave the presentation of the game, especially the nomenclature of the soil, less heavy. Soil science, especially the soil classification, is a very academic and scientific discipline, so we propose with this game make learning about soil classification more dynamic and interactive.

Keywords: Soil education, game, pedology

(4343 - 649) Very Low Competence of Scientists and Technical Personnel in Central America is a Critical Limitation to Advance in Soil and Plant Nutrition

Armando Tasistro[1]; Axel Schmidt[2]

Soil Science Advisor, Catholic Relief Services, Watkinsville, Georgia, USA[1]; Catholic Relief Services, Latin America and Caribbean Office, La Molina, Lima, Peru[2]

Restoring soils' health and advancing more sustainable agricultural systems demands highly competent technical personnel with effective holistic visions of the systems. In large parts of Mexico and Central America, however, the level of expertise in soil science and agronomy is extremely low, virtually at all levels: public or private sector, national or international, educational, research or extension. The seriousness of this situation has been largely neglected, particularly by decision-makers. Most of the time perceived educational needs are intended to be fixed with short courses taught by whoever is available, with erratic results at best. This state of affairs is specifically grave in soil science, which has been affected by a global decline since the 1980s. The number of qualified active soil scientists in the region has been reducing steadily compared to other professions. Thus, many key positions in education, research, and technology transfer are in the hands of staff without specific formation in soil science, which might explain the inability to realize the tremendous shortcomings that we are facing. Catholic Relief Services (CRS) has been working for the last three years in the Program "Agua y Suelo para la Agricultura (ASA)" (Water and Soils for Agriculture) in Guatemala, El Salvador, Honduras, and Nicaragua, and more recently in Oaxaca (Mexico), to promote increased sustainability in agro-ecosystems, restore soil health, and improve water use efficiency. Technical staff are continuously involved in in-service educational activities, so that in addition to the inherent value of their work for the Program, they can learn the practical application of taught theoretical concepts. This valuable link between theory and practice, is sorely missed by our agronomy graduates. The big challenge is clearly how to improve the integral formation of our agronomists, which implies reinforcing science-based instruction throughout all the educational system. Graduates need to be able to think critically using evidence-based methods in order to identify and prioritize problems, as well as their possible causes and solutions by means of hypothesis testing. This must go along with the teaching of the right contents, which is normally assumed to be the case, but not supported by the evidence. One way that CRS is supporting these efforts involves a regional MSc Program in

Soil Science with key universities in Guatemala, El Salvador, Honduras, and Nicaragua.

C4.4.2 - Soil education and public perception of soils

(6566 - 3002) Comprehensiveness in the forms of soil perception through educational institutions, traditional peoples and family agriculture in certain regions of Mato Grosso, Brazil.

Willian Marques Duarte[1]; Fernanda da Silva Ferreira[2]
Escola Técnica Estadual de Educação Profissional e Tecnológica de Diamantino[1]; Universidade do Estado de Mato Grosso[2]

The work is inserted in a national context where the education focused on the areas of agrarian and biological sciences perpasses by the study of the soil, and how this is fundamental for the survival of the living beings of planet earth. For it is from him that we extract the natural resources like: water, forest, ores, oil among others. Thinking about academic centrality and the importance of Soil in food production is that it is necessary to reflect on educational aspects arising from studies done by Soil Science. In this sense, the present work starts from activities developed since 2012. The objective was to verify the perception about the meaning and importance given to the Solo in this context. The methodology used included the insertion of learning activities (workshops, courses, lectures, studies, data surveys, reflections, mutirões, local research) that could address topics such as environment, soil degradation, burnings, soil cover, enrichment with organic matter, consortium, cultivation of vegetables, agroecological vegetable garden, medicinal plants, soil preparation, creole seeds, green fertilization, biological nitrogen fixation, protection of springs and rivers, among others. These activities were developed in the Agronomy courses, Federal Institute of Mato Grosso-2012 and in the State University of Mato Grosso-2013-2016, Civil Engineering (University of the State of Mato Grosso-2013), Technologist in Agroecology (University of the State of Mato Grosso-2016). And classes of Agricultural Technical Courses (Technical State School of Professional and Technological Education of Diamantino-2017) and Agricultural Technician (Federal Institute of Mato Grosso-2012), for these the soil has as main proposition the scientific production, research, development of technologies and inputs, being a resource that can make a profit and a substrate for food production. In the perception of the indigenous peoples (Tangará da Serra, Campo Novo do Parecis, Sapezal), family farmers and settlers (Caceres, Tangará da Serra, Diamantino, Cláudia, Sinop, ribeirinhos (Cáceres), quilombola people (Barra do Bugres) It is important to note that the two perceptions are extremely important, the line of thought of educational institutions is aimed at more efficient technologies in the food production and profit, and traditional people and family farmers see the soil as a place of living and food production for sustenance.

(1088 - 2043) Demonstration of the magnetic characteristic of Perferric Rhodic Oxisols for educational purposes

Clarice de Oliveira[1]; Maria Lídia Novaes Correa[1]; Gilberto Silva Rocha[1]; Marcos Bacis Ceddia[1]
Universidade Federal Rural do Rio de Janeiro[1]

Magnetism is a characteristic of soils associated with the presence of ferromagnetic minerals, being important for the indirect quantification of chemical, physical and mineralogical properties of the soil. In Brazil, magnetic soils occupy a significant area, estimated at about 5% of the surface of the country and, in most cases, they are of great economic importance, considering the relatively high potential for agriculture. The objective of this work is to demonstrate, in a didactic way, the magnetic properties of a Perferric Rhodic Oxisol by means of magnetic soil boards, made from a sample of the Bw horizon of a Perferric Rhodic Oxisol. The soil was collected in the municipality of Nova Lima, Minas Gerais State, Brazil, with a Fe_2O_3 content of 480 g kg^{-1}. In the laboratory, the soil sample was air dried, gently ground and sieved to 4 mm to be used for the preparation of the magnetic board. The wooden board(50 cm x 40 cm) was covered with cotton cloth and a thick layer of PVA glue was applied to the surface. A soil sample was evenly distributed on to the surface of the glue. After drying, this procedure was repeated until a soil sample layer of 0.7 cm thickness was obtained on the board. Then to reinforce the cohesion of the soil sample to the board more glue was applied weekly ; 100 ml of glue diluted in water, at a ratio of 1: 5, for a period of two months. In these soil board neodymium magnetic discs (10 X 1 mm N35) were positioned and adhered to the board demonstrating the magnetism of the soil. These materials are part of the didactic collection of the Museum of Soils of UFRRJ.

(8867 - 3072) Evaluation of geography and agronomy students on pet didactic materials presented in the science of the earth office of pet solos

Amanda Dias dos Reis[1]; Aline Roma Tomaz[1]; Maíra do Carmo Neves[1]; Ana Maria S. S. Moreau[1]
Universidade Estadual de Santa Cruz[1]

Environmental Education has as one of its aspects the Education in Soils, which has the fundamental role of raising and consolidating awareness on this resource. Therefore, based on the assumption that the task of soil education is not always easy, and since it is composed of a highly complex content, the implementation of teaching materials is fundamental as one of the tools to stimulate in students the importance of this knowledge and make them more aware of the need to review and re-establish the values and attitudes attributed to this resource. In this way, this paper aims to evaluate the efficiency of didactic materials presented at the Earth Science Workshop by PET Solos, through the Agronomy (AGR) and Geography Degree (GL) students of the State University of Santa Cruz - UESC. To obtain the data, a questionnaire was developed and applied to a sample of 18 students in Geography Teaching major and 12 students in Agronomy major, who participated in the Earth Science Workshop, presented by the PET Solos students. This workshop was divided into the following thematic axes: Origin of the Earth, Petrology (rocks), Formation of the Soil and Use and Conservation of Soil. Among the GL and AGR students, 94% and 83%, respectively, stated that the way the contents were approached in the workshop allowed them to understand the sequencing of the subjects covered in Earth Science. Among these same students, 100% stated that the didactic materials made it possible to understand the contents covered in each of the thematic axes. The models are one of the most cited materials: mentioned by 37% of the students in GL and 44% of those of AGR. According to reports of GL students, 37.5% agreed that didactic materials such as Earth globe, model of tectonic plates, experiments of convection current and volcanic eruption were the ones that most aided in understanding the thematic axis Origin of the Earth. Meanwhile, 43.4% of AGR students stated that mineral samples, rocks and weathering experiments contributed the most to understanding the thematic axis Petrology (rocks). In summary, it was possible to understand that the use of didactic materials in the Earth Science Workshop, contributed to the understanding of soil contents to students of Geography and Agronomy Degrees.

(6567 - 3055) Evaluation of the level of knowledge in pedology of the concluding students of the agronomy degree of the state University of Santa Cruz

Maíra do Carmo Neves[1]; Aline Roma Tomaz[1]; Amanda Dias dos Reis[1]; Ana Maria S. S. Moreau[1]
Universidade Estadual de Santa Cruz[1]

Bachelor's degrees in Agronomy or Agronomic Engineering must qualify their graduates so that they can make a reasonable and rational use of the resources available, with respect to the environment, promoting a balance between the production of food and the use of these resources. Within the curriculum frameworks of these degrees, the study of Soil Science comprehends a set of subjects that represent fundamental importance for the formation of the students, seeking to demonstrate the usefulness of the soil and its relationship with man. Pedology is understood as a branch of soil science that deals with studies related to different contents and is based on multidisciplinarity, studying the soil in its natural environment, and its interaction with the environment. The syllabus aims on the training of professionals with the potential to conceptualize soil in the pedological vision, identifying its different components and interpreting its diagnostic attributes; explaining how each factor and process contribute to the formation of soils in different environments, classifying them according to the Brazilian Soil Classification System (Embrapa, 2013) for environmental and agricultural planning and use. Therefore, this research aimed to evaluate the importance and the level of knowledge in Pedology of students graduated in Agronomy of the State University of Santa Cruz. Data were collected through the application of a questionnaire, composed of ten objective questions, to 10 students, which addressed the importance and application of several concepts related to Pedology. This is a quantitative approach, with a descriptive character, with the main objective, according to the literature, describing the characteristics of a given population. The analysis of the answers showed that 100% of the students consider Pedology knowledge important for their academic formation. Amongst these, 83% can identify the inherent aspects of soil formation factors, but 50% have difficulties in differentiating formation processes and diagnostic horizons, which may complicate soil management activities. Despite this, 100% of the students have high knowledge about the environmental problems resulting from the inadequate management. With this, we can conclude that the students have a small perception about the different diagnostic horizons of the soil, and that Pedology constitutes an important subject for the Agronomy degree.

(9798 - 2687) Perception regarding the importance of soil by middle and high school students from public schools in Northeastern Brazil

Carolina Malala Martins Souza[1]; Daniely Formiga Braga[1]; Lunara Gleika da Silva Rêgo[1]; Francisca Elisângela Maniçoba[1]; Gilson Dias Costa Filho[1]; Rodolfo Martins Formiga Fernandes[1]; Matheus Rodrigues de Oliveira[1]; Priscilla Ribeiro de Oliveira[1]
UFERSA[1]

Public perception in Brazil about soils and its importance as an essential mean to support the life on Earth has increased when compared to a few decades ago. Combined with the traditional and recognized soil functions, such as food, fiber and energy production, especially in a country with an agricultural vocation such as Brazil, this increased comes from the work on soil education that is being developed in the country. The objective of this work was to establish a constructive dialogue about soil science knowledgements with middle and high school students from public schools in the municipalities of Governador Dix-Sept Rosado and Caraúbas, Rio Grande do Norte state, Brazil. Students from all urban and rural schools of each municipality were selected, with a total of 60 students. The work consisted of three steps: 1st) application of a questionnaire with general questions about soil science; 2nd) theoretical and practical explanation on the main concepts and functions of the soil; 3rd) reapplication of the same questions that were applied during the first step. Most of the students were not able to respond satisfactorily the questions on the first step. Misconceptions about the soil formation were common for both municipalities. After the theoretical and practical explanation and reapplication of the same questions, the answers came to include the basic concepts that were commented during the presentations, such as: "the soil has O, A, B and C horizons" or "the soil is composed by sand, silt, clay and organic matter". When questioning about the importance of soil, the answers indicated an understanding about the importance of soil as an essential component for the life in the Earth since the first questionnaire was applied. Statements such as: "soil is important for all of us" and "soil is important for the survival of animals" were given both in the first and third step. When confronting the answers of the initial and the final step, the greatest change occurred in relation to the knowledge about the concept of soil. This indicates that despite not having more specific knowledge about soil, it is understood that soil is important for life. After the explanation the students were able to write what was approached about soil science in a clear and logical way, making it possible to understand that the initial construction of knowledge was accomplished. More actions are needed to strengthen the basic concepts of soils and their importance for the life.

(9533 - 2997) Soil Education in Northeastern Brazil, "Maciço de Baturité" Region: instruments and awareness

Susana Churka Blum[1]; Rosemery Alesandra Firmino dos Santos[1]; Smaiello Flores da Conceição Borges dos Santos[1]
Universidade da Integração Internacional da Lusofonia Afro-Brasileira[1]

Compared to other ecosystem components, soils are a natural resource that still had received little attention from general population. Primary and secondary schools are important resources for public awareness, reinforcing the role of universities in extension programs. From Agronomy students at UNILAB (Universidade da Integração Internacional da Lusofonia Afro-Brasileira), less than 5% had already had contact with the topic soil, supporting the importance of this work. During August 2016 to December 2017 we conducted a project aiming to produce and collect several didactic materials such as banners, experiments, lectures and workshops and to visit primary and secondary schools to talk about soils and their role in ecosystem and how its use affect our daily lives. Eight schools were visited in the municipalities of Redenção/CE, Barreira/CE and Acarape/CE, reaching a total audience of 345 students in ages varying from 8 to 20 years old. All schools visited were marked by a participative lecture and the development of simple experiments about soil formation, soil composition and soil conservation. In all visits, we applied a survey to verify the effectiveness of the process. We also conducted an exhibition to celebrate the National Day of soil Conservation (15/04/2017) at UNILAB. The visits were successful for student's awareness mostly about soil conservation and soil pollution. The State of Ceará in Northeastern Brazil and the "Maciço de Baturité" region still uses few conservation practices for soil management, being slash and burn a very common practice for land preparation. In urban areas, we still lack sewerage systems and proper waste disposal. Some challenges faced during the course of the project were the lack of interest from teachers in schools, since often the teachers responsible for environment-related topics have no specific formation for that. In the next project phases, we will focus on short courses to attend these issues.

Keywords: Ecosystem, primary schools, soil management, soil conservation, soil and society.

(8681 - 596) Soil in Environmental Education and the implementation of sustainable practices in Public Education of Belém, Pará.

Regilene Angélica da Silva Souza[1]; Dênmora Gomes de Araújo[2]; Selena

Mara Jesus Dias[2]; Maria Goreth Soares Teles[2]; Herika Gonçalves Soares[2]; Lia Rosa Cardoso de Loureiro[2]
Universidade Federal Rural da Amazônia, 2501 Avenida Presidente Tancredo Neves, Belém, 66077-830, Brasil (regilenesouza@yahoo.com.br)[1]; Universidade Federal Rural da Amazônia, 2501 Avenida Presidente Tancredo Neves, Belém, 66077-830, Brasil[2]

Soil is an important natural resource for life on earth, but misuse has caused serious impacts by compromising its functions in the environment. One of the ways to sensitize and raise awareness of its importance is through soil education, mainly in basic education. The objective of this study was to verify the knowledge of elementary school students about the concept, importance and functions of soil in the environment, as well the implementation of sustainable land use practices. The study was developed at the State School Virgílio Libonati and is part of "A Prática da Educação Ambiental no Ensino Público de Belém – PA" Project. The methodology adopted was the use of lectures with didactic materials and painting workshops, construction of gardens, vegetable gardens and seed planting. The classes were taught throughout the year of 2017 and integrated the discipline Natural Sciences. The work was carried out in the 1st to 5th grades of elementary school, formed by children and teenagers of low income. As result, students' interest in the soil theme was observed, which was demonstrated by participation with questions and answers. The presented didactic materials facilitated the understanding about the soils and the importance of the correct use of this resource. The workshops allowed the students contact with soil, being qualified as satisfactory. The students learned how to make paints from soils, which began to be used in painting activities; they knew and planted different seeds of agronomic and forestry importance; accompanied the construction of the garden and vegetable garden, and plant growth; and have learned about the importance of healthy foods to have a healthy life. The products grown in the garden have been used in school meals. Moreover, the garden has contributed to the well-being of students and school staff. In conclusion, the project's actions allowed the students basic knowledge about soils, awakening the sensitivity and awareness of children and teenagers regarding the importance of this natural resource by stimulating environmental perception and sustainable practices, also considering the Amazonian environment.

(9013 - 2691) Soils and environment: Conception of students from a rural and an urban school

Viviane Terezinha Sebalhos DalMolin[1]; Eva Cristiane Cortelini Gabriel[1]; Ricardo Simão Diniz Dalmolin[1]
Universidade Federal de Santa Maria[1]

In the Brazilian educational system, there is a proposition of sociocultural contextualization associated with the representation and communication between those involved in the pedagogical practice. Soil education, as a transversal theme in teaching, offers the possibility of contextualizing scientific knowledge addressed in the classroom with sustainability themes. The objective of this work was to analyze the conceptions about soils from students of a rural secondary school (RS) and an urban secondary school (US), as well as the alterations in knowledge, after interventions about topics related to soils and the environment. The work was developed in three stages, as follows: 1. Initial questionnaire (Qi); 2. Seminar on Soils and Environment (Ss) and 3. Reapplication of the questionnaire (Qf). 23 RS and 76 US students participated in this research. For the systematization of the responses, the methodology of content analysis, based on the categorical analysis, was adopted. The conception of soils was one of the issues addressed. The category: *Place of cultivation* was the response of 42.5% of the RS students in Qi and 33.4% in Qf. For US students, the values found were, respectively, 24.7% and 30%. The category: *Place to be preserved*, the conception was of 22.5% in Qi and 24.25% in Qf for RS students and 3.5% in Qi and 5.1% in Qf for US students. These results reinforce the difference in crop production and land use in the different realities. Another category observed was *The place where we stepped*, is the response of 27.5% of the RS students in Qi, and zero in Qf. The result found for US students in this category was 44.7% in Qi and 25.5% in Qf. *Soils as the foundation for life* was one of the answers found only in Qf with 33.4% in RS students and 20.4% in US students. In both schools, it is possible to notice that the conception of soils presented a greater comprehension after the Ss. The relationship between soils and Environmental Education was also discussed in Qi and Qf. For RS students, considering Qi and Qf, 92% and 95%, respectively, they believe in a relationship between these factors. For US students, 62% and 70%, respectively, they consider that the factors are interconnected and complementary. The results show that there is a different view about soils, their use, and preservation in these two groups of analyzed students. Soil Education can be an important pedagogical tool to corroborate in the re-signification and globalization of education.

(9771 - 3051) Survey on teaching, research and extension activities performed by pet solo between the years of 2011 and 2017

Aline Roma Tomaz[1]; Amanda Dias dos Reis[1]; Maíra do Carmo Neves[1]; Ana Maria S. S. Moreau[1]
Universidade Estadual de Santa Cruz[1]

The PET-Solos of the State University of Santa Cruz was implemented in 2011, being the first PET in the area of Brazilian soil. Currently it is composed of seven Agronomy and Geography Bachelor students with scholarships and the tutoring of a teacher. Within PET the student is offered the opportunity to work with teaching, research and extension, since PET is based on the development of this tripod in Universities and College Institutions. According to the Basic Guidelines Manual (2006), the articulation between teaching, research and extension allows a global training of both the student who receives a scholarship and other students of the major, providing a more complete understanding of what happens to himself and in the world. The aim of this project was to conduct a survey of the research, teaching and extension activities performed between the years of 2012 and 1017, by the PET-Solos of the State University of Santa Cruz. The activities developed by the group are based on the tripod, teaching, research and extension, and they are constituted in: Earth Science Workshop (OCT), Cycle of lectures (CP), collective and individual research, besides participation in the Science Truck (CC), National Science and Technology Week (SNCT) and SBPC. To obtain the data, a search was made using the logbooks with the activity records. From the survey it was obtained that between the years of 2011 and 2017, PET-Solos, attended through the CC 1723 people, OCT 2942 students from private and public schools, held 11 courses, 25 lectures, contributed to the scientific progress with the production of 49 academic papers, presented at Soil Science events. In addition, there was participation in the SBPC in 2016 and SNCT in the years 2011, 2012 and 2014, attending a total of 902 people in the latter. Therefore, it is evident that the PET-Solos of the State University of Santa Cruz has contributed to the spread of soil science, as well as its popularization besides contributing to the training of undergraduate students of the Agronomy and Geography majors in the Institution.

(9881 - 2486) The soil in an interdisciplinary approach through chemistry teacher training

Ednalva Dantas Rodrigues da Silva Duarte[1]; Valdinar Ferreira Melo[1];

Maria Lúcia Taveira[1]; Viviane Araújo Cardoso[1]; Augusto César Rodrigues Santos[1]; Kaio da Silva Vieira[1]; Ronilson José Pedroso Amorim[1]; José Frutuoso do Vale Júnior[1]
Federal University of Roraima[1]

The soil is one of nature's elements which is little explored by chemistry teachers in the approach to contents in High School and Higher Education, despite its importance for the life of man and nature. This study reports the experience gained from a program developed in 2017 to spread and promote this element. The focus of the study is the soil found in the lakes, buriti (*Mauritia flexuosa L.*) paths at Boa Vista's savannas, Brazil. The program was developed with the students of the discipline QA236 Internship Supervised in Chemistry IV and professors of the Degree in Chemistry-CLQ of the Federal University of Roraima - UFRR. The objectives were to spread and promote the study of the soil, as well as to know the perception of students and teachers about the subject, that is, chemical approach of the soil and its interactions with the environment. In order to reach these objectives, a guided tour was conducted at the Roraima's Solo Museum-MSRR, belonging to the Agrarian Science Center of UFRR, which enabled visual and sensorial contact with the soil profiles of Roraima and the discussion of the concepts of Chemistry and Soil Science, as well as common sense knowledge. The students were asked to make a text referring to the use of the soil as a transversal theme in the approach to the contents of Chemistry, as well as to take the students of the High School to visit the MSRR. With the accomplishment of these activities it was possible to raise a greater interest in the study of the interdisciplinarity between Chemistry and Soil Science, the perception of the relation between the soil and the landscape formed by the lakes and buriti paths, and to provide the chemistry's professors and to the CLQ's students a formation committed to the change of values and attitudes towards the soil, in order to contribute to the promotion, conservation and sustainable use of biodiversity.

(4366 - 369) Utilization non-formal education for the teaching-learning process of soil in the Manaus metropolitan region

Jean Dalmo de Oliveira Marques[1]; Elizalane Moura de Araújo Marques[1]; Juvenal Severino Botelho[1]; Alexandre Nicolette Sodré Oliveira[2]
IFAM[1]; SEMED[2]

The teaching of soil in non-formal spaces can to make a significant role in understanding of soil contents being a viable alternative for improvement in the teaching-learning process. The objective of this study was to investigate the contributions of non-formal spaces to the teaching-learning process of soil. It was developed in the metropolitan region of Manaus with 30 undergraduate students. The research is of the qualitative type and it was developed from the accomplishment of intervention activities characterized by dialogic expositive classes and practical activities in the field. The instruments of data collection used were questionnaires, field guiding script and image registration. The areas visited were: BR-174 (at km 5,12,44 and 51) (2^{o}56'S and 60^{o}02'W), Future Avenue (03º06'S and 60º01'W) and in the Brasil SokaGakkai Association at Ponta das Lajes (03º08'S and 59º52 'W). In the visited spaces, were identified and discussed thematic related with pedogenetic processes as: Laterization (km 5, Podzolization, km 12, new kaolinite, km 44, Clay Neoformation, km 51) both along BR-174; characteristics of Oxisol (Future Avenue) and rock of Alter Chão Formation, oxisol cliff, antropic soil and new caulinita), both at Ponta das Lajes. The results showed that the strategy of using non-formal spaces for soil education contributed significantly to the teaching-learning process. 85% of the students reported that they better understood the contents trained in the classroom after the field practice in the non-formal spaces visited. With the field practice it was possible to resignify concepts trained in the classroom, in addition to improving the understanding about the knowledge approached. But only using these spaces is not synonymous of success in teaching. It is necessary for the teacher to lead the classes in a dynamic perspective, not isolated, challenging, reflexive, regionalized, contextualized with regional factors and processes integrating rock-soil-landscape.

C4.4.3 - Placement and accreditation of soil science in the workforce related to natural resources

(3204 - 3229) Maanaim environmental: environmental education in practice.

João Luiz Lani[1]; Julio César Costa[2]; Marco Aurélio de oliveira Ribeiro[3]; Agnaldo Roberto de Jesus Freitas[1]
Department of Soils, Federal University of Viçosa[1]; General Administrator of the Sustainable City of Maanaim[2]; Direct responsible for the Sustainable City of Maanaim[3]

Over the last few years more than 1,200 children from different parts of Brazil and abroad have received and experienced in practice important concepts of Environmental Education in the Atlantic Florest Biome in the city of Marechal Floriano, ES, with theoretical and practical education. This place, called MAANAIM, with the frequency of approximately more than 3,000 people in fortnightly meetings, is already known as CITY MAANAIM SUSTAINABLE because of its housing complexity and the practical solutions adopted. Pleasant place, with excellent landscaping, where there is wise and architecturally intertwined interaction between man and nature. This aspect is one of the highlights. The effective actions are the result of working teams of different professionals from all over of Brazil and voluntarily with modern practices and concepts of rational and sustainable use of natural resources are applied. They are professionals specialized in the most diverse areas that interact and look for suitable solutions. Among the innumerable actions, each one of which seeks harmony between nature, beauty and spiritual, the following stand out: a modern project of garbage collection with recycling, plantings of more than 10,000 native tree seedlings in the areas of degraded pastures; use of rainwater for internal use; modern techniques of recovery of springs; interaction of residences and lodgings with vegetation; wildlife refuge, food waste control; modern techniques for using commonly used water such as automatic faucets in drinking fountains and toilets; treatment and reuse of waste water - ETE; implantation of the living museum (boards using QRcode) and distribution of didactic material (Play and Learn booklets). In this place the children are welcomed and remain for a day or more and participate in excursions in each one of the actions, first aid training with firefighters, in an instructive process where apply learning to do and to do to learn. They are explanations of each activity or solutions with lectures with professionals of high university level on the environment and also participate effectively in the planting of native trees in places of recovery of degraded areas. These actions of environmental education and citizenship have brought countless results through the testimony of family members and the community in which they live and even observed improvements in behavior, as responsible for environmental actions and surveillance in the SUSTAINABLE MAANAIM CITY.

(4682 - 1718) Reflections on the Gender Distribution and Parity of U.S. Soil Scientists

Chelsea Duball[1]; Karen Vaughan[1]; Amanda Pennino[1]; Yamina Pressler[2]; Eric Brevik[3]; Caitlin Youngquist[4]; Lorenne Lynn[5]; Samantha Ying[6]; Pam Thomas[7]

University of Wyoming[1]; Colorado State University[2]; Dickinson State University[3]; University of Wyoming Extension[4]; Red Mountain Consulting[5]; University of California, Riverside[6]; United States Department of Agriculture[7]

Most soil scientists have a personal impression about the distribution of female and male soil scientists in the United States. Until this time, no data were readily available to guide a discussion on the state of gender parity within soil science. In order to determine the gender distribution, data were collected on the gender of individuals employed by the federal government as soil scientists, academic faculty in soil science, private consulting soil scientists, professional society membership in soil science, and graduate students studying soil science. Unsurprisingly, we found that women make up approximately 27% of the professional soil scientists within the employers and groups stated above. Female federal soil scientists make up 26% of the workforce with greater percentages in the middle grades (9 and 11) than in the lower (3 and 5) and upper (12, 13, 14, and 15) grade levels. The overall distribution among soil science faculty is 24% female, however, distributions varied across faculty level, with assistant, associate, and full professors being 36%, 24%, and 18% female, respectively. Faculty gender distribution also varies considerably as a function of sub-discipline, ranging from 13 to 51% female for soil fertility specialists and soil ecologists respectively. Professional soil scientists in consulting positions are approximately 26% female, however, these data are more challenging to collect without a centralized database or uniformity in job titles. Twenty-seven percent of the membership of the Soil Science Society of America is female with 26% and 11% of division chairs and board representatives being female respectively. The gender distribution of graduate students studying soil science is more evenly split with 54% female M.S. students and 53% female Ph.D. students. With these data in hand, we can begin to unfold the complexity of gender equity in soil science, examine what gender parity should look like in soil science, and identify steps, if necessary to obtain parity.

(7419 - 3199) Regional Cooperation and Soil Awareness Raising for Sustainable Soil Management in Alps – the EU Interreg Links4Soils Project

Borut Vrščaj[1]
Agricultural Institute of Slovenia, Department of Agricultural Ecology and Natural Resources, Ljubljana, Slovenia[1]

The contribution discusses and points-out the importance of soil awareness rising and trans-border cooperation for better management and protection of soils. A self-reflection of a 'soil person' that deals with soils, land uses, soil quality and soil information quite some time, reveals the fact that soil science is still not successful enough in conveying the product of soil research (soil knowledge, soil information, soil awareness) to a variety of end-users of different sectors. At the same time it was recognised that recent global and regional soil awareness rising, a very much needed activities, are too often (or traditionally?) neglected by soil scientists, soil experts and even professors of soil science. The contribution presents the EU Links4Soils Interreg project that aims to mitigate sustainable soil management gaps by improving the systematic applicability of the Soil Protection Protocol of the Alpine Convention by raising awareness on soils amongst observers and stakeholders of different sectors. In particular, it focuses on linking (soil) experts and decision makers, creating a trans-border community dedicated to soil protection within a specific European region – the Alps. The important project aims are collection of existing Alpine and national soil data to generate user-friendly and applicable soil information, transfer of soil knowledge and best soil management and protection practices to policymakers and other stakeholders, and promotion of efficient soil protection strategies through the web-based Alpine Soil Platform. Very important project goal is the establishment of the Alpine Soil Partnership, a voluntary community of individuals, institutions, administrative bodies, soil experts, public servants, experts, NGOs and environmentalists committed to soil protection and sustainable management of Alpine soil resources. The Links4Soils project aims to generate an example of regional and transborder cooperation on sustainable soil management and protection in environmentally specific area (Alps) of six EU countries (Austria, Germany, France, Italy, Switzerland and Slovenia) and to act as a sub-regional initiative following the Global and European Soil Partnership, important soil awareness raising and soil protection activities coordinated/lead by the FAO.

(6187 - 1625) Genesis and diversity of loamy soils in Middle Taiga Zone of Siberia

Golovleva Iuliia[1]; Krasilnikov Pavel[2]; Korkina Elena[3]; Konyushkov Dmitry[4]
Lomonosov Moscow State University, Departments of Soil Science, Leninskie Gory 1, building 12, Moscow, 119991, Russia (Julango85@gmail.com)[1]; Lomonosov Moscow State University, Departments of Soil Science, Leninskie Gory 1, building 12, Moscow, 119991, Russia[2]; Nizhnevartovsk State University, Faculty of Ecology and Engineering, Dzerzhinskogo Street 11, Nizhnevartovsk, 628615, Russia[3]; V.V. Dokuchaev Soil Science Institute, V.V. Dokuchaev Soil Science Institute, Pyzhyovskiy lane 7, building 2, Moscow,119017, Russia[4]

Pedogenesis in Siberia occur in cold environment, and in the past the climate was even colder and permafrost was more common than now that implies the development of cryogenesis both in the present and in the past. The presence of texturally differentiated and practically undifferentiated soils at relatively short distances may be explained by the differences in hydrothermal regimes, which depend on topography, lithology and vegetation of particular sites. We aimed at revealing the dependence of processes leading to the formation of textural differentiation in loamy soils in the Middle taiga zone of Siberia on past and present pedoenvironments. The research was done in Western and Eastern Siberia. Western Siberia is characterized by flat topography. The climate is moderately cold with mean annual temperature -4 -2°C, mean January temperature -20°C and mean June temperature +18°C. The annual precipitation is 580 mm. The area has insular permafrost. Central Yakutia (Eastern Siberia) is located on plateau. Its climate is more continental with mean annual temperature -10.2°C, mean January temperature -38,6°C, and mean June temperature +19,5°C. The annual precipitation is 238 mm. The area has continuous permafrost. Both are covered with taiga forests with larch, pine and Siberian pine. The parent materials of the studied soils are loams, sandy loams, sands of alluvial and ancient alluvial origin. Soil pits on the Severo-Sosvinsk Upland, the Agan Uval, the left bank of the Kiryas's distributary in Western Siberia and the Prilenskoye plateau in Yakutia were studied. Soils is brownish and pale colors with specific caviar and cryo-platy structures, which are typical for permafrost-affected soils. Micromorphological study of soil thin sections in transmitted and reflected light showed the presence of rounded aggregates. Soil pairs with and without textural differentiation were identified as Cambisol and Alisol in Western Siberia, and Cryosol and Planosol in Eastern Siberia. We hypothesized that as a result of divergent evolution under similar conditions, there was a discrepancy between the types of soils studied. The texturally differentiated loamy soils can be formed in warmer areas and earlier thawing, and are characterized by leaching water regime practically throughout the growing season. In recent decades, global climatic changes have been observed, which have an impact on current soil formation, and can lead to increased differentiation processes in soil.

(7864 - 445) Greenhouse gas fluxes from forest soil in an upland black spruce stand in interior Alaska

Tomoaki Morishita[1]; Kyotaro Noguchi[1]; Yojiro Matsuura[1]; Yongwon Kim[2]
Forestry and Forest Products Research Institute[1]; University of Alaska Fairbanks[2]

Forest soils are sources of CO_2 and N_2O, and a sink of CH_4 those are konwn as greenhose gases. The purpose of this study is to evaluate the annual changes of these gas dynamics in an upland black spruce forest in interior Alaska. The study was conducted near Fairbanks in interior Alaska (65^{O}N, 147 ^{O}W). Three experimantal plots were set in black spruce stand (Picea mariana) those were upper (U), middle (M), and lower part (L) on a slope. Biomass of the trees, organic layer depth, and the species of moss and lichen were different among the plots. Soil CO_2, CH_4, and N_2O fluxes were measured by using a closed chamber technique. The differences of soil temperature and moisture were not clear smong the plots. The CO_2 flux at L was higher than that at U, maybe due to deep organic layer. On the other hand, the CH_4 uptake was relatively higher at U than at L. The N_2O flux was negligible small at all plots. At each plot, the CO_2 flux was positively correlated with soil temperature, on the other hand, the CH_4 uptake was negatively correlated with soil moisture. It was suggested that these gas fluxes were different among the plots due to the depth of organic layer and soil moisture.

An important question related to Antarctic research is how soil formation and microbial communities are affected by changes in climate conditions, such as higher temperatures and humidity. We explore this together with the fundamental question of how biotic and abiotic processes interact in a unique environment such as James Ross Island, eastern Antarctic Peninsula Region. Microbial communities (bacteria, archaea and fungi) are primarily controlling soil biological and chemical processes in the extreme environment of this region, a landscape characterized by a mean annual air temperature < 0° C and the absence of higher plants and borrowing animals. We investigate potential effects of changes in temperature and humidity on soil-forming processes, and responses of microbial communities on James Ross Island by conducting an incubation experiment. Samples from two sites (St. Martha Cove and Brandy Bay), which are similar in relief and parent material, but differ in position relative to the most southwestern winds, were collected during a field campaign in 2016. With respect to spatial heterogeneity, we sampled a central profile together with 12 additional satellite samples at a distance of 2 m and a depth of 0-20 cm. All samples were bulked and partially sterilized to obtain control samples. The prepared samples were exposed to 100 freeze and thaw cycles (-5°C - +5°C) at two different, constant soil moisture levels (40% and 80%). We will present the results of pH, EC, CNS, TIC, TOC, DNA content, microbial abundance and micromorphological analyses of the freeze-thaw cycle 0 compared to the results after 100 freeze-thaw cycles.

(6205 - 1650) mineralogical transformations and microchemistry of acid sulphate soils in Antarctica

Daví do Vale Lopes[1]; Fábio Soares de Oliveira[1]; José João Lelis Leal de Souza[2]; Carlos Ernesto G.R. Schaefer[3]; Luís Flávio Pereira[3]

Federal University of Minas Gerais (UFMG)[1]; Federal University of Rio Grande do Norte (UFRN)[2]; Federal University of Viçosa (UFV)[3]

The oxidation of sulphides is the most important pedogenetic process in acid sulphate soils from Antarctica. Although sulfate soils have been previously reported, no detailed study about microanalysis and its effect on pedogenesis has been carried out. The present study characterizes mineralogy and microchemistry of acid sulphate soil found in ice-free areas of Barton Peninsula, King George Island, Maritime Antarctica. Three pedons were selected, described, sampled, classified and soil microchemical/mineralogical properties were analyzed. The mineralogy was determined by X-ray diffraction (XRD) on powdered samples. The clay was separated by the centrifuge method and was subjected to the following treatments prior to analysis: removal of kaolinite with 5 M NaOH and iron oxides with dithionite-citrate-bicarbonate (DCB). Undisturbed soil samples were collected, dried at 40 °C and impregnated with resin for microchemical analysis. Glass slides were analyzed by means of polarizing microscope. Microanalysis (chemical maps and quantitative point analysis) were examined under a Transmission Electron Microscope Zeiss and Scanning Electron Microscope coupled to the X-ray tube. This study indicates that precipitation of secondary crystalline iron oxides results from an unusual pedogenic processes to Antarctic conditions. The XRD patterns in the clay fraction revealed the presence of chlorite, montmorillonite, Na-plagioclase, illite, pyroxene and goethite. The iron oxide removal treatment by DCB was efficient for the complete removal of goethite. Two microchemical domains were recognized, ferruginous microsites and other domain more diverse chemical composition, involving, in addition to Fe, higher content of Al and S. The chemical composition of the concretions involves reached more than 73% iron. This accumulating evidence that acid environment is able to enhance metal mobilization in soil system, landscape shows an important role of Fe mobilization along the slope, as well as freezing and thawing cycles. The microchemical results suggest a direct mineralogical transformation system of primary and/or secondary sulphides to iron-rich mineral phases. The sulfurization is chemical process that promote strong soil acidification and accelerate mineralogical changes even under periglacial conditions.

(1243 - 819) Modern dynamics of cryolithozone soil cover in siberia under conditions of climate change

Desyatkin R.V.[1]; Desyatkin A.R.[1]; Okoneshnikova M.V.[1]; Ivanova A.Z.[1]; Fedorov P.P.[1]; Filoppov N.V.[1]

Institute for biological problems of cryolithozone SB RAS, Yakutsk[1]

Large areas on the Earth are occupied by permafrost. The center of continuous permafrost is located on Eastern Siberia and has a depth of 500-700 m with ground temperatures from -3 to -15 °C. In the lowland and plain areas, the permafrost layer contains huge reserves of underground ice named ice complex. Modern climate changes, primarily the increase in air temperature, had a significant impact on the state of permafrost soils. During the 1966-2009 period, average annual air temperature in Yakutsk increased by 3 °C, Verkhoyansk - 1.8 °C and Oymyakon - 2.2 °C. Such dynamics of the average annual temperature caused an increase in the temperature of the upper layers of frozen soils by 0.4-1.3 °C, which caused an increase in the depth of soils summer thawing and activation of cryogenic processes. Degradation of ice began in the open and disturbed parts of the cryolithozone. Especially active thermokarst is manifested in abandoned arable lands and other territories with disturbed vegetation (fires, clear cutting, destruction of forest from insects, etc.) covering an area of hundreds and thousands of hectares. The melting of ice complex and associated deformations in the relief cause a transformation, and subsequently a degradation of the natural soil cover of the boreal taiga. The initial stage of soil transformation leads to a disruption of the morphological structure of the soil profile and water-physical properties. Further activation of thermokarst leads to complete degradation of the soil cover and flooding it by primary thermokarst lakes. The ongoing climatic changes will cause an intensification of thermokarst processes in the future, and in the coming decades (centuries), complete degradation of the soil cover on large territories with an ice complex with complete loss of soil fertility can occur. Further development of soils in these areas will proceed according to the type of alas soil formation. It is established that an increase in the depth of seasonal thawing of permafrost soils leads to a change in the water regime of soils. In the upper layers of permafrost soils (depth 1.5-5 m) under larch, pine and birch forests in Central Yakutia, in each 10-cm layer there are 25-40 mm of moisture. An increase in the soil thawing depth by only 10 cm results in the release of moisture reserves that have been preserved by permafrost for up to 30,000 t/km^2 of water. Abrupt increase in soil moisture affects the water balance of large areas on the permafrost zone.

(4373 - 1588) Soil climate and active layer depth, Ross Sea Region, Antarctica

Annette G. Carshalton[1]; Megan R. Balks[1]; Karin R. Bryan[1]; Cathy A. Seybold[2]

University of Waikato[1]; NRCS, USDA, Lincoln, Nebraska, USA[2]

The depth of seasonal thaw (the active layer), is a good integrator of a range of climate variables and has potential to provide a clear signal of climate change. Soil and permafrost climate monitoring has been undertaken in the McMurdo Dry Valleys across 9 stations: Mt Flemming (1700 masl, established in 2002); Wright Valley South Wall (700 masl, established in 2011); Wright Valley North Wall (835 masl, established in 2012); Wright Valley Floor (150 masl, established in 1999); Victoria Valley (410 masl, established in 1999); Marble Point (50 masl, established in 1999); Scott Base (38 masl, established in 1999); Minna Bluff (37 masl, established in 2003); and Granite Harbour (4.5 masl, established in 2003). At each monitoring station soil temperatures are measured at a range of depths down to 120 cm. Wind speed and direction, air temperature, relative humidity, and solar radiation are also monitored. Atmospheric data are measured every 10 seconds, and soil temperature every 20 minutes, with hourly means recorded. The data are downloaded annually. Mean active layer depths ranged from 7.5 cm at Mt Flemming, through to 37.5 cm at Wright Valley South Wall, 40 cm at Wright Valley North Wall, 23.5 cm at Victoria Valley, and 50 cm at the Wright Valley floor, to 47 cm on the coast at Marble Point. At the remaining coastal sites mean active layer depths ranged from 36 cm at Minna Bluff, through 34 cm at Scott Base, to 81 cm at Granite Harbour. There was a moderate correlation between active layer depth and altitude (R^2 = 0.7). There was marked between-season variability, however, no distinct warming or cooling trends are evident over the length of the record. The lag between maximum soil temperature at the soil surface and maximum temperature near the permafrost interface was; 15 days at Mt Flemming, 11 days at Wright Valley South Wall, 20 days at Wright Valley North Wall, 22 days on the Wright Valley Floor, 18 days at Victoria Valley, 22 days at Marble Point, 17 days at Minna Bluff, 21 days at Scott Base, and 10 days at Granite Harbour.

(8360 - 3235) Spatial heterogeneity and environmental controllers of

permafrost SOC stocks

Umakant Mishra[1]; Julie Jastrow[1]; Roser Matamala[1]

Argonne National Laboratory[1]

Permafrost affected soils are a key component of the global carbon cycle and play an important role in moderating the global climate system. Previous permafrost soil organic carbon (SOC) stock estimates used a variety of upscaling approaches and reported substantial uncertainty in SOC stocks estimates. In this study, we used spatially referenced data of soil-forming factors (topographic attributes, land cover types, climate, and bedrock geology) and SOC pedon description data (*n = 2552*) in a regression kriging framework to predict the spatial and vertical heterogeneity of SOC stocks across the Northern Circumpolar and Tibetan permafrost regions. Our approach allowed us to take into account both the environmental correlation between SOC and environmental factors and the spatial autocorrelation among SOC observations to separately estimate SOC stocks and their spatial uncertainties (90% CI) for three depth intervals at 250 m spatial resolution. In Northern Circumpolar region, our results show 510 (449 – 572), 355 (324 – 401), and 298 (255 – 348) Pg C in 0 – 1, 1 – 2, and 2 – 3 m depth intervals, respectively. In Tibetan region, our results show 11 (9 – 13), 3 (0.5 – 6), and 3 (1.4 – 5) Pg C in 0 – 1, 1 – 2, and 2 – 3 m depth intervals, respectively. We captured large spatial variability (13 – 129% coefficient of variation) depending upon the study region and depth interval. Our estimates show larger uncertainty range in 1-2 m depth interval in both permafrost regions. Soil wetness index and elevation were significant controllers of SOC stocks in both permafrost regions. Surface air temperature was only significant controller of permafrost SOC in the circumpolar region. However, precipitation was a significant controller in the Tibetan region. Similarly bedrock geology, which was a significant controller of SOC in circumpolar region, was not a significant controller in the Tibetan region. Flat areas (<2% slope angle) stored largest amount of SOC in the Northern circumpolar region, whereas hill toe-slope positions stored largest amount of SOC stocks in the Tibetan region. Largest uncertainty in SOC stocks (27%) was found in the hill toe-slope positions in the circumpolar region whereas the uncertainty was highest (62%) in flat areas in the Tibetan region. We think our results provided the first global assessment of permafrost SOC stocks and quantified their relations to environmental factors at a high spatial resolution (250-m).

(3629 - 384) Statistical analysis of the soils of the James Ross Islands Group, Antarctica

Mayara Daher de Paula[1]; Carlos Ernesto Gonçalves Reynaud Schaefer[1]; Elpídio Inácio Fernandes Filho[1]; Matheus Manso Cóser[1]

Universidade Federal de Viçosa[1]

The James Ross Islands Group (JRIS) is located southeast of the Antarctic Peninsula and consists of four main islands: Vega, James Ross, Seymour and Snow Hill, and several smaller islands: Cockburn, Lockyer, Humps, among others. The present study includes three JRIS islands (Cockburn, James Ross, and Seymour), where 71 soil profiles were collected. The descriptive statistical analyzes included the calculations of mean, median, the coefficient of variation (CV), maximum values and minimum values of the physical and chemical properties of the soils. Statistical analyzes were performed in R program. The results of the statistical analysis of the soils showed that there is a great difference between the maximum and minimum values of all the properties of the soils. Mean and median values were close to the physical properties, and some chemical, such as pH, Mg, base sum, base saturation, CTC at pH 7.0 and effective CTC. In the soil properties in which the mean and median values are very different, the values of medians are always lower, indicating that the maximum values were responsible for the increase of the average, with emphasis on the values of Na and P (Mehlich-1). Regarding the coefficient of variation (CV), K, Na, and P (Mehlich-1) had the highest CV (>250 %). The other properties had CV <24 %. The studied profiles presented texture with a greater sand contribution (65 %), revealing the predominance of physical weathering in these soils, to the detriment of chemical weathering. However, in certain areas, the chemical weathering and/or the source material demonstrated more influence. An example is the high clay content (58 %) in a profile on Seymour Island, related not only to the sedimentary material but also to the sulfurizing process. The Na median was high (616.8 mg dm^{-3}), reaching maximum levels of 7000.00 mg dm^{-3}. The maximum levels were recorded in the marine terrace, concluding that these salts are originated from marine aerosols. In Seymour Island most of the soils have a sodic character, indicating salinization as one of the main processes of soil formation in this region. The maximum extractable P content by Mehlich-1 was very high, recording the 2018.9 mg dm^{-3} content on Seymour Island. However, the median value of P (Mehlich-1) was only 68.5 mg dm^{-3}, related to the occurrence of penguin nesting, and limited to a few areas of Seymour Island.

WG02 Digital soil mapping: Progress in digital soil mapping

(6256 - 1937) Applying machine learning methods for large-scale soil types prediction

Anna Petrovskaia[1]; Nikolai Lozbenev[2]

Skolkovo Institute of Science and Technology, Moscow, Russia[1]; Dokuchaev Soil Science Institute, Moscow, Russia[2]

One of the main challenge to digital soil mapping nowadays is giving the formal account of the soil mapping process, which implies all stages of the cartographic data model development. The complexity of soil-landscape relationships determination encourages soil scientists to use modern powerful instrument - the methods of the machine learning. Model of soil-landscape relationships was constructed in our study using four machine learning methods: linear discriminant analysis, random forest, supported vector machine and bayesian neural network. The model is then applied to predict probability of each soil class and find dominant soil on a fine-scale key plot. Field data for providing this study were collected in 2013-2016 during detailed mapping of the soil cover in the virgin forest-steppe of the Central Russian Upland. The source materials include a digital elevation model (DEM) with a resolution of 2.5 m, created by more than 10000 points of GNSS survey. Soil data consist of 157 soil descriptions and the depth of the top of the calcic horizon. The soil points were located considering specific hollow microrelief of virgin forest-steppe. It was revealed that soil cover of the study area is presented by four soil types ("Classification and Diagnostics of soils of the USSR", 1977): chernozems typical, chernozems typical mycelial-calcareous with bioturbations, chernozems leached, meadow-chernozemics. The main factor of soil cover differentiation is runoff depth, which determines the depth of carbonates occurrence in the soil profile. Therefore, the models were created based on a set of drainage morphometric parameters that describe distribution of soil moisture by microrelief. The parameters were calculated from DEM. Models of soil-landscape relationships were created in the R environment. The comparison of the obtained models were made by the overall accuracy (the correspondence between the simulated and actual soil types in particular point), by the Cohen's kappa coefficient, which takes into account the possibility of the variables agreement occurring by chance, and by the assessment of expert. In general, all four models have high predictive accuracy (at least 70%).

(9489 - 440) Artificial neural networks and object-based classification

for digital soil mapping

Fabrício Fernandes Coelho[1]; Elvio Giasson[1]; Alcinei Ribeiro Campos[1]; José Janderson Ferreira Costa[1]; João Augusto Coblinski[1]; Elisângela Benedet da Silva[1]

Universidade Federal do Rio Grande do Sul[1]

Detailed soil maps are not available in most of the Brazilian territory. Remote sensing data and artificial intelligence techniques can be integrated into an object-based classification to improve spatial prediction of soil class and soil map availability. This work aimed (i) to compare the spatial predictive of soil class of Artificial Neural Network (ANN) and Decision Trees (DT), (ii) to produce digital soil maps by an object-based classification. The study area is located in northwest Rio Grande do Sul State, southern Brazil. The surface area is 900 km². In this area, there are four soil orders: Oxisols, Molisols, Inceptisols and Entisols. Normalized Difference Vegetation Index (NDVI), Normalized Difference Water Index (NDWI) and Normalized Difference Soil Index (NDSI) were derived from Landsat 8 OLI (Operational Land Imager) sensor imagery. Fifteen terrain attributes were derived from SRTM (Shuttle Radar Topography Mission) using RSAGA package in RStudio environment. This spectral indices and terrain attributes were used as discriminating variables. The multiresolution segmentation (MRS) algorithm (eCognition Developer 9.0) was used to create image objects. The shape and compactness criterion were 0.1, the scale parameter (SP) tested were 1, 2, 5, 10, 25 and 50. Three classification repetitions with Multilayer Perceptron (ANN), Simple Cart (DT) and J48 (DT) algorithms were performed with 4993 random samples using cross-validation technique (5 folds) in Weka Experiment Environment. The algorithm with the greater overall accuracy (OA) was used to object-based classification. The object-based digital soil maps accuracies were evaluated by the agreement with a legacy soil map. The Multilayer Perceptron algorithm had the highest OA (61%), followed by Simple Cart (59%) and J48 (52%). The MRS provided the reduction from 999,206 pixels to 23,616 (SP 1), 9,528 (SP 2), 3,658 (SP 5), 2,350 (SP 10), 1,769 (SP 25) and 1,660 (SP 50) image objects. The object-based approach OA with original legend were 62% (SP 1), 60% (SP 2), 57% (SP 5), 53% (SP 10), 50% (SP 25) and 45% (SP 50). The object-based approach OA with simplified legend were 77% (SP 1), 75% (SP 2), 72% (SP 5), 69% (SP 10), 66% (SP 25) e 62% (SP 50). The classifier based on ANN had the higher OA than the classifiers based on DT. Larger SP provides greater object's size and smaller its number to classify thus reducing the OA. The object-based classification is a promising approach for digital soil mapping.

Keywords: multiresolution segmentation, multilayer perceptron, data mining

(8818 - 2256) Calibration of a pedological conceptual model for digital soil mapping in Colombia. Case study municipality of La Virginia, Risaralda.

Yolanda Rubiano Sanabria[1]; Edinson Chacon Pardo[1]; Juan Carlos Loaiza Usuga[2]; Luis Marino Santana[3]

Universidad Nacional de Colombia, Campus Bogotá[1]; Universidad Nacional de Colombia, Campus Medellín[2]; Universidad del Valle[3]

It is necessary to improve and generate a regional pedological conceptual model for soils in Latin America. In this way, knowledge of the genesis of the soil could be linked to soil properties through the use of digital soil mapping tools (DSM). A pedological conceptual model was generated and calibrated in field conditions. The model is based on structural equations (SEM) to predict the horizontal and vertical distribution of clay, sand, silt, fragments, pH and organic carbon (CO) in the horizons A, B and C of the soils of La Virginia, Risaralda, Colombia (1700 ha). The most representative factors and processes of soil formation in the study area were identified to define the conceptual model (soil-landscape relationship.) Factors and processes were associated with the properties of the soil modeled, and with these relationships the SEM graphical model The SEM equations were derived and implemented in the R program using the latent variables analysis (washing) package The model was calibrated with the data of 15 modal profiles, 140 detailed observations and eight layers of environmental covariance. Five maps of soil properties and the SEM diagram that shows the relationships between the properties of the soil under analysis, the accuracy of the maps was estimated using the cross validation approach, while the overall precision was determined using the error medium quadratic (RMSE), the predicted properties, clay content and pH showed the highest precision. To the environmental covariates, the attributes of the terrain and the material of the parents were the best predictors among the different auxiliary variables studied. Similar models have been applied in soils of the Argentine pampas, demonstrating that the integration of the knowledge and experiences of Latin America to generate more representative pedological models of the region is a priority

Keywords: auxiliary variables, DSM, SEM

(1001 - 1982) Digital segmentation of hillslope position to improve detailed soil mapping

Karina P. P. Marques[1]; José A. M. Demattê[1]; Bradley A. Miller[2]; Igo F. Lepsch[1]

Department of Soil Science, "Luiz de Queiroz" College of Agriculture, University of São Paulo, Pádua Dias Avenue, 11, CP 9, Piracicaba – São Paulo, Code 13418-900, Brazil.[1]; Department of Agronomy, Iowa State University, Ames, Iowa, USA; Leibniz Centre for Agricultural Landscape Research (ZALF) e.V., Institute of Soil Landscape Research, Eberswalder Straße 84, 15374 Müncheberg, Germany.[2]

Exploratory or reconnaissance soil maps cover most of the Earth's ice-free land surface. These maps were produced using knowledge of soil-landscape relationships, which is largely based on the tacit knowledge of field experienced pedologists. A quantitative approach to generate and store information of the landscape characteristics would be useful to make this knowledge explicit to improve soil mapping in an objective, consistent, updatable, and reproducible method. Among the detailed landscape features, hillslope elements have considerable potential to predict the soil attributes and types because they identify functional zones in the context of water and sediment flow in a landscape. The purpose of this research was to apply a previously developed digital hillslope position (DHP) model, calibrate it as needed to a Brazilian landscape, and test its utility as a basis for identification of detailed soil map units. The study area covers 2,500 ha and is located on the border between the municipalities of Piracicaba and Santa Bárbara d'Oeste, São Paulo state, Brazil. A digital elevation model, with spatial resolution of 5 meters, was used to obtain slope gradient, profile curvature, and relative elevation with different analysis scales. Hierarchical rules for these digital terrain derivatives were used to identify the hillslope position. The DHP model was validated by identifying the hillslope position in the field and comparing it with the model classification using the Kappa index and a confusion matrix. Soil samples were collected across multiple hillslopes with different lithologies. These samples were analyzed for chemical composition and particle size distribution, and their results were assessed for statistical significance by variance analysis among hillslope position, parent material, and the interaction between the two. After that, student's t-tests were performed iteratively across each hillslope position within a given parent material to identify specifically which soil properties were significantly different among the hillslope position map units. When calibrated to local knowledge of the landscape, the model allowed the hillslope position segmentation with high accuracy. Summit, backslope, and toeslope were the hillslope elements best identified by the method used. Statistical comparison of soil properties between hillslope positions within different parent materials demonstrated that the DHP model can

be useful to identify soil mapping units.

(9443 - 1095) Digital soil mapping in peruvian highlands: predicting soil classes

Carlos Julian Mestanza Novoa[1]; Julio César Nazario Ríos[1]
Universidad Nacional Agraria La Molina[1]

In Peru, the production of soil maps is done using factors of soil formation model. The boundaries of the cartographic units are determined by intersecting physiography, geology and life zones maps, which represent relief, parent material, time, and climate factors. With the peak of digital age, numerical methods to infer and analyze spatial distribution of soils began. The use of statistics to model soil forming factors is called Digital Soil Mapping (DSM). The present investigation seeks to verify this new methodology by establishing a soil map for the agricultural zones of the San Mateo de Otao district in Huarochiri province (Peru) and comparing it with the traditional soil map. Qualitative and quantitative information was used, derived from the digital elevation model, Landsat 8 images, WorldClim information, geological and life zone maps for model estimation. Sampling was done using geopedologic approach. Twenty-one pits and four checkpoints were evaluated and classified to subgroup level using twelfth edition of soil taxonomy. Profiles were modeled using naïve bayes algorithm and twenty covariates of climate, organisms, relief and parent material. The uncertainty measures were obtained with a confusion matrix using the predicted values and checkpoint values. As a result, a map of taxonomic units was obtained, with the subgroups Aridic Haplustolls, Cumulic Haplustolls, and Typic Torriorthents. The global accuracy and Kappa index were 0.75 and 0.50, respectively. The comparison of the map of cartographic units (traditional method) and taxonomic units (digital soil mapping) was carried out by chi-square independence test and visual comparison. The results show a high association (no independence) between both and similar limits between cartographic units and taxonomic units.

(2896 - 2027) Digital Soil Mapping of functional soil properties - Tool for decision making at various levels and a technical training process in El Salvador

Minero Norma[1]; Tobar Jaime[1]; Torres Luis[1]; Vásquez Fernando[1]; Saleh Douglas[1]
Catholic Relief Services[1]

Results obtained through a multi-institutional digital soil mapping training process from a pilot area of El Salvador will be presented. A series of digital maps of continuous properties such as organic matter and effective soil depth were developed. These maps were developed in a training process of government institutions, universities and the development sector with the aim to establish a critical mass of digital soil mapping capacity in El Salvador. Throughout the learning process and validation period the resulting maps were identified as useful information for enhanced decision making at several scales, from farmer's field to country level. Particularly information for soil fertility management and water harvesting are important elements for improved management of rain fed agriculture systems in El Salvador. Although it is very early in the process to talk about the impacts, the project has generated a growing interest in solving the problem of lack of data and information about soils. Different groups in the country receive requests from additional institutions, universities and public-sector entities to join the mapping process. The innovative approach of the mapping process through the creation and strengthening of capacities of multi-institutional groups at a national level facilitated the respect and response to the interests of the participating institutions in the definition of concrete output products (demand), the planning of the work process without data transfer outside the country, and provision of technical assistance according to the needs of each institution. It also facilitated the emergence of strong national leaders for ongoing mapping processes, which is expected to be a key factor for post-project sustainability

(1956 - 3211) High resolution mapping and soil organic carbon stocks in the Colombian savannas.

Mayesse da Silva[1]; Phillip Owens[2]; Zamir Libohova[3]
International Center for Tropical Agriculture (CIAT)[1]; United States Department of Agriculture, Agriculture Research Service[2]; United States Department of Agriculture, Natural Resources Conservation Service[3]

Colombia's economy is highly dependent on agriculture and natural resources. Considered the last agriculture frontier, the Colombian savannas has been highlighted as a key region for future economic and social development of the country. Government projections indicate a potential of 278 percent increase in the area dedicated to annual crops. In order to understand what the consequences of land use might be for the sustainable development in this region, we evaluated the land use effects on soil organic carbon (SOC) stocks in order to guide future land management strategies and monitor changes in ecosystem services in the Colombian savannas. The study was carried out at Meta state in an area of 970,000 ha. Approximately 3,660 soil samples distributed over 158 sites were taken at 8 different soil depths up to 1 meter. SOC and soil bulk density were determined in laboratory and SOC stocks for each sampled depth were calculated. A Digital Soil Mapping (DSM) approach based on expert knowledge and fuzzy logic was used and calibrated for two scenarios: with and without including land use as covariate. About 80% of total field data were used for model development and calibration while the remainder 20% was used for model evaluation and comparison. The results showed that both models predicted well the SOC average when compared with the observed values. However, under both scenarios the maximum and minimum values were underestimated and overestimated respectively. Also, the model that included land use as covariate showed a greater improvement for the first 40 cm of soil depth with a 20% error reduction. The incorporation of land use showed slight or no improvements for SOC for soil layers below 40 cm. The region mapped represents 0.08 Gt of carbon up to 1 m of soil depth. This value constitutes 1% of total global emissions in 2010 in which Colombia contribution was 0.46% (224 Mt de CO_2eq) according to its greenhouse gas emissions (GHG) inventory for the same year. Most of the carbon reserves in this area are found in the first 40 cm of soil accounting for approximately 63% of total carbon (0.05 Gt C). This is also generally the depth of soil management in agricultural lands indicating the need to adopt management practices that enhance carbon sequestration as well as reduce emission. Further estimates of land use change impact in SOC for different scenarios is necessary for adequate planning of management practices and sustainability of environmental resources.

(1118 - 3175) Incorporating expert knowledge into iterative digital soil mapping

Minerva J Dorantes[1]; Phillip R Owens[2]; Zamir Libohova[3]; Bryan

Fuentes[4]
ORISE[1]; ARS-USDA[2]; NRCS-USDA[3]; University of Arkansas[4]

Soil degradation, water pollution, soil erosion, and a changing climate are just some of the problems that impact food production and ecosystem services in Central America. Understanding the soil resource is integral to managing it efficiently. The current state of soil data limits its use in decision-making for people in this region, many of whom practice subsistence farming from small plots. An initiative began in 2015 to develop new soil maps for El Salvador, Guatemala, Honduras, and Nicaragua that can be used as an instrument for land planning. The project merges the expert knowledge of local scientists with digital soil mapping techniques to develop nationwide, continuous soil property maps. The DSM approach will be presented for a pilot study in El Salvador. Focus will be made on the integration of local scientists' knowledge of the patterns in the area into the predictive mapping model. The first version of the maps will be validated by expert knowledge and statistical analysis and will be used as inputs for the iterative process to produce a more accurate version of the maps.
Keywords: expert knowledge, central america, digital soil mapping

(3024 - 1335) Mapping and analysis of soil types in the agro-pastoral transitional landscape system of Bashang area in North China

Zhuodong Zhang[1]; Mingjian Xiahou[1]
State Key Laboratory of Earth Surface Processes and Resource Ecology,Faculty of Geographical Science, Beijing Normal University[1]

There are a wide variety of soil types with high spatial variability in the agro-pastoral transitional zone (APTZ) in North China even at landscape scale, which is a result of the complex soil-forming environment such as the topography, transitional climate and different land uses. In this study, two study areas of different sizes were chosen in the APTZ of Bahsang area in Hebei province, China. In the smaller study area of 18 km^2, traditional soil mapping approach based on field investigation and the other approach Random Forest (RF) algorithm using environmental factors including parent material, climate, topography, hydrology, land use and so forth were employed respectively to identify the spatial distribution of soil types. The results of the traditional method and RF were compared and evaluated. Then, RF was applied to the larger study area of 166 km^2 which covered the smaller one, and the soil type distribution was achieved. Results show that there are eight different soil types in the whole study area, and there is a strong spatial variability of the soil type distribution. The controlling factors of soil type distribution are hydrology, slope, and aspect, which means hydrological conditions, micro topography and micro climate have great influences on soil forming process. RF based digital soil mapping approach shows good performance and high efficiency. Soil mapping is of great importance to the utilization and conservation of soils in the APTZ. Fragile natural environment and serious human disturbance lead to higher risks of soil erosion and degradation in the APTZ. Therefore, conservation tillage and control of the grazing intensity are expected to prevent soil degradation in the APTZ in North China.

(8443 - 2121) Mapping soil bulk density in Brazil by machine learning

Raiza Moniz Faria[1]; Lucas Carvalho Gomes[1]; Gustavo Vieira Veloso[1]; Eliana de Souza[1]; Elpídio Inácio Fernandes Filho[1]; Carlos Ernesto Gonçalves Reynaud Schaefer[1]; Márcio Rocha Francelino[1]
UFV[1]

The bulk density is a key soil property that allows understanding soil quality and process, hence using more precise map of bulk density can lead to more effective soil monitoring. To achieve the best performance on bulk density mapping, in this study, we used techniques for selecting powerful variables and robust predictive model to estimate soil bulk density in Brazil territory at five depths (0-5, 5-15, 15-30, 30-60, 60-100 cm). The soil dataset accounted for 37,000 soil samples from 8,227 sites distributed across Brazil. A total of 62 spatial dense maps of environmental variables used as predictors variables, with 1 km resolution, included map of soils, vegetation, lithology, terrain attributes and bioclimatic variables (temperature and rainfall). For each soil depth the most important variables were selected by applying the Recursive Feature Elimination algorithm, implemented in R software and the bulk density estimated using the Random Forest algorithm. The most important variables were soil class map, Gross primary production vegetation index, slope height, latitude, topographic wetness index and NDVI index. Model assessment with external validation showed R^2 range from 0.36 to 0.40, related to the depth 60-100 and 15-30 cm, respectively. The average value of bulk density was 1.30 kg / dm^3. Overall, bulk density in depth, showed lower variation with no evident abrupt changes in the soil texture, in soil types where this change usually happens. The highest values of bulk density occurs in the North of Minas Gerais State, Northeast and the Midwest of Brazil, with values around 1.35 kg / dm^3. The lowest values are in the southern Brazil. The variables selection proceed allowed to reduce the number of predictor with good performance of Random Forest on mapping bulk density at all depth

(8034 - 3166) Morphometric functional units as an input for inferring the spatial variability of soils

Bryan Fuentes[1]; Phillip R Owens[2]; Zamir Libohova[3]; Minerva J Dorantes[4]
University of Arkansas[1]; USDA - University of Arkansas[2]; NRCS[3]; ORISE[4]

Data mining techniques are useful to identify patterns associated with datasets. Among data mining techniques, clustering is an efficient way to group data into homogenous units based on similar criteria. When no prior knowledge of the data under analysis exists, clustering can recognize patterns that become useful for subsequent analysis. Given the complex nature of terrain, hardening continuous morphometric derivatives into homogenous classes becomes useful when analysis based on discrete units, rather than on pixels, is needed. This research aims to perform an exploratory analysis of different clustering techniques and to evaluate the perfomance of clustering algorithms in hardening morphometric derivatives into classes. The impact of dimensionality reduction of the morphometric derivatives on the quality of the resulting classes, was assesed through expert knowledge of the study area. In addition, a comparison of different statistical indices to select the optimum number of classes was conducted. The final selection of the tested algorithms and parameters was made based on the performance of the classes as inputs for a predictive soil mapping model.

(7888 - 2144) Soil pH spatial distribution with digital soil mapping (DSM) in central Andes of Peru

Julio Cesar Nazario Rios[1]; Carlos Julian Mestanza Novoa[1]; Guillermo Federico Olmedo[2]; Domingo Marcelo Portuguez Maurtua[1]
Universidad Nacional Agraria la Molina[1]; EEA INTA - Mendoza[2]

In last years, climate change has alerted about the influence of human activities on natural resources. Activities such as agriculture require better and detail spatial information for proper management with minimal impact on the environment. Digital soil mapping (DSM) is a tool that allows obtaining high quality information using statistical models to

infer and study soil properties and classes, having assigned error measures that differentiate it from traditional mapping. The present investigation was carried out to determine the spatial distribution of soil pH in some areas of six provinces of the department of Junin, in central Andes of Peru, using digital soil mapping. One hundred twenty four randomly distributed sampling points were used in homogeneous units of land whose limits were obtained by combination of physiographic, lithological, and ecological maps. The pH was modelled using regression kriging technique, initially entering 39 covariates that were reduced to 7 by selection with stepwise. The results showed a direct relation between soil pH and the average temperature of the warmest month, Enhanced Vegetation Index (EVI), slope, Multiresolution Index of Valley Bottom Flatness (MRVBF), and some rocks (sandstones and shales, conglomerates, boulders, gravels and sands). On the other hand, and inverse relation was found with the longitudinal curvature, LS factor, and acid intrusive rocks (granite and granodiorite). The spatial distribution of pH is shown in aggregate patterns, with the highest values in alluvial valley of Mantaro and middle basin of Tulumayo, while the lowest values were found in zones of highest altitudes.

(3481 - 3161) Soil property prediction: comparing covariates spatial resolution

Renato Corrêa Taques[1]; Eliana de Souza[2]; Elpídio Inácio Fernandes Filho[3]; Márcio Rocha Francelino[3]; Nerilson Terra Santos[3]
Institute of Research, Technical Assistance and Rural Extension of Espírito Santo - Incaper, Vitória-ES[1]; Federal University of Viçosa – UFV, Av. P.H. Rolfs, s/n. CEP 36570-000 Viçosa (MG) (e-mail: eliana.souza@ufv.br)[2]; Federal University of Viçosa (UFV), Viçosa-MG[3]

This study assessed the prediction of soil properties (pH-H2O, CEC, OC, clay, silt, sand) using covariates with spatial resolution of 90, 30, 10 and 5 m. The study case was carried out for the Rio Pongal basin, in Anchieta-ES, Brazil. The area is 11,000 ha where soil were sampled in 154 sites at 15-30cm depth. A total of 31 covariates were used. The terrain attributes was derived from the digital elevation models (DEM) with different spatial resolutions (SRTM-90m, Aster GDEM-30m; Cartographic base at 1:50,000 scale interpolated to 10m and Aerophotogrammetric survey at scale 1:10,000, interpolated to 5m). From each DEM fourteen terrain attributes were derived: elevation, slope, aspect, curvature, profile of curvature, multiresolution ridge top flatness-MRRTF, multiresolution valley bottom flatness-MRVBF, mean slope position (MSP), terrain ruggedness index-TRI, topographic wetness index-TWI and solar radiation (total solar radiation, direct solar radiation, diffuse solar radiation and duration of direct solar radiation). From gamma-spectrometry (125m spatial resolution) were used images of concentration of thorium-Th, uranium-U and potassium-K. Additionally we calculate the ratio of Th/K, U/K and, U/Th. The bands 2 to 7 of Landsat-8 were used, as well as the indexes: clay mineral index-CMI, iron oxide index-IOI, normalized difference vegetation index-NDVI, and the band ratio band-4/band-3 and band-4/band-7. The approach of covariates selection combined the stepwise method combined with the variance inflation factor. All analyses were run in R program with prediction by Random Forest and accuracy assessed by 5-fold cross-validation. The number of covariates selected per soil property increased with decreasing the spatial resolution. For the 90m dataset was selected between 4 to 9 covariates, whereas for 5m, the datasets contained from 2 to 5 predictors. The most frequent selected attributes, derived from DEM were TWI, slope, MRRTF, MRVBF and direct solar radiation, and from Landsat: (NDVI, B4/B7). From gamma-spectrometry were selected: K, Th and Th/K and U/K ratio. Overall, accuracy using the dataset of 5m was higher than prediction using lower resolution, except for sand and OC, whose best performance were using the dataset of 10 and 30m, respectively. Among soil properties, pH scored the lowest R^2, 0.09 for the best model, while CEC showed the highest (0.40) followed by OC and clay (0.16), silt and sand, 0.13 and 0.09 respectively.

(4113 - 1977) Validating POLARIS and DSMART disaggregated soil maps using field-scale soil surveys

Jason P. Ackerson[1]
Purdue University[1]

The United States soil database (SSURGO) represents soils as compound classes referred to as map units. Map units are displayed as polygons on SSURGO maps with map units containing several components, or unique soil class. A major limitations of SSURGO is that maps units contain no information on the location of components within polygons. In order to improve the representation of SSURGO data, it is desirable to disaggregate SSURGO polygons into their respective components so the resulting database will have a polygon representing each component. One of the most widely implemented disaggregation tools is DSMART which has been applied to soils in SSURGO in the contiguous United States and published as the POLARIS database. One of the chief challenge with all disaggregation strategies is that ground-truthing maps is difficult due to the expense of developing sufficiently high-resolution component maps. In this paper we utilize existing component-level soil maps developed by USDA soil scientists for agricultural research farms. We use these component-level maps to evaluate the accuracy of POLARIS products and validate the assumptions of the DSMART algorithm.

WG03 Digital Soil Morphometrics: Soil imaging and image analysis at multiple scales

(6191 - 1775) Assessment of water reservoir sediment by ground penetrating radar and x-ray fluorescence analysis

Elaine Caliman Sposito[1]; Athos Alves Vieira[1]; Rafael Gomes Siqueira[1]; Márcio Rocha Francelino[1]; Elpídio Inácio Fernandes Filho[1]; Elton Eduardo Novais Alves[1]
UFV[1]

Currently, around estimated 80% of the world's population is exposed to risks related to water security. Brazilian National Water Agency (ANA) predicts future deficits in water supply in more than half of the Brazilian municipalities due to lack of infrastructure and investments. Thus, protecting the world's freshwater resources requires diagnosing threats at global and local scales. Similar to what happens in other cities, Viçosa, in Minas Gerais State (Brazil), has been frequently exposed to deficit of water supply to the population. Since 2014, Viçosa has accumulated precipitations below the historical average. In Viçosa, there are two water treatment plants, and one of them uses water from the reservoir located on the campus of the Federal University of Viçosa. Over the last year, this dam has been suffering silting process with sediments coming from the São Bartolomeu stream basin, upstream of the catchment area. In order to evaluate the thickness of the deposition layer near the reservoir, a Ground Penetrating Radar (GPR) equipped with a 200 MHz antenna was used. Auger observations were carried out to calibrate the radargram generated. Sediment samples were collected at twelve different depths and, after their preparation in pellets, analyzed using Energy Dispersive X-Ray Fluorescence Spectrometry (XRF), in order to determine the presence of heavy metals. GPR analysis showed that the reservoir has a sediment layer with 3 m of average depth, which corresponds more than half of lose in the initial water storage capacity of the dam. The chemical elements contents, obtained by XRF, indicated that As, Co, Cr, Cu, Hg, Ni, Pb, V and Zn were higher than the minimal

values established by National Environment Council (CONAMA). In addition, Mn had the highest value observed among heavy metals, which can be related to the yellow color of the water supplied to the population of Viçosa in the second semester of 2017. P content were also high. The use of GPR allowed the evaluation of the layer depth of sediment of the reservoir, indicating that its removal could increase the storage capacity of the water dam. In addition, the analysis with XRF evidenced the presence of heavy metals in amounts above the limits established by regulation, which can lead to health problems to the population.

WG04 Global Soil Map: Progress and challenges

(8920 - 1523) A GlobalSoilMap Prototype for the Conterminous United States: Characterizing Uncertainty

Norman B. Bliss[1]

USGS/EROS[1]

The legacy soil survey geographic databases for the United States have been processed to match the standards of the GlobalSoilMap. The source data are primarily from the detailed Soil Survey Geographic (SSURGO) dataset, and areas that are not yet mapped by SSURGO are filled from the General Soil Map (STATSGO2). These legacy databases were developed by the U.S. National Cooperative Soil Survey under the leadership of the U.S. Department of Agriculture, Natural Resources Conservation Service. The source data structure includes map units, which are delineated spatially on a map, and components, which have attribute information representing a percentage of the map unit but are not mapped. Although the 'representative value' for each quantitative attribute was used to calculate the values used for the GlobalSoilMap results, the source databases also include 'low' and 'high' values that can be used to represent the uncertainty. Although the standards for coding 'low' and 'high' values were not well defined, by assuming that they represent a 90% confidence interval, it is possible to estimate the uncertainty for each component. Each component may have a distinct range of 'low' and 'high' values, but the goal is to have an uncertainty measure representing the map unit. I developed a method to create 1000 'pseudo-observations' for the map unit, distributed according to the confidence interval for each component, from which it is possible to determine the 90% or 95% prediction interval for the map unit. This method makes it possible to merge component records with differing confidence intervals into a single map unit prediction interval. Not all data records are populated with the 'low' and 'high' values. For example, in the attribute representing the percentage of sand, only 115,274 of the 309,916 map units (37%) had both 'low' and 'high' values. The size of the 90% confidence interval varies considerably for these records. I developed methods to extrapolate uncertainty estimates to the remaining 63% of the sand records by using other GlobalSoilMap attributes to identify similar soils. For example, the sand percentage has narrower uncertainty ranges near zero or 100% sand, whereas near 50% sand, there is a much larger prediction interval. Providing uncertainty estimates will fulfill a requirement of the GlobalSoilMap specifications and enable these data to be distributed, leading to improved decision making by farmers and resource managers.

(7115 - 288) Comparisons between splines and weighted means for filling missing soil horizon data for GlobalSoilMap standard depths

Zamir Libohova[1]; Phillip R. Owens[2]; Jim Thompson[3]; Skye Wills[1]; Steve Peaslee[1]; Davis Lindbo[4]

USDA-NRCS-National Soil Survey Center[1]; USDA-Agricutural Research Service[2]; West Virginia University[3]; USDA-NRCS-Soil Science Division[4]

The GlobalSoilMap specifications require the generations of high resolution gridded soil property maps for 6 depths (0-5, 5-15, 15-30, 30-60, 60-100, and 100-200 cm) based on equal area splines. The use of equal area spline is advantageous as it provides standardization of soil data from different vintages as well as means to fill in gaps in soil data horizons with missing values. We explore the impact of equal area splines for filling in values for missing soil horizons and/or soil layers and compare them with the weighted mean approach for Soil Survey Geographic (SSURGO) Database, U.S. General Soil map (STATSGO2) and Kellogg Soil Survey Laboratory (KSSL) National Cooperative Soil Survey Soil Characterization Database (Pedons). The correlations coefficients between adjacent layers were significant and varied from 0.37 to 0.99 depending on the soil property and depth across all three databases. The correlation coefficients were higher for the adjacent surface horizons varying from 0.80-0.99 compared to the one- (0-5 vs. 15-30 cm) to five-removed (0-5 vs. 100-200 cm) varying from 0.95 to 0.09. Within each soil database the correlation coefficients between splined and weighted means were comparable with a mean difference of only 0.02 for SSURGO and 0.04 for STATSGO2. For all the depths combined the correlation coefficients were higher for STATSGO2 (0.78) compared to SSURGO (0.66) and KSSL (0.43). However, the root means square errors (RMSE) were generally higher for STATSGO2 compared to KSSL and SSURGO. Though these relationships are unique to the U.S soil databases it demonstrates the promise this approach brings to fill in data gaps for missing soil horizons for other similar data bases and standardize them to meet the GSM standards.

(6949 - 1179) Updating the categorical soil map of Iran using limited soil legacy data

R. Taghizadeh-Mehrjardi[1]; K. Schmidt[1]; K. Eftekhari[2]; T. Rentschler[1]; T. Scholten[1]

Soil Science and Geomorphology Department, Institute of Geography, Eberhard Karls University Tübingen, Tübingen, Germany[1]; Soil Genesis and Classification Department, Soil and Water Research Institute, Karaj, Iran[2]

However, there are a large number of available DSM techniques, but little attempt has been made to explore the impact of sample size used to train machine learning algorithms on the quality of DSM products. The use of limited soil legacy data to produce digital soil maps is vital, particularly in large, remote and public arid regions of Iran where traditional soil survey is difficult to perform. Therefore, the main objective of this research was to explore whether prediction improvements could be achieved using the higher sample sizes. At present research, we applied four random forest (RF) models with different sample sizes (i.e. 25, 50, 75 and 100% of total data set) and different environmental covariates including remote sensing images (e.g. Landsat and MODIS), digital elevation models (e.g. SRTM and ALOS), categorical covariates (e.g. soil map, land use, geology), soil properties (e.g. pH, clay, sand, silt), climate (e.g. precipitation and temperature) to produce a digital map of soil class in Iran. Results of 5-fold-cross-validation indicated the constructed $RF_{25\%}$ model with 25% of data set could capture 54% of the variation of soil classes. However, $RF_{100\%}$ with 100% of dataset result in capturing the highest variation of soil classes (OA=67.2% and Kappa=0.60). It is worth noting, the obtained overall accuracy of the $RF_{75\%}$ was fairly similar to $RF_{100\%}$ (OA=64.73% and Kappa=0.57). As an expectation, all four models could not correctly predict the Chernozems which have the lowest density (i.e. nine soil samples). Our findings recommended the use of random forest model for the spatial prediction of soil classes in Iran.

(4309 - 258) A Hybrid Soil Laboratory Analysis for low environment impact

José Alexandre M Demattê[1]; Andre Carnieletto Dotto[1]; Luis Gustavo Bedin[1]; Veridiana Maria Sayão[1]; Arnaldo Barros e Souza[1]; Jose Lucas Safanelli[1]
College of Agriculture Luiz de Queiroz - ESALQ, University of São Paulo - USP[1]

Soil analysis is an important information for agriculture and environment monitoring. They are usually performed by wet combustion analysis with high cost and chemical products consumption. In the world, it is estimated that 1.5 billion ha is used for agricultural area, reaching around 600 million soil samples for chemical and granulometric analyses. Considering just organic matter method, we would be using about 840 thousand kg of dichromate and ammonium ferrous sulfate, and 3 million L of sulfuric acid, with huge ecological impact. Therefore, the objective of this work was to discuss the possibility of a hybrid laboratory with low environment impact. For this, we did the following: i) evaluate the analytical quality of soil attributes via different traditional laboratories and sensors, ii) evaluate the prediction of the models using sensors, iii) assess the uncertainties of lime recommendation (LR) analyzed by the laboratories and sensors. We utilized 96 soil samples distributed along São Paulo State, Brazil. The determination of 15 soil attributes (SA) was performed by 4 different routine laboratories, and predicted by 4 sensors (400-2500 nm). The results showed that the performance of predictive models was influenced by the analytical precision and accuracy of the laboratory reference. The variance of analysis between laboratories, for a same attribute, was higher than between sensors. Sensors indicated more stability than traditional methods. Overall, predictions of SA using different sensors showed high reproducibility, which are associated with the analytical capacity of reflectance spectroscopy technique. The quality of the spectral prediction models reached great result ($0.71 < R^2 < 0.92$) for sand, silt, clay, OM, CEC, K, and pH. According to the criteria for classification of analytical performance (inaccuracy, imprecision, and excellence indexes), the results were quite interesting for sand, silt, clay, pH, OM, CEC, and V. The LR can be determined by spectral analysis, since it presented a high correlation with the laboratory result. The Hybrid Soil Laboratory Analysis must be stimulated. The indication is to analyze one part of the samples (20%) via routine laboratory and the remainder (80%) via sensor analysis. The reflectance spectroscopy can complement the traditional methods, reducing costs, demanded time, and decreasing the use of harmful toxic elements for the characterization of soil attributes.

(2142 - 691) Application of Hyperspectral and GF-1 remote sensing data to predict and map soil carbon content

Liu Ting[1]; Wang Laigang[1]; He Jia[1]; Zheng Guoqing[1]; Guo Yan[1]
Institute of Agricultural Economics and Information, Henan Academy of Agricultural Sciences[1]

During the early twenty-first century, China has developed and launched a variety of satellites, such as the China and Pakistan resources satellite (CBERS), the environment satellite (HJ-1A/1B), and the resources satellite (ZY-3) that are intended for studying multi-scale land cover change, monitoring natural resources, and assessing environmental quality and changes in the ecological environment. As part of the "High-Resolution Earth Observation System", many major projects have being implemented. The Chinese GF-1 satellite is a new high spatial resolution satellite successfully launched by the Long March II rocket on April 26, 2013. GF-1 was equipped with two types of sensors. One is the wide field view sensor (WFV sensor); the other is the panchromatic and multispectral sensor (PMS sensor). The WFV sensor can acquire multispectral image in blue, green, red, and near-infrared bands with 16 m spatial resolution and 4 days temporal resolution. The PMS sensor can acquire a panchromatic and multispectral image with 41 days temporal resolution. The present study focused on assessing the feasibility of multi-spectral data in monitoring soil carbon (SOC). The data source comes from hyperspectral measured under laboratory condition, and simulated multi-spectral data from GF-1 remote sensing images. According to the reflectance response function of GF-1, the hyperspectra were resampled for the corresponding bands of multi-spectral sensors. The correlations between hyperspectral, simulated reflectance spectra with different soil vegetation indexes and SOC content were calculated, indicating the highest correlation coefficient for the first derivatives of hyperspectral and simulated GF-1 reflectance. The partial least square regression (PLSR) method was used to establish experiential models to estimate SOC content. The first order derivative hyperspectral data showed good result to predicted SOC with R^2=0.962, and the model was steady with RPD=4.87; Simulated GF-1 spectral data can also be a good prediction of SOC (R^2=0.557), but relatively poor stability of the model (RPD=1.43). Meanwhile, the spatial distribution of SOM showed that similar spatial characteristics between measured SOC and predicated SOC with the first derivative of the measured hyperspectral data and simulated GF-1 multi-spectral data. Therefore, it has potential ability to evaluate SOC in large-scale with multi-spectral data.

(7547 - 1131) Contribution of different Vis-NIR spectral regions to the prediction of soil organic carbon content

Alexandre ten Caten[1]; Fabiana Zorzi Breda[2]; Geisy Bahls Fogaça[2]; Luiza Mantiça Kreimeier[2]
UFCS - Curitibanos[1]; UFSC - Curitibanos[2]

Relevant information on soil attributes and types can be obtained using spectradiometers, which allow the detailed observation of soil, spectral behavior. Soil organic carbon (SOC) influences spectral response of the soil, producing different features along the Vis-NIR region. The objective of this study was to verify, through the segmentation of a spectral dataset, the influence of different Vis-NIR spectral regions to the prediction of SOC. The study area is the region of Marombas river watershed located in the mountainous region of Santa Catarina state. We collected 594 soil samples, and divided them into 416 for calibration and 178 for validation. Spectral readings were performed with a FieldSpec 3 Spectroradiometer (ASD Inc.) with a spectral range of 350-2500 nm. Spectral data processing was performed using the R programming language and the Alrad Spectra interface. Noise of the spectral signatures was removed at the edges of the spectra, and reflectance values of 400-2400 nm were used. For modeling two sets of radiometric data were produced. The first one was made out of adding increasing segments of 100 nm intervals (e.g. 400-500,..., 400-2400). For the second dataset the segmentation occurred inversely (e.g. 2400-2300,..., 2400-400). Modelling was conducted with Partial Least Squares Regression (PLSR), and as a pre-processing technique the Smoothing procedure was applied. Quality of statistical adjustment was accessed by the R^2 and RMSE values. Climatic conditions of the region influenced SOC content due to the low temperatures throughout the year (mean anual temperatures of 16 °C). High levels of SOC were found in the samples with maximum values up to 6.87%. The validation of the PLSR model

reached R^2 = 0.78 and RMSE = 0.54%, corresponding to the spectrum 400-2300 nm. It was observed that a continues addition of spectral segments up to 500-1100 nm reflected also in an increased R^2 value. This spectral region covers, very important absorption bands for SOC accordingly to literature. However, with the addition of the remaining segments of the spectrum, an increase of only 3% in R^2, and even 2% decrease in RMSE was noted. Higher and less variable R^2 values occurred predominantly in the infrared region. Thus, the investigation of the influence of a particular region of the spectral, via the segmentation of spectral data, may be relevant for SOC prediction.

(6068 - 1969) Diffuse Reflectance spectroscopy for determination of soil texture

Alexandre ten Caten[1]; Fabiana Zorzi Breda[1]; Geisy Bahls Fogaça[1]; Luiza Mantiça Kreimeier[1]

Universidade Federal de Santa Catarina - Campus Curitibanos[1]

Diffuse Reflectance Spectroscopy (DRS), a Soil Proximal Sensing technique, records the electromagnetic radiation reflected by soil samples revealing a series of features characterizing its spectral signatures, related to the physical, biological and mineralogical characteristics of the soil. The objectives of this study were: i) to test a model to predict soil texture through the DRS technique; ii) to identify spectral regions important for soil texture prediction related to spectroradiometer costs. The development of this study comprised the region of the Marombas river basin, located in the Serrana mesoregion of Santa Catarina state. A total of 594 soil samples were collected from 104 locations, divided into 416 samples for calibration and 178 samples for validation of soil texture models. Spectral readings were performed by the FieldSpec Pro 3 Spectroradiometer (ASD inc.), with a spectral range of 350-2500 nm. Spectral signature noise was removed from the samples at the initial and final edges of the spectra, which kept reflectance values between 400-2400 nm. For data processing, the programming language R was used, through the graphical interface AlradSpectra. For modeling, a radiometric dataset was produced by adding increasing segments of 100 nm intervals (e.g.: 400-500 nm, 400-600 nm,..., 400-2400 nm). For the pre-processing, the smoothing statistical technique was used, and for modeling the statistical method PLSR (Partial Least Squares Regression) was applied. The evaluation of model quality was verified by R^2 values and RMSE. The sand fraction presented the best model with R^2 = 0.83 and RMSE = 0.77% in the spectrum range of 400-1700 nm. The silt fraction presented R^2 = 0.55 and RMSE = 0.62% in the spectrum range of 400-2200 nm. The clay fraction presented a model with R^2 = 0.68 and RMSE = 0.83% in the spectrum range of 400-1400 nm. Soil has characteristic features in visible and near infrared regions of the spectrum. Sand predictions were influenced by quartz minerals in the 400-880 nm regions. And Clay predictions are related with the influence iron oxides, hematite and goethite in the 480-900 nm region. According to soil and its contend of sand, silt and clay fractions, prediction models reached good performance, reaching R^2> 0.50 between the 400-1000 nm region, indicating that low cost spectroradiometers can be used to predict soil texture.

(8030 - 1112) Estimation of soil organic matter content in the Yangtze River Delta by Vis-NIR in situ

M H Yang[1]; Z Shi[1]; H Y Li[1]

College of Environmental and Resource Sciences, Zhejiang University, Hangzhou 31008, China[1]

Paddy soils are very important in China and they are widely distributed in the Yangtze River Delta in South China. Organic matter (OM) are essential soil properties for assessing the fertility of paddy soils. It can be measured with visible and near infrared (vis–NIR) spectroscopy effectively in the field using the Chinese soil spectral library (CSSL) of dry ground after removing the influences of the environmental factors. However, A needed steep is the development of soil spectral libraries and models (calibrations using multivariate techniques). The model of calibrations only can be useful when it contains the variability of the target site soils. A classical way to use is by the spiking of models with a few samples from the target site (local samples), and the subsequent recalibration of models. For these reasons, we hypothesized that the accuracy of the regional-scale calibrations can be improved when a small subset of local samples (spiking subset) is added to recalibrate the initial calibration. In this paper, we investigated the possibility of using the Chinese soil spectral library (CSSL) of dry ground soils to predict OM using spectra of fresh (non-processed) paddy soil samples measured in situ using spiking sample methods in the Yangtze River Delta. Here we first removed the influences of the environmental factors implementing external parameter orthogonalization (EPO). Next, we used two spiked methods to select the best spiking subset according to spectral characteristics and geographical range spiked from target sites. A partial least squares regression (PLSR) of SOM on the laboratory spectra and spiked sample spectra of the training set was then used to predict the EPO-transferred field spectra. Results showed that spiking methods led to simultaneous improvement in the predictions of OM. The accuracy was improved significantly when the spiking subset was obtained according to spectral characteristics than those obtained with 'geographically-local' models.We recommended that the use of EPO and CSSL models for the efficient prediction of SOM using field scans of paddy soils when a few sample the spiking subset was used.

(4537 - 2402) Evaluation of soil humidity with the use of ground penetrating radar (GPR)

Nathalie Cruz Sena[1]; Francis Henrique Tenório Firmino[1]; Lucas de Carvalho Gomes[1]; Judyson de Matos Oliveira[1]; Márcio Rocha Francelino[1]; Elpídio Inácio Fernandes Filho[1]

Universidade Federal de Viçosa[1]

Ground Penetrating Radar (GPR) is a non-invasive subsurface survey method that generates a variety of soil information. However, in Brazil few studies used GPR to access soils information. The objective of this study was to verify the volumetric moisture data obtained indirectly from the GPR, in relation to the standard method and the Time Domain Reflectomery (TDR) method. The study was carried out in a 30 m transect in a hilly experimental area of the Federal University of Viçosa, Minas Gerais, Brazil. We used the GSSI SIR-3000 device, composed 900 MHz shielded antenna, with a sweep in the slope - valley direction. The radargrams were processed in RADAN 7® software. In the transect we determined equidistant points by each 6 m, where undisturbed samples were collected at a depth of 0.20 m, to determine volumetric moisture method (standard). In addition, we installed 5 TDR sensors (model CS616, Campbell Scientific Inc.), vertically on the surface of the soil. The values of the dielectric constant obtained by GPR and TDR were inserted into the equations of Topp et al. (1980), Roth et al. (1992), and in the equation calibrated in situ for these soils developed by Pires (2016). The data obtained were compared to the standard method. The relief performance in the water dynamics was confirmed by the higher values of humidity in the valley bottom. In general, the 3 equations show higher values of soil moisture by GPR and TDR methods in relation to the standard method. However, the equation of Roth et al. (1992) and Pires (2016) presented better adjustment, because of its empirical character and the fact that it is correlated with the attributes of the area,

respectively. Soil volumetric moisture obtained by GPR showed good correlation with TDR data. In addition, the radargrams allowed to determine the level of the water table and, horizontally from the dielectric constant gradient, it was possible to demarcate the transition between Oxisol and Entisol (based on previous mappings and confirmed from mini-trenches in the field). The information obtained by the radargrams helps both the estimation of soil moisture and spatially can diagnose non-homogeneous areas, with low cost and time, for soil studies integrated to the toadsequences.

(5093 - 1319) Experimental evidence of internal scattering and absorption in soil particles

William Philpot[1]

Cornell University[1]

Observations of transmission through a thin layer of quartz sand indicate that the transmitted radiation – from the visible through the shortwave infrared – is essentially diffuse after little more than one attenuation length. This was the case whether the sample was air-dry or saturated. A simple model designed to describe the observations suggests that the directional nature of reflectance is controlled by the near-surface layer; below that, transmission was diffuse. The spectral attenuation coefficient for the air-dry samples indicated an increase in attenuation at shorter wavelengths that could be modeled with an inverse power law, a pattern that was suggestive of a long optical path and absorption within the particles. The implication was most of the transmitted light had passed through the sand particles, undergoing multiple scattering and wavelength-dependent absorption. The addition of water decreased the wavelength dependence over the visible somewhat, while exhibiting very strong water absorption features in the shortwave infrared. These results are confirmed and expanded using similar observations of the quartz and other soil samples.

(9310 - 2563) Ground Penetrating Radar in the determination of gravimetric moisture in Oxisols

Viviane Flaviana Condé[1]; Adalberto Rodrigues Lira Gomes[1]; Elpídio Inácio Fernandes Filho[1]; Márcio Rocha Francelino[1]

Universidade Federal de Viçosa (UFV) - Viçosa, Minas Gerais, Brazil[1]

The use of proximal sensors is still incipient in soil science. Ground Penetrating Radar (GPR) allows to survey soil properties in a quickly and non-invasively ways. The study of dynamics and spatial distribution of moisture is fundamental for decision-making and soil management. Therefore, this study aimed to evaluate the applicability of GPR to determine the soil gravimetric moisture. The study was developed in a hilly grassland in Viçosa, Minas Gerais, Brazil. Two sweeps were performed on three different transects, with 70, 100 and 130 meters long, from the top towards the valley in a mountainous relief, and the soil was identified as an Oxisol. We used the GPR SRI-3000 model from GSSI® with shielded antennas of 200, 400 and 900 MHz and the radargrams were processed in RADAN 7® software. We applied several processes to radargrams, as filters, gains, and migration, aiming to improve the electromagnetic signal and determination of the dielectric constant. In adittion, we collected at 26 samples points disturbed soil samples at 0-20, 20-40, 40-60, 60-80, 80-100 cm depths to evaluate soil moisture analysis. To calculate the volumetric soil moisture using GPR data, it was used the dielectric constant, which was obtained by processing the radargrams, applying the equations of Topp et al. (1980), Ledieu et al. (1986), Roth et al. (1992) and Malicki et al. (1996). R statistical software was used to adjust the regression equations and correlation between soil moisture measured in the laboratory, and the data obtained by GPR. Roth et al. (1992) model shows the highest coefficient of Pearson's correlation of 0.73 and R^2 of 0.53. The models described did not show significant statistical differences by t-test, at 5% significance. Then, a local calibration equation was generated, with the humidity being a function of the dielectric constant and the depth of sample collection. As a result, a correlation of 0,83 and R^2 of 0,69 were found, which improved the model performance. The values of volumetric moisture obtained by GPR were satisfactory, which indicates the possibility of using the methodology in the spatialization of the soil moisture variable, optimizing studies that require moisture values as a variable with continuous distribution.

(7704 - 518) Hyper-spectral Characteristics of Major Types of Soils in Red Soil Region of Jiangxi Province, China

Xiaomin Zhao[1]; YANG Meihua[2]
Land Resources & Environment College/Key Laboratory of Poyang Lake Basin Agricultural Resources and Ecology of Jiangxi Province, Jiangxi Agricultural University[1]; Nanchang Teachers College[2]

Soil spectrum, as a comprehensive reflection of soil properties, is important significance to soil quality management, digital soil mapping, analysis of soil properties and soil classification in the red soil regions. In this paper, a total of 443 surface soil samples were collected in the typical red soil regions, e.g. Ji'an County, Yujiang County, Xingguo County and Wanli District of Jiang Province, and visible and near infrared reflectance hyper-spectra (350～2 500 nm) of the samples were measured with an ASD spectrometer in laboratory. After the treatment of the spectra with the continuum-removal and second order derivative methods, the spectra of the four major soil subgroups and their subordinate soil families in this region were characterized. Then, 19 characteristic variables, such as spectral reflection and absorption of parent materials, iron oxide (goethite and hematite) minerals, organic matter and clay minerals and hyper-spectral reflectance, were cited as indices for Fastclus cluster analysis of the spectra. Results show that the soils in the region varied sharply in spectral reflectance from sub-group to subgroup. In terms of spectral characteristic absorption area, in the 620～740 nm spectral bands, the four subgroups exhibited an order of yellow red soil＞red soil＞brown red soil＞weakly red soil, but in terms of the difference between second order derivatives at 420 nm and at 447 nm, they followed an order of yellow red soil＞brown red soil＞red soil＞weakly red soil. The brown red soil was higher in reflectance in the Vis-NIR spectral range, but lower and wider in spectral absorption intensity in the range of 1 900 nm than all the other subgroups.The weakly red soil was the steepest in spectral curve and the highest in reflectance in the near infrared region, showing two relatively strong absorption peaks at 1 400 nm and in 1 900 nm, separately, and a super strong peak at 2 200 nm. In terms of the peak at 2 200 nm, the sub-group of red soil was similar to the sub-group of reddish soil in spectral curve variation tendency, but lower in absorption intensity at 900 nm, 1 400 nm, 1 900 nm and in 2 200 nm and higher in position of the curve.As a result of variation of the duration of flooding, paddy soils of the four sub-groups of red soils varied greatly in spectral characteristics. Classification, based on the 19 indices, of red soils in the region by soil subgroup reached 86.23% in accuracy and by soil family 66.37%.

(4457 - 749) Hyperspectral proximal sensor to evaluate the spectral behavior of soil with mining co-product application

Marlon Rodrigues[1]; Marcos Rafael Nanni[1]; Carlos Augusto Posser

Silveira[2]; Glaucio Leboso Alemparte Abrantes dos Santos[1]; Renato Herrig Furlanetto[1]; Luis Guilherme Teixeira Crusiol[1]
State University of Maringá[1]; Embrapa Temperate Weather[2]

Proximal sensing is an important tool for collecting information quickly and non-destructively. This is possible because all material presents a spectral behavior resulting from the interaction between electromagnetic radiation (EMR) source and object. Thus, it is possible to relate EMR to soil attributes, giving support to better decision of the rural producer. The aim of this paper was to evaluate the spectral behavior, obtained by the proximal hyperspectral sensor, in two classes of soils submitted to the application of different co-products from limestone mining. The soils evaluated were a Oxic Dystrudepts (OD) and an Typic Quartzipsamments soil (TQ). The co-products used were extracted from a limestone mining and consisted of materials from the Irati and Corumbataí Formations. The treatments were: T1: 100% Irati Formation (Ca^{2+} source); T2: 100% Corumbataí formation (source of K^{+}); T3: 50% Formation Irati + 50% Formation Corumbataí (sources of Ca^{2+} + K^{+}). Based on the initial characterization of the soil, corresponding amounts of the co-products were used to increase the Ca^{2+} (T1 and T3) and K+ (T2) contents to the critical soil level, according to the Brazilian Soil Science Society – RS/SC. The experiment was conducted in pots (10 replications per treatment) of 2.8 kg of dry soil, kept near the field capacity, and allocated inside a greenhouse. After 150 days incubation of the soil with the co-products the radiometric data were obtained in the spectral range between 450 and 2,500 nm using FieldSpec spectrorradiometer ASD (20 readings per treatment). Multivariate statistical analyzes were performed using The Unscrambler 10.3 software for the construction of calibration models. By the collected data, it is possible to observe a significant difference between the reflectance of the two classes of soils evaluated, in which the TQ presented the highest values. This was due to the high levels of sand and low organic matter and Fe oxides present in this class. Among the co-products used, in the TQ class there was a significant difference between all the treatments. In the OD, there was no difference between the spectral curves evaluated. Regarding the inflections in the spectral curve of each treatment, especially in the TQ, they may be related to the presence of carbonates and silicates. Thus, it can be concluded that the different classes of soils and co-products have different spectral behavior and can be discriminated by proximal hyperspectral sensing.

Institute of Soil Science, Chinese Academy of Sciences[1]; Nanjing Normal University[2]

Classification of soils is of fundamental importance to soil use and management. The conventional method of classifying soil profiles is based on the characterization of many morphological, physical, and chemical properties, which involves a wide range of laboratory analyses and is time-consuming and expensive. Visible-near infrared (Vis-NIR) diffuse reflectance spectroscopy has shown to be a potential analytical technique to measure soil properties rapidly and cheaply, especially those properties important for soil taxonomic diagnosis. The objective of this study was to develop a new method for identifying soil profile classes at order, suborder and group level of the Chinese Soil Taxonomy (CST) by using soil Vis-NIR diffuse reflectance. We used 2260 legacy soil samples collected from genetic horizons of 527 soil profiles in the soil series survey of China, and divided these profiles into a training set (75%) and a validation set (25%). The Vis-NIR (350-2500 nm) diffuse reflectance spectra for soil samples were measured using a Cary 5000 Spectrophotometer. For each soil profile, the measured reflectance from genetic horizons were interpolated to its maximum depth with 1 cm increments by fitting an equal-area spline function, to produce three dimensional (Depth-Wavelength-Reflectance) spectral surface. All the soil profile spectra were preprocessed with Savitzky-Golay first derivative. The feature points of the 3D spectral surface were extracted including top-points and bottom-points at various wavelength ranges. Random forests (RF) algorithm was used to predict soil profile classes based the attributes of the feature points. The results showed that for the identification of soil orders, suborders, and groups, the overall validation accuracies were 0.63, 0.62, and 0.40, respectively. It is concluded that the 3D spectral surface has the ability to identify soil profile classes at higher taxonomic levels in the CST system, and the identification ability will be improved with the algorithm optimation for extracting feature points.

(2951 - 2132) Kaolinite and Gibbsite spectral characterization in different geological and geomorphological compartments of the Western Paulista Plateau

Kathleen Lourenço Fernandess[1]; Angélica Santos Rabelo de Souza Bahia[1]; José Marques Júnior[1]; Milene Moara Reis Costa[1]
UNESP/FCAV[1]

Diffuse reflectance spectroscopy (DRS) is a technique known worldwide and used as it is fast, practical and presents encouraging results for the characterization of different soil attributes. However, the characterization of kaolinite (Kt) and gibbsite (Gb) in different geological and geomorphological compartments is still controversial. Thus, the aim of this study was to use DRS to characterize the occurrence of Kt and Gb minerals in the soils of different geological and geomorphological compartments of the Western Paulista Plateau. Samples were selected from soils of Basalt and Sandstone in the area of the Western Paulista Plateau. Each sample represents a geomorphological compartment: highly, moderately and not dissected. The level of dissection refers to the level of carving of the landscape. Highly dissected environments have higher geomorphogenicity rates than pedogenesis rates. While in a few dissected environments the rates are opposite. The spectral curves interpretation allowed the identification of characteristic valleys of Kt and Gb, for the pure minerals. The different combinations of the Kt and Gb ratios have a direct effect on the reflectance and intensity of the valleys from 2100 nm. Soil samples with higher percentages of Kt present higher reflectance and more characteristic valleys up to 2220 nm. The addition of Gb in the samples reduces the reflectance and increases valleys intensity as from 2220-2230 nm. In the soil samples it is also possible to characterize the Kt and Gb valleys, with different expressions for the geological and geomorphological compartments. For the Sandstone soils, the characteristic valley is between 2100 to 2230 nm, allowing to indicate the predominance of Kt in this compartment. Whereas in the Basalt soils from 2100 nm two valleys are observed, the first characteristic of Kt, between 2100-2130 to 2240-2260 nm, and the second of Gb, between 2240-2260 to 2280-2300 nm. The valleys intensities from Kt and Gb, for both geological compartments, did not allow the differentiation of the geomorphological compartments to the dissection levels. The intensity of the valleys and the reflectance still allows the identification of the geological compartment to which the sample belongs, facilitating even more studies of this magnitude. The kaolinite has a characteristic spectral range between 2130 and 2260 nm, while gibbsite has a higher occurrence between the bands of 2240 to 2300 nm, for the soils of Western Paulista Plateau.

(4052 - 1212) On-farm technique to assess the nitrogen status of winter crops from optical sensors

Jaime Andres Gomez[1]; Marisa Domenech[2]; Fernando Ross[2]; Mauricio Castro-Franco[3]

Unillanos[1]; INTA[2]; CONICET[3]

Agriculture precision (AP) technologies allow increasing the efficiency of nitrogen (N) application. However, it is necessary to optimize those using AP techniques that allow evaluating N spatial status in a fast, accurate and robust way. The objective was to propose and test a field technique to determine the spatial status of N in wheat/barley, combining on-farm strip-trials and optical sensors. The technique includes: *(i)* to delimitate zones within field using an algorithm coupling spatial principal components and Fuzzy K-means (sPC-FKM); (*ii*) to design a strip-trial of increasing dose of N; and (*iii*) to determine sampling points in each strip, using Latin Conditioned Hypercube (cLHS). Three agricultural field located in the southeast of Buenos Aires Province, Argentina (Lat: -38,529; Lon -60,419) were used. Zone within field were delimitated based on elevation, terrain and vegetation indices, using sPC-FKM. A strip-trial was designed including a wide range of soil series. The treatments were: control (0 N), doses commonly used by farmer and double dose used by farmer. A total of 10 sampling points were determined per strip using cHLS. At each point, NDVI using GreenSeeker®, chlorophyll content with SPAD 502® and biomass per m^2 at tillering, stem elongation, heading and ripening stages were measured. Also, grain yield and quality parameters were determined. Yield indices such as agronomic efficiency (AEN), grain yield response index (GYRY) and N recovery efficiency (R_{EN}) were calculated. Sensor indices such as INSEY (in-season estimated yield) and grain N uptake were also calculated. Two zones were delimitated in all fields. The results suggest that the on-farm technique proposed was able to capture the spatial variability of AEN, GYRI and R_{EN}, per zone and field. The ranges of differences for AEN, GYRI and R_{EN} were 12.06 kg grain kg N^{-1}, 76.12 % and 11.02 kg grain kg N^{-1}, respectively. INSEY, calculated from the sum of NDVI at tillering and stem elongation, showed a high correlation with yield (R^2=0.72), as have been reported in other studies. INSEY, calculated from SPAD, showed a low correlation with yield (R^2=0.2). Grain N uptake showed a high correlation (R^2=0.72) with SPAD measured at heading. These results demonstrated that the technique was efficient to evaluate the spatial variability of N status at regional scale, in a fast, accurate and robust manner.

(7818 - 613) Potential of synergy of multiple sensor data layers to predict soil properties

Julyane Vieira Fontenelli[1]; Paulo S. Graziano Magalhães[1]; Viacheslav I. Adamchuk[2]; José Alexandre M. Demattê[3]; Clécia Cristina Barbosa Guimarães[3]; Arnaldo Barros e Souza[3]; Bruna Cristina Gallo[3]

University of Campinas[1]; McGill University[2]; University of São Paulo[3]

Site-specific management of crops is essential to ensure maximum crop production profitability with minimum negative environmental impact. Today, systematic (grid) soil sampling is the most common practice to obtain the data needed to produce variable rate prescription maps. However, the cost and the labor needed to obtain this high-density soil sampling limit the ability to accurately represent spatial and, in some cases, temporal variability of soil properties across a field. Thus, it is expected that emerging proximal soil sensing technologies could help to reduce significantly the cost of data acquisition while increasing the accuracy of thematic soil maps. The objective of this work was to evaluate the synergy of multiple sensor data layers to predict maps for several important soil attributes (e.g., texture, organic matter content and chemical soil properties). The work was performed in Brazil on a 100-ha agricultural field used for sugarcane production. Within a couple of days, 423 soil samples were collected and subdivided randomly into a calibration (70% - 296) and a validation (30% - 127 samples) set of soil samples. All the samples were simultaneously sent to a commercial soil-testing laboratory for wet chemical and physical analysis. Gamma-ray spectroscopy and apparent soil electrical conductivity measurements were collected *in situ*. Field topography was measured using a real-time kinematic (RTK) global navigation satellite system (GNSS) receiver. To represent bare soil imagery, a Landsat 8 satellite image obtained within five months of soil sampling with minimum crop coverage was used. Each data layer provides unique information pertaining to soil characteristics. Based on these data, predictive variables were calculated and used to compose a series of prediction models to estimate both physical and chemical soil properties. As a result, it was determined that successful models were obtained to predict percent clay and sand, organic matter content, cation exchange capacity and copper using all data layers together, mostly achieved by bare soil imagery, field topography and apparent soil electrical conductivity. Unfortunately, a relatively poor connection was found between the gamma-ray count with the most soil properties. Such capability was not found for chemical soil properties typically used to prescribe mineral fertilization rates such as phosphorus or potassium.

(5752 - 1182) Predicting soil clay content from NIR, gamma-ray and XRF curves

Gustavo M Vasques[1]; Hugo M Rodrigues[2]; Sílvio R L Tavares[1]; Mauricio R Coelho[1]

Embrapa Solos[1]; Universidade Federal Rural do Rio de Janeiro[2]

Near-infrared spectral reflectance curves, and gamma ray and x-ray fluorescence (XRF) energy curves contain data that can be exploited as covariates in multivariate models for soil property prediction. This is the typical approach in the case of NIR reflectance curves. However, for gamma ray and XRF energy curves, the usual approach is to use the derived information they provide, that is, K, eU and eU contents, and multiple element contents, respectively. These element contents are derived from algorithms that are pre-calibrated in the factory using data from the energy curves, whose shapes and peaks relate to specific or multiple elements. In this study, data from NIR, gamma ray and XRF curves, and three multivariate methods (partial least squares regression - PLS, random forest – RF, and support vector machine - SVM) were used to predict soil clay content at 0-10-cm depth. Training and validation data included 103 and 25 samples, respectively. Gamma ray and XRF data were taken *in situ* at the soil surface, using portable sensors, whereas NIR reflectance curves (800-2500 nm) were measured from air-dried fine earth samples in the laboratory. Clay contents were measured by the densimeter method. In the case of XRF, curves from the three x-ray beams were used separately to derive distinct prediction models. Clay contents minimum, maximum, mean, median, and standard deviation were 40, 360, 180, 170, and 90 g kg^{-1}, respectively. Training R^2 and root mean squared errors (RMSE) for NIR, gamma ray and XRF (x-ray beams 1 through 3) models were (R^2/RMSE): 0.91/26, 0.86/33, 1.00/4, 0.85/34 and 0.90/28 (PLS); 0.95/22, 0.96/21, 0.98/17, 0.98/17 and 0.96/20 (RF); and 0.90/28, 0.99/9, 1.00/0, 1.00/0 and 1.00/0 (SVM), respectively. Validation RMSE were: 49, 109, 45, 35 and 44 (PLS); 43, 61, 54, 52 and 46 (RF); and 50, 63, 45, 30 and 52 (SVM), respectively. In validation, the XRF curves derived the best clay content predictions from PLS and SVM models, and the NIR curves were superior in RF. Compared to NIR, the XRF sensor is field-portable, and thus, it is preferred for faster and cheaper clay content prediction. The same applies for the gamma

ray sensor if the magnitude of the errors are acceptable for the desired use. Overall, the results support NIR, gamma ray and XRF curves as potential covariates for soil clay content prediction, though there is room for improvement, for example, by testing other prediction methods or pre-processing the curves.

(4145 - 2672) Prediction of Soil Organic Carbon using Neural Network with Vis–NIR spectra in highlands of Itatiaia National Park, Rio de Janeiro

Gelsleichter, Yuri[1,2]; Anjos, Lúcia H. C. dos[1,2]; Antunes, Mauro H. A.[1,2]; Valente, Gabriela[1,2]; Costa, Elias M.[1,2]; Marcondes, Robson A. T.[1,2]
[1]Federal Rural University of Rio de Janeiro, Rodovia BR 465, km 07, Seropédica - RJ, 23890-000, Brazil (yuriplanta@gmail.com); [2]Szent István University, Gödöllő, Páter Károly u. 1, 2100, Hungary[1]; [1]Federal Rural University of Rio de Janeiro, Rodovia BR 465, km 07, Seropédica - RJ, 23890-000, Brazil[2]

Visible and near-infrared reflectance (Vis–NIR) techniques are alternative methods to conventional chemical laboratory soil analyses for many soil attributes, including soil organic carbon. Besides, Vis–NIR techniques are fast, environment friendly, and non-destructive of samples. In this study soil organic carbon (SOC) was predicted applying Vis–NIR, and the spectrums on 305 soil samples by using a FieldSpec 4® spectrometer (350–2500 nm). The study area is located at the western region of Rio de Janeiro State, in the highlands of Itatiaia National Park (INP) that has its highest point at 2.791,6 m. Conditioned Latin hypercube sampling (cLHS) method was used to design the collection of samples from 90 soil profiles. The INP plateau has a relatively expressive area of organic soils, located in the valleys formed among the rocky outcrops. Organic carbon was also measured in all samples in the laboratory by using the dry combustion method. Prediction was performed with Neural Network using the R package neuralnet. The RMSE for normalized 0-1 values was of 0.067 and the R^2 0.90. The technique shows potential for large application, and it is especially important in areas of limited access such as the INP. Considering the SOC is an important indicator of soil quality and degradation, it is also relevant for the management plan of the INP, since the good correlation with Vis–NIR techniques allows for future monitoring by using remote sensing tools.

(1469 - 2887) Qualitative evaluation of soil organic matter using Vis-NIR diffuse reflectance spectroscopy in an agroecological production system in Seropédica, Rio de Janeiro (Brazil)

Marcela Lopes Lázaro[1]; Gustavo M. Vasques[2]; Maria Gabriela Ferreira da Mata[1]; José Guilherme Marinho Guerra[3]; Marcos Bacis Ceddia[1]; Érika Flávia Machado Pinheiro[1]
UFRRJ[1]; Embrapa Solos[2]; Embrapa Agrobiologia[3]

Soil organic matter (SOM) is a key component to understand and monitor soil quality and processes, providing information on agronomic and ecological use and management of agroecological production systems. Visible and near infrared reflectance (Vis-NIR) has presented potential as a non-invasive and non-destructive method to characterize soils and their chemical, physical and mineralogical attributes. The aim of this study was to compare SOM contents and associated Vis-NIR spectral curves among areas with different agroecological production systems/treatments.The experiment was carried out in 2014 at the *Sistema Integrado de Produção Agroecológica* (Integrated System of Agroecological Production), in Seropédica city, Rio de Janeiro state, Brazil. The area has Planosols and was divided in two sub-areas: Sub-area 1 (3578 m²) – for organic vegetables production with (3051 m²) and without shading screens (527 m²), and Sub-area 2 (4676 m²) – for biomass production (straw) with 3982 m² of elephant grass cv. Cameroon (*Pennisetum purpureum*) and 694 m² of shrub legumes (*Gliricidia sepium*). A total of 246 soil samples were collected at a depth of 20 cm on a 0.5 by 0.5 m regular grid. After air-drying, they were sieved (2 mm) and analysed for SOM via wet oxidation. Then, Vis-NIR reflectance spectral curves (350-2500 nm) were obtained in the laboratory and interpreted qualitatively in relation to the SOM contents and chemical groups. The screen-covered area (36 samples) showed the highest SOM contents (1,55% of SOM and 25% of reflectance on average) whereas the shrub legumes area (27 samples) showed the lowest SOM contents (0,86% of SOM and 30% of reflectance on average). The sun-exposed organic vegetables area (120 samples), and elephant grass area (63 samples) showed similar Vis-NIR curves and intermediate SOM contents of about 1,43% of SOM and 28% of reflectance on average. The spectral curves of soils from the four areas/treatments showed absorption peaks at the same wavelengths, related to water and C-H, O-H, C-O, N-H and S-H groups. On the other hand, higher SOM contents produced lower Vis-NIR reflectance (albedo), enabling to rapidly (qualitatively) screen and monitor SOM contents among the different agroecolgical production system/treatments.

(7630 - 1940) Soil analysis through portable fluorescence X-ray (pXRF) spectrometer: predicting sum of bases (SB) and cation exchange capacity (CEC) in tropical soils.

Marcelo Mancini[1]; Wilson Missina Faria[1]; Sérgio Henrique Godinho Silva[1]; Michele Duarte de Menezes[1]; Luiz Roberto Guimarães Guilherme[1]; Nilton Curi[1]
Federal University of Lavras[1]

Traditional methods to evaluate important soil chemical properties such as cation exchange capacity (CEC) and pH require laborious chemical analysis that are often expensive and time consuming. As an alternative to these methods, some studies have recently introduced the use of portable X-ray fluorescence (pXRF) spectrometry as a means to infer soil properties. However, such analyses are still scarce in tropical soils and, thus, need to be evaluated. This work further studies this possibility by utilizing data obtained via pXRF to predict the sum of bases (SB) and the CEC of Brazilian soils. 594 samples of soil A horizon were collected in 6 Brazilian states and subjected to laboratory analyses of SB and CEC. The samples were also analyzed by a Bruker® pXRF S1 Titan, in triplicate for 60 seconds using Trace mode. Ordinary least square (OLS) and random forest (RF) methods were used to create SB and CEC predictive models with 70% of the total data. The models were further validated by calculating the root mean square error (RMSE), mean error (ME) and R^2 using the remaining 30% of the data. Results by the RF method were evaluated through the mean of squared residuals (MSR) and the percentage of explained variance obtained from the generated models. The models achieved through OLS to predict SB and CEC, respectively, are given by: $SB = 2.5411 + 38.2560CaO + 14.0360Cl - 13.8962K_2O + 7.6625Mn + 7{,}0441Rb$ ($R^2 = 0.45$); and $CEC = 8.838 - 4.9681Al_2O_3 + 38.0318CaO - 9.1297K_2O + 13.1336Ni + 36.2903Y + 4.1521Zn - 14.2889Zr$ ($R^2 = 0.31$). Random forest resulting mean of squared residuals (MSE) and explained variance were 8.52 and 52.83% for SB and 22.52 and 29.36% for CEC. Random forest models performed better in validation tests when compared to OLS, providing overall higher R^2 (0.8 vs. 0.63 and 0.59 vs. 0.54, for SB and CEC models, respectively), as well as lower RMSE (1.95 vs. 2.6 and 3.13 vs. 3.78) and ME (1.32 vs. 1.92 and 2.41 vs. 3.04). pXRF spectrometry can ease the efforts to gather important information about tropical soils and the models generated show it is conceivable to apply and further improve this idea for these

and other soil properties in different types of soils, reducing the cost and time required for characterizing soils around the world, especially in developing countries, such as Brazil, where there is a lack of financial support for such activities.

Keywords: random forest, ordinary least square, soil properties prediction, soil characterization.

(5947 - 767) Soil apparent electrical conductivity correlated with crop yield

João Pedro Moro Flores[1]; Ricardo Simão Diniz Dalmolin[1]; Jean Michel Moura Bueno[1]; Diego José Gris[1]; Luciano Campos Cancian[1]; Nicolas Augusto Rosin[1]; Taciara Zborowski Horst[1]

Universidade Federal de Santa Maria[1]

The apparent electrical conductivity (ECa) of the soil has a high correlation with the physical-chemical attributes of the soil, for example, texture and cation exchange capacity. These attributes are related to crop yields. In this sense, ECa maps can serve as indicators of soil suitable for high crop yields. However, few studies have addressed the correlation between ECa obtained by proximal sensors and crop productivity. Thus, the objective of this study was to analyze the spatial variation of soil ECa obtained by the Veris sensor and its correlation with cotton yield. The study was carried out in an agricultural area in Primavera do Leste county, state of Mato Grosso, Brazil. Soil ECa evaluation were performed using a Veris 3100 sensor, capturing ECa values at depth 0.0 - 0.3 m (shallow) and 0.0 - 0.9 m (deep). Quantification and spatialization of the production was performed by a mass flow sensor installed in the cotton harvester. ECa and yield maps were interpolated by the nearest neighbor method as an approximation technique, using SAGA GIS® software, generating spatialized maps of soil ECa and cotton yield. The data were evaluated through descriptive statistics to characterize the spatial variability of ECa and cotton yield. Data were also analyzed by Pearson correlation with an error probability of 5% through t-test. From the analysis of the data, it is possible to verify that shallow ECa and deep ECa have a high correlation with each other (0.95), and cotton yield correlated significantly with shallow ECa (0.69) and deep ECa (0.65). The shallow and deep ECa and cotton yield presented an adjustment to a polynomial of order 2, with values of R^2 = 0.63 and 0.54 respectively, indicating that the higher the ECa value, have relation with the higher the crop yield. Both correlation coefficients obtained for the present study were moderate, indicating that this soil parameter can be a useful alternative for the delimitation of different management zones within the agricultural field. There is a great potential for the use of soil ECa in order to identify and predict productivity zones in an agricultural area, which may be influenced by soil physical-chemical attributes, especially clay, cation exchange capacity and consequently the soil classes present in the area. Future studies should be carried out using digital soil mapping techniques to predict and map ECa, identifying areas of management according to the soil's agricultural potential.

(3598 - 2195) Spatial variability of elemental contents in a Brazilian cerrado Ustept profile through portable X-ray fluorescence (pXRF) spectrometer

Thaís Santos Branco Dijair[1]; Sérgio Henrique Godinho Silva[1]; Anita Fernanda dos Santos Teixeira[1]; Luiz Roberto Guimarães Guilherme[1]; Nilton Curi[1]

Universidade Federal de Lavras[1]

In recent years, new tools have become available to support soil-related studies, such as proximal sensors. Among these sensors, the portable X-ray fluorescence spectrometer (pXRF) has been increasingly used, especially for rapid field and laboratory analyses. The pXRF is able to obtain the content of several elements of the Periodic Table and, in this way, has been used in the characterization of soil profiles, but these so-called digital soil morphometrics studies are still very rare in Brazilian soils. The objective of this work was to evaluate the spatial distribution of the contents of CaO, K_2O, Fe_2O_3, and SiO_2 present in a profile of Ustept of the Brazilian cerrado derived from phyllite. 24 places in an Ustept profile were analyzed with pXRF in Trace mode, during 60 s, in triplicate, forming a regular grid with 12.5 cm distance between analyzed places. The analyses included the A, B, C, and Cr horizons in order to capture variability of these compounds following weathering pathways. The spatialization of CaO, K_2O, Fe_2O_3, and SiO_2 contents was performed using the inverse distance weighting method. Through these data, it was possible to observe the change of concentration of these compounds across the horizons. CaO and K_2O presented higher contents in depth due to the greater amount of these compounds in the horizons closest to the parent material (C and Cr horizons), where there are more Ca- and K- bearing minerals. SiO_2 showed a slight increment of concentration in depth, where analyses of X-ray diffraction showed higher amounts of silicates than in the upper horizons. Fe_2O_3 presented a varied concentration along the profile, which is a probable reflection of the variability of the concentration of this compound in the parent material. The use of pXRF in the morphometric characterization of an Udept profile enabled us to obtain detailed results on the spatial variability of chemical elements in a soil profile in a rapid and more economical way. Future work will focus on the analyses of these and other elemental contents in the sand, silt and clay fractions of the A, B, C, and Cr horizons of this profile to better understand the particle size fraction in which each element tends to concentrate and, then, correlate such data with mineralogy of such particle size fractions.

(1470 - 3028) Spectroscopic mining of soil archives to fill critical data gaps.

Jonathan Sanderman[1]; Shree R. S. Dangal[1]; Jeffrey Baldock[2]; Richard Ferguson[3]; Syke A. Wills[3]

Woods Hole Research Center[1]; CSIRO Agriculture and Food[2]; USDA National Soil Survey Center[3]

Proximal soil sensing using visible, near and mid infrared spectroscopy has become an indispensable tool in a soil scientist's tool box. For mapping and survey work, the small sacrifice in accuracy and precision is typically more than offset by the time and cost savings of spectroscopy-based inference systems. A number of nations have now built substantial soil spectroscopic libraries each with differing sets of accompanying analytical data. Here we report on progress in linking the mid infrared spectral library and soil carbon fraction database from the Australian Soil Carbon Research Program with the large and growing spectral library of the United States Department of Agriculture Kellogg Soil Survey Laboratory with a goal of mapping the distribution of organic carbon into biologically significant fractions across the agronomically important Great Plains ecoregion of the United States.

(4735 - 1565) Stratification of a spectral library accordingly to soil texture produces more accurate soil organic carbon predictions?

Jean Michel Moura-Bueno[1]; Ricardo Simão Diniz Dalmolin[1]; Alexandre

ten Caten[2]; Diego José Gris[1]; Nicolas Augusto Rosin[1]; Taciara Zborowski Horst[1]; João Pedro Moro Flores[1]
Universidade Federal de Santa Maria[1]; Universidade Federal de Santa Catarina - Campus Curitibanos[2]

Prediction models for soil organic carbon (SOC) using spectral data have shown variable accuracy due to multivariate calibration methods and the number of samples used for model calibration. However, few studies have demonstrated the performance of the models when using a regional spectral library (RSL) composed by samples with distinct soil properties, characterizing a heterogeneous RSL (HRSL). Considering the hypothesis that the predictive ability of the models is linked to soil data complexity, the stratification of a spectral library based on soil texture is a strategy to improve the accuracy of SOC predictions. Therefore, the objective of this study was to evaluate the performance of SOC prediction models after the stratification of a HRSL, using soil texture as criterion. A HRSL (n = 1,922 samples) from the Rio Grande do Sul (RS) and Santa Catarina (SC) state, south of Brazil, was used. The database is composed by samples from the Planalto and Depressão Central of RS and from the mountain region of SC. The spectral reflectance measurements were performed in laboratory with a spectroradiometer in the 350-2500 nm range. Spectral data were submitted to normalization preprocessing analysis. The multivariate partial squares regression (PLSR) calibration method was used to generate the models. Firstly, a model was generated using all the samples in the HRSL and then the spectral library was stratified in two groups based on soil texture, namely sandy, silt and medium texture (> 15% sand and < 35% clay – 332 samples) – T1; and, clayey and very clayey texture (> 35% clay – 1,590 samples) – T2. Models were built with 70% of the samples for calibration and 30% for validation. Coefficient of determination (R^2_V) and root mean square error ($RMSE_V$) of validation were used to assess the performance of the models. The model generated with all the samples reached an accuracy of R^2_V = 0.60 and $RMSE_V$ = 0.67%. After stratification, the model generated for group T2 showed the best accuracy (R^2_V = 0.70, $RMSE_V$ = 0.46%), followed by group T1 (R^2_V = 0.41, $RMSE_V$ = 1.52%). This study highlights that samples with sandy and medium texture have smaller accuracy of regional prediction models for SOC. The application of VIS-NIR spectroscopy shows potential as a reliable and inexpensive tool to quantify SOC for subtropical soils with high clay contents. Predictive models for soil properties can be improved when the variability of soil characteristics is considered in HRSL.

Luiz de Queiroz College of Agriculture (ESALQ), University of São Paulo (USP), *Corresponding author[1]; ESALQ - USP[2]; Universidade Federal de Santa Maria[3]; Universidade Federal de Pernambuco[4]; EPAGRI[5]; Universidade Estadual de Maringá[6]; Universidade Federal Rural da Amazônia[7]; Faculdade de Agronomia e Medicina Veterinária da Universidade de Brasília[8]; Embrapa Solos UEP - Recife[9]

The Brazilian Soil Spectral Library (BSSL) began its collection in 1995 at the Department of Soil Science (ESALQ-USP). Currently, SSLB has gathered data from all the 26 States of Brazil, reaching more than 38,000 soil samples. This achievement was only possible to reach due to the collaboration (33instituitions) and 49 researchers. The objective of this manuscript is to present the system on the utilization and applications of this dataset. The spectral data range from visible to shortwave infrared (350 to 2.500 nm). The BSSL allow identify the main spectral behavior of Brazilian soils. With the development of BSSL, it is possible to: a) locate partners for joint research development; b) assess, via internet, whether a local, regional, or national estimative of your own spectra, based on calibrated models. In this context, we also can perform the prediction of soil color by using the reflectance data. In the present work, we determined how many spectral patterns are required to represent Brazilian soils. The preliminary results showed that 5 spectral curves can represent the spectral patterns of Brazilian soils. The BSSL can be informative regarding classification, soil surveys and quantification. It will be presented the utility of national spectra to predict soil attributes, such as organic matter (OM), sand, silt, clay, cation exchange capacity (CEC), and pH. The result of national estimation model for these attributes showed that the granulometry presented good performances (R^2 between 0.55 and 0.70) and slightly smaller for OM, CEC and pH. New contributions to the BSSL are still encouraged for a second round for 2019. We hope that this work reinvigorate our community's discussion towards the importance of sensors in agriculture, environment and extend the soil researches.

(1791 - 3209) The geographic and environmental characterization of the Brazilian Soil Spectral Library (BSSL)

José Alexandre Melo Demattê*[1]; Ariane Francine Desidério da Silveira[2]; André Carnieletto Dotto[2]; Marcus Vinicius Sato[2]; Ricardo Simão Diniz Dalmolin[3]; Maria do Socorro Bezerra de Araújo[4]; Elisângela Benedet da Silva[5]; Marcos Rafael Nanni[6]; Norberto Cornejo Noronha[7]; Marilusa Pinto Coelho Lacerda[8]; José Coelho de Araújo Filho[9]; Rodnei Rizzo[2]
Luiz de Queiroz College of Agriculture (ESALQ), University of São Paulo (USP), *Corresponding author[1]; Luiz de Queiroz College of Agriculture (ESALQ), University of São Paulo (USP)[2]; Federal University of Santa Maria[3]; Federal University of Pernambuco[4]; EPAGRI[5]; State University of Maringa[6]; Federal Rural University of Amazônia[7]; University of Brasília[8]; Brazilian Agricultural Research Corporation - Soils[9]

The Brazilian Soil Spectral Library (BSSL) started with a collection of soil samples in 1995 at the Department of Soil Science (ESALQ-USP). Currently, BSSL has gathered data from 26 States of Brazil, totaling more than 38,000 soil samples. Thus, the objective of this work was to present the first results of this databank in relation to Brazilian soils and its soil attributes. The BSSL allows to extract and associate the inherent spectral information with the geographic and environmental variables. With the development of BSSL, it was possible to demonstrate the potential of this tool for tropical soils management, and relate the soil spectral reflectance to the regions and states, biomes, geology, soil classes, and vegetation. Principal component analysis was performed to explore and visualize correlated data. The average spectrum was determined for each group. The group of spectra of Amazonas and Pernambuco States, the North and Northeast regions showed higher reflectance corroborating the presence of sandy soils. While spectra from the States of Rio Grande do Sul, Rio de Janeiro, and Mato Grosso do Sul, also the South, Southeast and Center-West regions revealed low spectral

reflectance. This low reflectance is correlated with clayey soils, which are iron oxides and organic matter abundant. In relation to the types of geology, spectral curves from igneous rocks, rich in calcium and iron, had low reflectance, while metamorphic rocks exhibited with high reflectance and well-defined features mainly linked to the minerals of feldspar, quartz, and plagioclase. Among the soil classes, the behavior of the Oxisol spectral curve showed the lowest reflectance due to the high levels of clay and iron oxide contents. The spectral curve of the Histosol presented low reflectance in the visible region due to the high content of organic matter in these soils. On the other hand, the Spodosol had the highest reflectance followed by Aridisol class, since these soils present very high sand content. With SSLB, it was possible to characterize and group the intrinsic spectral soil information geographically and environmentally. The use of sensors and geotechnologies, due to their agility and low cost in the analysis, allows a higher sample density practice, improve the problem of detailed soil mapping, and generate data for the soils survey and mapping that can assist in the management of agriculture in a rational way.

(7452 - 519) The Research of Paddy Soil Quality Spatial and Temporal Change in Fengxin County, Jiangxi Province of China

Guorui Hu[1]; Xiaomin Zhao[2]
Yichun University[1]; Land Resources & Environment College/Key Laboratory of Poyang Lake Basin Agricultural Resources and Ecology of Jiangxi Province, Jiangxi Agricultural University[2]

Soil Quality is the comprehensive reaction of soil properties, and the crop yield react the crop grow situation. The differences of the soil quality cause the crop growth difference and then intensify the soil fertility variability. To research the spatial and temporal change of soil quality is the basis of scientific to manage soil fertility and crop fertilization. In the research, 2016 paddy soil samples was surveyed and analyzed in Fengxin County, and then, the analysis results was compared with the results from the second soil survey to research spatial and temporal change of the soil properties by GIS. Then, the soil quality was evaluated and classified. The results show that soil fertility in Fengxin County was raised in last 30 years, the highest raised paddy field are located at east low hill region, especially the field at plain nearby the main road by compared the soil properties between soil samples analysis and the second soil survey paddy. The ratio of soil quality class which highest raised for effective phosphorus to total paddy field is 98.2%, especially the ratio of class rise 2 or 3 are 37.87% and 33.40%, respectively. The ratio of raised soil quality class for effective potassium, organic matter content and total nitrogen are 71.34%, 68.39% and 47.44%, respectively. Based on GIS, the paddy soil quality evaluation index system and evaluation models were established, and the paddy soil quality was evaluated comprehensively. The results include 7 soil quality class, the ratio of each class area to the total area are 10%, 13.86%, 17.81%, 18.63%,11.80%,15.35% and 12.55%, respectively.

(5122 - 2152) Accuracy of clay content prediction through spectroscopy affected by multivariate method

Nícolas Augusto Rosin[1]; Ricardo Simão Diniz Dalmolin[1]; Jean Michel Moura-Bueno[1]; Diego José Gris[1]; Taciara Zborowski Horst[1]; João Pedro Moro Flores[1]
Universidade Federal de Santa Maria[1]

The determination of clay content is important for sustainable soil management. Soil particle size distribution have a direct impact on physical, chemical and biological functions of soil. Clay content can be predicted allying the spectroscopy technique with multivariate statistical models. Among the factors that influence the accuracy of prediction models are the many different of multivariate methods. According to the literature, the method of partial least squares regression (PLSR) is better for samples of homogeneous areas at local scale. However, there is a lack of papers using a spectral library derived from distinct soils and places, presenting samples with a sharp variation in the physical, chemical and mineralogical attributes. Therefore, the objective of this study was to evaluate the accuracy of different multivariate methods for clay content prediction from of a heterogeneous soil spectral library. A database with 1992 samples from the south region of Brazil was used, encompassing soils from Planalto and Depressão Central of Rio Grande do Sul and mountain region of Santa Catarina. Clay content was determined via pipette method. Spectral analyses were performed using a spectroradiometer in range 350-2500 nm. The spectral data was submitted to smoothing pre-processing with a mobile window of 9 nm. The following multivariate methods were tested: PLSR, random forest (RF), support vector machine (SVM) and multiple linear regression (MRL). 70% of samples were used for calibration and 30% for validation of the models. Model accuracy was evaluated coefficient of determination (R^2_V) and root mean square error ($RMSE_V$). The models were generated in the graphic interface AlradSpectra. The best accuracy was achieved using the PLSR model, with R^2_V = 0.78 and $RMSE_V$ = 8.82%, followed by the models SVM, with R^2_V = 0.77 and $RMSE_V$ = 9.09%, MRL, with R^2_V = 0.76 and $RMSE_V$ = 9.19% and RF, with R^2_V = 0.68 and $RMSE_V$ = 10.72%. The PLSR method demonstrated superiority in the accuracy in relation to the others, however, the difference was less accentuated than in the studies with homogeneous samples. More studies should be performed approaching the effect of spectral processing techniques and number of samples in the calibration of models with heterogeneous data.

WG06 Soil Monitoring: Soil monitoring evolving tools and challenges

(4231 - 542) Turning Band Co-simulation algorithm approach to multivariate mapping of heavy metals spatial contamination in a Cu-Ni exploration field

Peter N. Eze[1]; Nasser Madani[2]; Amoussou Adoko[2]
Department of Earth & Environmental Science Botswana International University of Science & Technology, Palapye, Botswana[1]; Department of Mining Engineering, School of Mining and Geosciences, Nazarbayev University, Kazakhstan[2]

The mining and smelting of copper and nickel around Selibe-Pikwe in the Central Province of Botswana is capable of releasing heavy metals including Pb, Fe, Mn, Co, Ni and Cu into the soil environments, thereby exposing humans, plants and animals to health risks. In this study, turning band co-simulation, a multivariate geostatistical model, was presented here as a tool for spatial uncertainty quantification and probability mapping of cross-correlated heavy metals (Co, Mn, Fe and Pb) risk assessment in a semi-arid Cu-Ni exploration field of Botswana. A total of 1050 soil samples were collected across the field at a depth of ~10 cm in a grid sampling design. Rapid elemental concentration analysis was done using an Olympus Delta Sigma portable x-ray fluorescence device. Enrichment factor (EF), geoaccumulation index (Igeo) and pollution load index (PLI) were used to assess the potential risk of heavy metals contamination in soils. The partially heterotopic nature of the dataset and strong correlations among the heavy metals favours the use of co-simulation instead of independent simulation in the probability mapping of heavy metal risks in the study area. The strong correlation of Co and Mn to iron infers they are of lithogenic origin, unlike Pb which had weak correlation pointing to its source in the area being of anthropogenic source. Manganese, Co and Fe show low enrichment,

whereas Pb had high enrichment suggesting possible lead pollution. We, however, recommend that speciation of Pb in the soils rather than total concentration should be ascertained to infer chances of possible bioaccumulation, and subsequent health risk to human by chronic exposure.

WG08 WRB: Soil Classification for understanding soil genesis, map legends and soil functions. Experiences with WRB and other systems

(8773 - 1002) Applying the World Reference Base 2015 to soil profile databases of various nomenclatures: Tool, performance and feedbacks

Einar Eberhardt[1]; Peter Schad[2]
Bundesanstalt für Geowissenschaften und Rohstoffe, Stilleweg 2, D-30655 Hannover, Germany (einar.eberhardt@bgr.de)[1]; Technical University of Munich, TUM School of Life Sciences Weihenstephan, Chair of Soil Science, Emil-Ramann-Str. 2, 85354 Freising, Germany[2]

An MS Access-based application for identifying soils according to the World Reference Base for Soil Resources (WRB), third edition, update 2015, has been developed. The derivation procedures use soil description data and laboratory data. The description data are either according to the German Soil Survey Guidelines, 5th ed. (2005), or according to the FAO Guidelines for Soil Description, 4th edition (2006). Various levels of data quality are accepted and uncertainty of the derivation result is addressed. The tool is basically multi-lingual; currently English and German are implemented. The modular architecture allows flexible adaptations and easy bug-tracking. Earlier, we developed a similar tool according to the second edition of the WRB. The comparison of the algorithms of the two versions reveals that the new WRB follows a better logic and makes many algorithms clearer and less complex. Performance has been tested using a 200-profile dataset representing the most abundant soil types of Germany, Switzerland and Austria. Classification results depend on data quality; medium level data quality is sufficient for > 80 % correct identification of the reference soil group (RSG) and the qualifiers. Algorithm design and classification results enable some feedback for soil description guidelines and their use, and for further enhancing WRB. It is suggested to define a better structure of soil description data, complete codelists and enhance soil description in the field. We also recommend some improvements of diagnostic criteria of the WRB for better applying them to soil data in databases.

(9703 - 2021) Beyond Earth: Can we classify Martian soils with WRB?

Jérôme Juilleret[1]; Giacomo Certini[2]; Riccardo Scalenghe[3]; Stefaan Dondeyne[4]
Luxembourg Institute of Science and Technology, Department Environmental Research and Innovation, 41 rue du Brill, L-4422 Belvaux, Grand Duchy of Luxembourg (jerome.juilleret@list.lu)[1]; Università degli Studi di Firenze, Dipartimento di Scienze delle Produzioni Agroalimentari e dell'Ambiente, Piazzale delle Cascine n° 28, 50144 Firenze, Italy (giacomo.certini@unifi.it)[2]; Università degli Studi di Palermo, Dipartimento di Scienze Agrarie, Alimentari e Forestali, Viale delle Scienze 13, 90128 Palermo, Italy (riccardo.scalenghe@unipa.it)[3]; University of Leuven, Department of Earth and Environmental Sciences, Celestijnenlaan 200E, B-3001 Leuven, Belgium (stefaan_dondeyne@yahoo.co.uk)[4]

With interplanetary exploration in recent years planet Mars is a priority for future potentially manned missions. Since the first missions in 1970s, multiple landers have delivered data and new knowledge on Mars' surface. With new missions scheduled in the future, there is a need for classification tools adapted to extra-terrestrial soils. This stands as a prerequisite for solving issues related to space or farming and mining. The classification of Martian soils stands as an exercise, just as for terrestrial soils, to group our knowledge and increase our understanding on soil evolution. Historically, soil classification has been conducted in support of agriculture and tended to focus on the *solum* part of the Earth's skin characterised by addition and decomposition of organic matter, which largely drives pedogenic processes. In the last decade research on soil classification has extended its focus to the underlying *subsolum*, as it is recognized as being essential to critical zone sciences. While the Earth's *solum* is unique in our solar system, equivalents to the *subsolum* are present on all rocky planets. A recent paradigm shift in soil classification – essentially excluding biotic agents – offers the potential for exploring new avenues towards extra-terrestrial soil classification. In the 2006 edition of WRB, to "*avoid sterile discussions on a universally agreed definition of soil*" soil is considered to be "*any material within 2 m of the Earth's surface that is in contact with the atmosphere, excluding living organisms, areas with continuous ice not covered by other material, and water bodies deeper than 2 m*". Ultimately, this definition could potentially be applied to Martian soils defined by planetary geologists as "*any loose, unconsolidated materials that can be distinguished from rocks, bedrock, or strongly cohesive sediments. No implication of the presence or absence of organic materials or living matter is intended*." Based on this extended concept of soils, we propose a blueprint for transposing terrestrial soil classification concepts to Martian soils. We used a simple geopedological approach, including outcrops and landscape pictures taken by NASA's Curiosity Mars rover inside the Gale Crater, aiming at triggering a discussion on exo-pedology classification systems for rocky planets. This debate will contribute to overcome current limitations and open questions, in soil classification in general, as well as in extra-terrestrial soil exploration.

(4243 - 2413) Comparative adaptive world soil classification systems for map legend design in Nigeria: Soil Association [Local System], Soil Taxonomy, and World Reference Base.

Temitope A. Okusami[1]
Federal University, Wukari. Taraba State.Nigeria[1]

The objective is to use the characteristics of soils mapped from some selected agroecological areas within Nigeria to do a comparative classification for adaptive mapping legend using the "USDA-Soil Taxonomy" and the " World Reference Base [WRB]" systems with the Soil Association –Soil series sequence serving as the dependent variable. In this instance the concern of this paper is what is applicable during the mapping phase , i.e., when mapping legend is being defined for the different soils identified during field research and/or field activities for actual mapping work. The soils used are derived from basement complex rocks[Ilero at 08.05N/03.22E] and the coastal sediments [at Igbodu [6.28'13'N/4.19'30"] in the sub-humid and humid parts of southwest Nigeria respectively. The soils pattern reflect the toposequence and/or lithosequence concepts with a typical sequence of soils on the crest, shoulder and/or upper slope, middle slope, lower slope, fringe and/or valley bottom positions. At the mapping phase, the WRB nearly corroborates the intrinsic qualities of the Soil Association-Soil Series concept. This comparison is fully developed when the characteristics of the different classification units are compared to the morphological expression as shown in the Soil Association-Soil Series concept. Although it should be noted that the philosophy behind these two systems only slightly overlap as classification systems adaptabke for soil mapping purposes at the level of soil management requirements.

(1443 - 224) Red book of soils of Georgia – experiences with a competitive use of the national soil classification and the WRB

Tengiz F. URUSHADZE[1]; Tamar O. KVRIVISHVILI[2]; Winfried E.H. BLUM[3]
Agricultural University of Georgia, Michail Sabashvili Institute of Soil Science, Agrochemistry and Melioration, Tbilisi, Georgia[1]; Agricultural University of Georgia[2]; University of Natural Resources and Life Sciences (BOKU), Vienna, Austria[3]

The establishment of a Red Book of Soils is a first important step towards soil protection. Some countries have already realized such activities. Unfortunately, there is no general standard for classifying and grouping soils within those Red Books, what would be necessary in order to compare endangered soils across national borders. Georgia as a natural Open-Air Museum of Soils'' raised a great interest among many generations of soil scientists. Therefore, special studies of the soil cover on the basis of the World Reference Base for Soil Resources (WRB) are required. The concept of the WRB aims at establishing a unified soil language making it possible to compare and to correlate national soil classifications under its umbrella. For the Red Book of the Soils of Georgia we classified soils into 3 groups: Unique, Rare and Standard. Unique soils are represented by three soil types: Cinnamonic soils (Cambisols & Kastanozems); Meadow-cinnamonic soils (Kastanozems) and Yellow brown forest soils (Luvisols & Stagnosols). All these three types of soil were described in Georgia for the first time: Cinnamonic soils in East Georgia, near the town of Mtskheta, by Prof. S. Zakharov in 1904. Meadow-cinnamonic soils were first described by Prof. V. Fridland in 1957 also in East Georgia, near the village of Mukhrani. Yellow-brown soils in West Georgia, near the town of Batumi, were described by Acad. T. Urushadze in 1967 for the first time. Under the group of rare soils the following soil types were distinguished: Terra Rossa (Rendzic Leptosols (Brunic), Mountain-meadow humus-illuvial soils (Sombric horizon); Brown forest black soils (Stagnosols) and Andosols (Andosols). Terra Rossa soils are formed on carbonate rocks (mainly limestones). Mountain-meadow humus-illuvial soils are formed in depressions of high mountain areas. Brown forest black soils are characterized by thick humus horizons with a humid water regime. Andosols occur in mountain plateau areas. Within the group of standard soils we distinguish all other soil types in Georgia: Red (Nitisols); Yellow (Luvisols); Bog (Gleysols & Histosols); Yellow Podzolic (Acrisols); Brown Forest (Cambisols); Raw Carbonate (Leptosols); Grey Cinnamonic (Kastanozems); Meadow Grey Cinnamonic (Kastanozems); Black (Vertisols); Chernozems (Chernozems); Mountain Forest Meadow (Umbrisols); Mountain Meadow (Umbrisols); Mountain Meadow Chernozems (Phaeozems); Saline (Solonchaks & Solonetz); Alluvial (Fluvisols); Alluvial (Fluvisols).

(7885 - 3234) Soils on calcareous rocks in recent soil classification systems

Dmitry Konyushkov[1]; Maria Gerasimova[1]; Tatiana Ananko[1]
Dokuchaev Soil Science Institute[1]

The first stage of updating of the Soil Map of Russia (1:2.5 M, 1988) assumes finding proper equivalents to soil names on the map in the new Russian soil classification system (2004, 2008); in parallel, their correlation with other classification systems, including WRB-2014 is being performed. This work is based on the analysis of diverse soil information for each polygon rather than a simple renaming of soils in the legend. In this report, we consider the problems related to reclassification of soddy-calcareous soils (Rendzinas). For a long time, Rendzinas were considered intrazonal soils with the A–C(R) profile and classified at the high taxonomic level. This decision was preserved on the FAO Soil Map of the World and on the Soil Map of Russia, where Rendzinas occupy about 500 000 sq. km and occur in a wide range of environments. At lower levels, their subdivision was based on evolutionary stages of soil development; thus, leached and podzolized Rendzinas and soils with residual carbonates (calcaric or dolomitic materials) were identified. In the new Russian soil classification system, as well as in the WRB and other recent systems, Rendzinas are not distinguished at the high (order or reference group) level. If the depth to the underlying calcareous bedrock is less than 30 cm, they fall into the order of Lithozems with the types of Dark-Humus and Mucky–Dark-Humus Carbolithozems analogous to Rendzic Leptosols in the WRB system, except for the depth to the bedrock criterion (25 cm). Primitive shallow Rendzinas without dark-humus horizon are classified as Typic or Humic Carbopetrozems corresponding to Rendzic Nudilithic or Lithic Leptosols. The humus horizon of Carbolihozems does not always fit the criteria of dark-humus or mollic horizons. In cold humid regions, it is enriched in weakly decomposed comminuted plant residues and/or may be overlain by a thin peat layer; upon active leaching of carbonates, it is replaced by the acidic gray-humus horizon. In the case of a greater depth to the underlying calcareous rock, the former soddy-calcareous soils mainly fall into the order of organo-accumulative soils subdivided into several types (by the character of their topsoils) and subtypes (by pedogenic features in the middle part of the profile). There is no analogue to this order in the WRB system, which complicates correlation decisions. Geographic regularities of pedogenesis on calcareous rocks as displayed on the updated Soil Map of Russia are discussed.

(4413 - 3142) WRB Classification of anthropogenic soils in Korea

Yeonkyu, Sonn[1]; Sangho, Jeon[1]; Byungkeun, Hyun[1]; Sungang, Yun[1]; Sukyoung, Hong[1]
NAS[1]

In Korea, human influence on soil formation has dramatically increased by urbanization, industrialization and using heavy equipment for the agricultural practice. The increase of anthropogenic soils induced researchers to study on the anthropogenic soils; classification, chemical and physical properties of anthropogenic soils. In 2004, Korea already developed a classification system of anthropogenic soils that was modified from the Soil Taxonomy. The anthropogenic soils classified to 1 order, 5 suborders, 10 great groups and 16 subgroups by the Korean soil classification system. However, this classification has many rooms to improve such as a precise description of the type pedon because majority studied area including agricultural soils and some mine remnants. The World Reference Base for Soil Resources (WRB) has one reference soil group (RSG) to classify anthropogenic soils Technosols. Artefacts and technic hard materials were defined as diagnostic materials. Artefacts are substances that are modified or created by man or brought to the surface from a depth and Technic hard material is substances resulting from an industrial process (unlike natural rock). This classification system is relatively new and may not enough to cover newly developed anthropogenic soils. We surveyed 7,727ha of remodeling farmland and our study showed that most of the level of soils are increased by adding other soil on the top of the original soil to improve soil conditions for agricultural or constructional purposes in Korea. The most distinguishable result was the stack of soil was 1~10 m. That even changes topography in its area. We assume this phenomenon may not exist in other countries and there is not anthropogenic soil classification system to classify this type soil in WRB. We propose that this type soil need to classify as Technosols in the WRB system because there are significant human influences to form. Our future research will focus on classification and characterization of urban soils including metropolitan area such as parks, apartment complex, landfills, and various sports facilities.

WG09 Soil Modeling: Challenges and perspectives in soil modelling

(2682 - 1591) Hydroponic nutrient solution for pineapple cultivation

Ronald Alberto Chaves Corea[1]; Marco Vinicio Gutierrez Soto[2]

Centro Investigaciones Agronómicas, Universidad de Costa Rica[1]; Estación Experimental Agrícola Fabio Baudrit, Universidad de Costa Rica[2]

A nutrition solution was formulated for the hydroponic cultivation of Ananas comosus, var. MD-2 in a greenhouse between August 2015 and June 2016. The plants were sown in pots of 20 L filled with coconut fiber, distributed in 6 double rows of 7m of length (2m of each other), and 40 cm of each other. An automated system was used to control time, volume, flow rate and irrigation frequency, pH, electrical conductivity (EC), and the proportion of minerals dissolved in the nutrition solution. The substrate moisture content (v/v) was maintained between 30- 50%. The pH of the nutritive solution for irrigation remained around 5.5, and the electrical conductivity between 2.4-2.6 ds m-1. A randomized design was used, with three treatments distributed chronologically, during the vegetative cycle of the crop. The elements were determined through foliar analysis. The analysis of correlation and clustering performed using principal components analysis were used to determine factors that significantly affected the leaf concentration of each nutrient. Prediction models allowed concluding that the N concentration in solution should be maintained between 102-188 mg L-1 to achieve foliar concentration levels between 1.3-1.8%. Similarly, to maintain foliar concentrations (%) of P (0.15-0.25) solution concentrations (mg L-1) should be keep (39-65); and for K (3.5-4.1) solution concentrations (107-185). To maintain Fe and B foliar concentrations (mg kg-1) at (70-100) and (13-18) solution concentrations (mg L-1) should be maintain at (5.88-12.70), and (0.5-1.0), respectively. The foliar contents of Ca, S, Zn, Mn, did not respond to the fluctuations of solution concentrations but were significantly affected by the fluctuations of N in the solution. Nevertheless, when maintaining the concentration of N in solution between 102-188 mg L-1, and that of Ca between 140- 200 mg L-1, S concentrations between 45-60 mg L-1, Zn between 0.2-1.0 mg L-1 and that of Mn between 0.5-2.0 mg L-1, the foliar concentration of Ca, S, Zn, Mn, remained between 0.3-0.5%, 0.10-0.15%, 11-19 mg kg-1, and 60-180 mg kg-1, respectively. The foliar concentration of elements such as Mg and Cu did not generate any statistically significant prediction model. With the concentrations used in this work no symptoms of Mg or Cu deficiencies were detected, so it is recommended to maintain their contractions in solution between 50-70 mg L-1 and between 3-6 mg L-1, respectively.

(7935 - 2646) Litter dynamic in different landscape compartments of the Brazilian Southern Amazon

Marco Antônio Camillo de Carvalho[1]; Fabiana Ferreira Cabral Gomes[2]; Diego Silva Siqueira[3]; Alan Rodrigo Panosso[4]

UNEMAT – Mato Grosso State University, Rodovia MT 208, km 145, Jardim Tropical, Alta Floresta, MT, 78580-000, Brazil. (marcocarvalho@unemat.br)[1]; UNEMAT – Mato Grosso State University, Rodovia MT 208, km 145, Jardim Tropical, Alta Floresta, MT, 78580-000, Brazil. (fabiherbam@gmail.com)[2]; FCAV/UNESP – College of Agricultural and Veterinarian Sciences, Sao Paulo State University, Via de Acesso Prof. Paulo Donato Castellane s/n, Jaboticabal, SP, 14884-900, Brazil. (diego_silvasiqueira@yahoo.com.br)[3]; FEIS/UNESP – College of Engineering of Ilha Solteira, São Paulo State University, Av. Brasil Sul, 56 – Centro, Ilha Solteira, São Paulo, 15385-000, Brazil[4]

The processes of litter production, accumulation and decomposition are controlled by biotic and abiotic factor such as environmental conditions, quantity and quality of the deposited material, besides the decomposition community. These factors are often related to the landscape form and, therefore, presenting spatial variability. The aim of this work was to evaluate the litter production, accumulation and monthly decomposition, as well as the influence of dendrometric parameters of the trees on these processes, in two Southern Amazon native forest fragments (open ombrophilous forest) located in different landscape compartments: F1) linear-concave surface whit high slope and F2) concave-convex surface whit low slope. Litter components were evaluated during 12-month periods (November 2014 to October 2015). Data were initially analyzed by classical statistics (mean, analysis of variance, coefficient of correlation, linear and non-linear regression), followed by geostatistical and multivariate analysis (cluster analysis and principal components analysis). Multivariate analysis of the data allowed the division of litter production and accumulation among the highest values (months of drought), the lowest values (rainy months), and a transitional period (October) coinciding with the period of soil water replenishment. Positive and significant coefficients of correlation ($p < 0.01$) were observed between litter production and diameter at breast height (0.65), volume (0.58), total height (0.63) and number of trees (0 , 63) located at distances until 10 m from the collectors, only for F2. The rates of litter decomposition were 0.70 $year^{-1}$ for F2 and 0.83 $year^{-1}$ for F1 and the time for the decomposition of 50% of the initial mass was from 305 to 359 days, respectively. In the first 150 days, the linear-concave compartment presented a decay rate of 21.05% greater than the concave-convex compartment. Spatial patterns of principal components indicated the formation of homogeneous groups of individuals for F2 in relation of dendrometric parameters being the concave-convex compartment more favorable to the higher values of diameter at breast height, stem and total height. Therefore, our results confirm the potential of the hybrid approach (using multivariate and geostatistical techniques) to identify compartments with different litter production, accumulation and decomposition potentials in the southern Amazon forest.

(4017 - 2103) LS-SVM data mining analysis: how does biochar influence soil net nitrogen mineralization in the field

Jianqiang Deng[1]

Enshi Tobacco Company of Hubei Province[1]

Purpose Biochar was considered as a stable-carbon source for improving soil quality and the long term sequestration of carbon. However, in view of the ecological environmental feedback function and the high coupling system of carbon-nitrogen cycling, it attracted further attention to the effect of biochar on soil net nitrogen mineralization (SNNM). Recently, ecological environmental evaluations of biochar were mostly based on laboratory incubation or pot experiments, ignoring the external and uncontrollable natural factors. Therefore, the essential characteristics of local environment were not accurately described. Materials and methods In this paper, the nonlinear stochastic model of SNNM based on Least squares support vector machine (LS-SVM) was set up to study the effect of biochar on nitrogen cycling in a field experiment. In order to explore this effect in natural conditions, Partial Derivatives (PaD) Sensitivity Analysis of LS-SVM was firstly proposed, evaluated by the data from a known equation, and was then applied to open the "black-box" stochastic model of SNNM. Results and discussion Comparing with the sensitivity analysis of ANNs, the RD values by LS-SVM PaD1 algorithm were almost the same with the ones of ANNs PaD1 algorithm. However the RSD values of LS-SVM PaD2 algorithm were more adequate to the given equation. In the SNNM model, RD values of initial nitrogen, time and precipitation by LS-SVM PaD1 algorithm were 21, 15 and 14%, and the one of biochar was only 0.51%, implying that biochar did not influence SNNM directly. However, the cumulative RSD of boichar with the other factors by the PaD2 algorithm was 15.05%, which was maximal of the interactions, implying that it could greatly enhance the tendency

for SNNM by interacting with other factors. Conclusions PaD Sensitivity Analysis of LS-SVM was a stable and reliable data mining method. In the SNNM model, initial nitrogen, time, precipitation and relative humidity were main control factors of SNNM model. Biochar did not directly influence SNNM, however it could greatly enhance the tendency for SNNM by interactions with other factors by decreasing the inhibitory effect of initial nitrogen on SNNM and modifying soil condition to change the effect of other factors on SNNM.

(4784 - 2069) Machine learning applied to the mapping of mountain coffe from terrain atribute.

Raiza Moniz Faria[1]; Elpídio Inácio Fernandes Filho[1]; Maola Monique Faria[2]; Cibele Hummel do Amaral[1]; Márcio Rocha Francelino[1]
Federal University of Viçosa[1]; Development Company of the State of Roraima[2]

The state of Minas Gerais is the main producer of coffee in the country, responsible for much of the national production. Because of the importance of coffee, we had intended to work with this map the Mountain coffee from the spectral data and terrain attributes. For the study were developed methodologies of classification of coffee areas in three municipalities of the state of Minas Gerais. The database consisted of 59 variables, including a Sentinel 2A image, vegetation indexes and attributes derived from the ALOS / Palsar digital elevation model (MDE). The sample set was separated in training and validation in the proportion 0,90: 0,10. In order to reduce the dimensionality of the model, the Recursive Feature Elimination variable selection method was applied to the data. Two areas had their crops validated in a high resolution image. The selected variables were submitted to the Random Forest (RF), Stochastic Gradient Boosting (GBM), Logistic Model Tree (LMT) and CTREE algorithms, where the performance evaluation of each classifier was performed. The most important variables for the classification of mountain coffee were the NDVI index, band 12, band 2, band 8 and MDE with 0.86 correlation. The CTREE and LMT were not satisfactory for classification of coffee areas in mountainous terrains, not being able to separate coffee from other tree coverings such as forest and eucalyptus areas, with great confusion among these classes. The GBM and RF algorithms had a Kappa index of 0.86 and 0.88, with the accuracy of the user and producer with values above 0.90 for the entire area with the insertion of the terrain attributes. In the validation area I, the user accuracy was 0.66 for RF and GBM and in area II, the user accuracy was 0.79 and 0.81. The area II presents a diversity of coverings with spectral patterns similar to coffee larger than area I and the busiest relief, and the RF and GBM algorithms were efficient in separating the coffee areas from the others. Both GBM and RF are good classification algorithms for coffee areas in mountainous relief.

(5217 - 1736) Modeling Evapotranspiration and Crop Growth of Irrigated and Non-irrigated Corn under Warm Climate

Huihui Zhang[1]; Robert Wayne Malone[1]; Lajpat R. Ahuja[1]; Liwang Ma[1]; Saseendran S. Anapalli[1]; Gary Marek[1]; Prasanna H. Gowda[1]; Steve Evett[1]; Terry Howell[1]
USDA-ARS[1]

Accurate quantification and management of crop evapotranspiration (ET) are critical to optimizing crop water productivity for both dryland and irrigated agriculture, especially in the semiarid regions of the world. In this study, four weighing lysimeters were planted to maize in 1994 with two fully irrigated and two non-irrigated for measuring crop ET in Bushland, Texas. The two fully irrigated lysimeters were used for calibrating the Root Zone Water Quality Model (RZWQM2) and the non-irrigated ones were reserved for model evaluation, in terms of leaf area index, biomass, soil water contents, and daily ET. The Nimah-Hanks approach in RZWQM2 was used for calculating actual crop water update (AT), and the Richards' equation was used for actual soil evaporation (AE). The Shuttleworth and Wallace method (S-W) and ASCE Standardized alfalfa Reference ET plus crop coefficients (ASCE) were used to calculate potential ET (PET), which were partitioned into potential evaporation (PE) and potential transpiration (PT) based on leaf area index. As a result, four water stress factors were tested in the model against the lysimeter data, i.e., AT/SW-PT, AT/ASCE-PT, (AT+AE)/SW-PET, and (AT+AE)/ASCE-PET. Root Mean Squared Deviations (RMSDs) and relative RMSDs (RMSD/observed mean) values for leaf area index, biomass, soil water contents, and daily ET were within simulation errors reported earlier in the literature. For the two non-irrigated lysimeters, the simulated daily ET values were also reasonably close to the measured values, but were under-estimated during mid-growth stage. In general, water stress factor defined by (AT+AE)/SW-PET was better than other stress factors in simulations of non-irrigated corn biomass and grain yield. Additional studies of crops grown under dryland conditions using weighing lysimeters are needed to corroborate these findings and aid in the development of new water stress algorithms.

(2738 - 908) Modeling for fertilization and liming for sugarcane in low fertility soils

Fernando José Freire[1]; Fábio Cesar da Silva[2]; Victor Hugo Alvarez Venegas[3]
1Universidade Federal Rural de Pernambuco, 52171-900 Rua Manuel de Medeiros, s/n - Dois Irmãos, Recife - PE, Brazil (Email: fernandojfreire@uol.com.br);[1]; 2Embrapa Informática Agropecuária, 13083-886 Av. Dr. André Tosello, 209 - Cidade Universitária, Campinas - SP, Brazil (Email: fabio.silva@embrapa.br)[2]; Universidade Federal de Viçosa R. Purdue, 392-486 - Santo Antonio, Viçosa - MG, 36570-000,Brazil[3]

Currently fertilizers recommendation for the sugar cane culture in Brazil are based on growth curves, obtained from the relationship between fertilizer rates and yield increment. Predictive recommendation systems are desirable and of wider application. This work was carried out aiming to structure and develop a System to estimate the nutritional balance and recommend lime and fertilizers to sugar cane plants (SBNR-C) based on the nutritional demand (ND) and expected yield (EY). The input information required by the System is the expected yield and the nutrient use efficiency (NUE). The nutrient demand is estimated dividing EY by NUE. Specifically for P, S and Zn, besides the EY and NUE values, the System requires information related to soil's buffer capacity. This way, the System estimates the critical level for each nutrient for the EY and compares this value with the nutrient availabilit y in the soil, indicating the need or not for lime and, or, fertilizer application. The recommended fertilizer rate may be multiplied by a factor that increases the amount of nutrient added in order to avoid soil nutrient depletion and to assure yield sustainability. The proposed model for lime recommendation showed itself consistent for being possible variable recommendations depending on the EY, allowing a wider inter-relationship with the plant-soil system and estimating the final pH value for any lime dose. The estimate of the critical level and K doses for ratoon were coherent with the nutrient recommendation for sugar cane plants and ratoon, specially for the last cultivation since it's not contemplated in any recommendation tables in Brazil. The estimate of the residual effect of P in first and second ratoon was consistent, allowing to infer that shorter cultivation periods, for example with early cultivars, results in more pronounced residual effects. The adjustment of a predictive model for quantification of the mineralizable N in Sugar

cane plants, first and second ratoon, using organic matter and clay content in the soil allowed the th estimation of this nutrient's necessity. The simulations for Zn, B and Cu resulted in compatible critical values when compared with critical levels in the literature. The little information existing for Fe and Mn didn't allow the complete modeling for these elements. The SBNR-C represents na efficient tool for the recommendation of lime and fertilizers for sugar cane plants.

(2559 - 1706) Modelling soil respiration and net ecosystem exchange in agrolandscapes

Sukhoveeva O.E. 1[1]; Karelin D.V. 1,2,3[2]
1 Institute of Geography, Russian Academy of Sciences, Staromonetniy 29, Moscow, 119017, Russia (olgasukhoveeva@gmail.com)[1]; 1 Institute of Geography RAS, Staromonetniy 29, Moscow, 119017; 2 Lomonosov Moscow State University, 1-12 Leninskie Gory, Moscow,119991; 3 Center for Problems of Ecology and Productivity of Forests RAS, Profsoyuznaya 84/32, str. 14, 117997, Moscow, Russia[2]

The goal of the research was to evaluate the possibilities and quality of different modelling approaches to estimate major CO_2 fluxes in agroecosystems. The regression method and simulation biogeochemical model DNDC (DeNitrification-DeComposition) were applied to the following field objects and data sets: (a) soil respiration (SR) of the arable Haplic Chernozem under crop rotation in Kursk region, Russia, 51°54'N, 36°10'E, 2017; (b) SR of the arable Luvic Phaeozems under unfertilized cereal-fallow rotation in Moscow region, Russia, 54°49'N, 37°34'E, 1997-2009 (field data by I.N. Kurganova, Institute of Physical-chemical and Biological problems of Soil science RAS); (c) net ecosystem exchange (NEE) of semidesert sagebrush pasture in Uzbekistan, 39°40'N, 65°46'E, 1998-2001 (field data by M.G. Nasirov, Samarkand State University). The quality of modelling was estimated by use of Nash and Thail coefficients, and ANOVA. In Kursk region mean seasonal (April - October) SR was equal to 0.138 ± 0.068 (barley), 0.143 ± 0.075 (potato), 0.146 ± 0.095 (sunflower), 0.173 ± 0.114 (winter wheat) g C m^{-2} h^{-1}. Measured and modelled estimates don't differ significantly; for all crops Thail coefficients were less than 0.30 (good quality). DNDC predicts that during the next 50 years SR will increase by 19 (potato) – 50 (wheat) kg C ha^{-1} yr^{-1}, if the CO_2 concentration in the atmosphere will follow the current trend (+3 ppm/yr). In Moscow region the observed mean SR was equal to 0.038 ± 0.046 (fallow) and 0.050 ± 0.048 g C m^{-2} h^{-1} (winter wheat), whereas the corresponding modelled estimates were 0.040 ± 0.033 and 0.035 ± 0.031 g C m^{-2} h^{-1}, respectively. The modelling was particularly effective for fallow: Nash coefficients were higher than 0.50. Proportion between root and microbial respiration was estimated by DNDC at 33.2/66.8%, accordingly. Regression modeling based on shallow soil temperature and moisture explains 31-41% of soil respiration variance. In Uzbekistan experimental site NEE was estimated at +0.129 ± 0.046 g C m^{-2} h^{-1} (source of carbon to the atmosphere). The results of DNDC also prove this region to be the annual net source of CO_2. Intensity of NEE was correlated to air temperature and heat flux, whereas it was negatively correlated to relative humidity and amount of precipitation. These controls were able to change the sigh of the net CO_2 flux from source to sink in a short time. Nevertheless only 16% of net CO_2 flux variation was due to weather conditions.

(4297 - 273) Redox potential and nitrous oxide emissions in response to flood irrigation with waste water in central Mexico

Blanca Gonzalez Mendez[1]; Richard Webster[2]; Christina Siebe[1]
Unam[1]; Rothamsted Research Station[2]

Irrigation with untreated sewage water is becoming a common practice in the arid and semiarid regions around the world. Waste water adds labile carbon and nitrogen compounds to the soil, and when applied by flooding it rapidly changes the redox potential and soil's atmosphere, as consequence of temporarily waterlogged and depleted oxygen, generating nitrous oxide (N_2O) emissions. We monitored the redox potential, E_h, in the soil and the nitrous oxide emissions at two sites in the Mezquital Valley to discover whether the short-term gas emissions matched the changes in *E*h. One site is irrigated periodically by flooding with waste water and has alfalfa, rye grass and maize grown in succession; the other site grows rain-fed maize only in summer. At each site we buried platinum electrodes at different depths in the soil and around them, on the surface, we installed static chambers to measured the N_2O emissions simultaneously. Measurements were made all along 21 months considering the time before, during and after each irrigation event. We also measured both variables in the rain-fed maize before and shortly after two rain events. The data from repeated measurements from the same chambers and electrodes were correlated in time, so we modelled the correlation and took it into account to analyse the effects of the irrigation by residual maximum likelihood (REML). After each flooding, the redox potential under alfalfa and rye grass decreased by 150–200mV from a norm of about 450mV for 2 days, after which it returned to its norm. The short-term response to flooding under maize was similar, but the redox potential did not recover completely; instead there was a decrease from one irrigation event to another, in particular as a result of heavy rain in September that saturated the soil. The soil under rain-fed maize was slower to respond, partly, we believe, because infiltration into the less aggregated clay soil and drainage from it were also slow. Irrigation with untreated sewage water caused a sharp decrease in E_h lasting 1–2 days. The emissions of N_2O increased dramatically during the next few days after irrigation and then declined. It seems to be related with the water infiltration that replace the gas from air-filled pores and with the soil oxygen depletion, causing reduction in microhabitats rich in carbon and nitrogen and generating N_2O, which was captured in the closed chambers that we had installed.

(2119 - 1064) Simulating the effects of soil heterogeneity on grazing management strategies in semi-arid rangelands of the western North American Great Plains

Liwang Ma[1]; Justin Derner[1]; Daren Harmel[1]; Patricia Bartling[1]; Cody Ziverberg[2]; Jimmy Williams[2]; David Augustine[1]; Loren Porensky[1]; David Hoover[1]; Dana Blumenthal[1]
USDA-ARS[1]; Texas A&M University[2]

Aspirational management strategies for semi-arid rangelands in the western North American Great Plains are needed to collectively sustain livestock production, improve profitability for ranchers, reduce adverse environmental impacts, and enhance vegetation structure and composition heterogeneity for wildlife habitat, all of which will occur under a changing climate. We compared traditional grazing management (TGM, mid-May to October grazing at moderate stocking rate with low stocking density and cattle remaining in the same pasture for the full grazing season) to an adaptive grazing management (AGM, at ten-fold higher stocking density but grazing pastures for short periods – weeks – and rotated among 10 pastures) strategy using the APEX model. Primary emphasis here was to simulate effects of soil heterogeneity on grazing management. 5 years (2013-2017) of

experimental data from the Central Plains Experimental Range (CPER), shortgrass steppe rangeland, were used to calibrate the APEX model for plant biomass and animal production across a range of soil textures (sand to silty clay loam with clay content from 4% to 40%). Initial results indicate that APEX effectively simulated differences in plant biomass and cattle gains between the AGM and TGM using a representative soil type. Additional efforts will focus on expanding modeling simulations to incorporate the soil texture gradient and slope (0 to 30%) in the field for plant biomass and cattle gains, as well as evaluating environmental impacts and influences on plant diversity.

(5527 - 2449) Soil Macroinvertebrates under a livestock system in an Oxisol of Colombian Eastern High Plains.

Lina Moreno[1]; Nubia Rodriguez[1]; Orlando Arguello[1]; Miguel Arango[1]; Jaime Bernal[1]; Jose Baquero[1]; Otoniel Perez[1]
Corpoica[1]

Agricultural practices related to livestock systems affect the soil ecosystems services such as biological diversity, nutrient cycling and climate regulation. The objective of this work was to assess the impact of agricultural practices on the soil macroinvertebrate community. In Corpoica`s research center Carimagua (Meta), agricultural practices to improve productive and reproductive parameters of breeding livestock were adjusted and validated. Such practices included: Improved pastures (*B. dyctioneura)*, corn-soybean rotation, timber trees and a spontaneous trees patch cover. Biodiversity indicator was evaluated since 2012. The soil sampling was carried out following the methodology described by the Tropical Soil Biology and Fertility Program (TSBF). The data were analyzed using a principal components analysis (PCA) and the Simpson's diversity index (H) was estimated. An indicator value was generated from the first two components principal and ranged from 0.1 to 1. The PCA explained an average of 55.23% of the macrofauna variability found during three years of evaluation. The systems established with *B. dyctioneura* and a spontaneous trees patch cover had the highest indicator value. The order *Isoptera* had the highest correlation with abundance and highest dominance based on the Simpson's diversity index. The Isoptera was dominant under corn-soy rotation system (H = 0.23) followed by the forest (H = 0.28). Overall, the ecosystem engineers such as termites, ants and earthworm were found across all practices.

(6090 - 913) Stolf-Scardua model for estimating soil water retention curve (WRC) by clay content

Rubismar Stolf[1]; Douglas Roberto Bizari[1]; Rubens Scardua[2]
Federal University of São Carlos-campus Araras[1]; University of São Paulo (retired)[2]

The proposed model differs by using, for each tension, an equation correlating "water retention" with "clay content". In this way, the model is composed of a set of equations, each one representing one point of tension. We searched, for a work with wide variation of clay content and tension in order to adjust the model. The selected one (Scardua, 1972) presents Water Retention Curves (WRC) in soil samples of 12 different clay contents (Clay %): 7.1; 10.6; 17.2; 17.9; 22.4; 21.8; 34.8; 39.4; 37.4; 53.4; 59.2; 60.5 and in 13 tensions (kPa): 0; 0.1; 2; 6; 8; 10; 20; 33; 70; 100; 300; 600; 1500, each one as average of four replicates. That is, a data universe of 12 retention curves, with 13 tensions, 156 points. Each point average of four repetitions, totaling 624 measurements of soil sample. The model that best represented the variation for each tension was the linear one: water retention WR= a + b.Clay. The correlation coefficients (r^2) resulted in the following values, respectively (for each tension from 0 to 1500 kPa): 0.940; 0.906; 0.930; 0.904; 0.885; 0.882; 0.881; 0.892; 0.886; 0.889; 0.850; 0.882; 0.938. Comparing the measured (Scardua, 1972) with the estimated data (model), absolute mean error ME = $(\Sigma|Y_{measured} - Y_{estimated}| / N = 0.018\ cm^3\ cm^{-3}$ (1.8%) was obtained, classifying the adjustment as excellent. Using the 13 equations, an abacus was been calculated for estimation of retention curves of 2.5 in 2.5 % clay, in the range of 5 to 70%. This option dismiss the direct use of the equations. By the other hand, we can generate a spreadsheet in which we enter the clay content to generate the data of the curve. The application of the model, especially for the analysis of available water capacity (AWC) is been discussed.

(2252 - 1692) The importance of the rizospheric priming effect for Eucalyptus nitrogen nutrition in Brazil and Australia

Rafael Vasconcelos Valadares[1]; Maurício Dutra Costa[1]; Júlio César Lima Neves[1]
Universidade Federal de Viçosa[1]

Nitrogen (N) is one of the most accumulated nutrients in *Eucalyptus* plantations, with values between 120 and 1,300 kg/ha. Interestingly, the stands often present little or none N fertilization response in tropical contries, like Brazil. The responses, when present, occur within the first two or three years, and cease to exist during the time of the harvest. Therefore, *Eucalyptus* plants can meet their high N demand without fertilization or with the application of low doses, between 40 and 70 kg/ha of N. To explain this phenomenon, we hypothesized that rhizosphere priming effect (RPE) is quantitatevely important for *Eucalyptus* nitrogen nutrition. To test this hypothesis, it was simulated the *Eucalyptus* growth using the general *Eucalyptus* APSIMex model and the rhizosphere processes using ForPRAN model. It was projected the *Eucalyptus* growth in four sites, being two at Brazil (Aracruz/ES and Curvelo/MG) and the other two at Australia (Wagga Wagga/NSW and Coffs Harbour/NSW). The planting space was of 3 x 3 m for all the sites and the soil and climatic conditions were specific of each city. It was considered the N cycling in the first 20 cm layer of the soil. At the end of seven years rotation, it was estimated that 12, 11, 10 and 5 % of the total soil was occupied by the rhizosphere at Aracruz, Coffs Harbour, Wagga Wagga and Curvelo sites, respectively. As a result of the rhizodeposition, the ForPRAN model suggests in all four sites an increase in the rhizospheric microbiota activity, in which the average values were between 70.3 µg/cm³ and 246.1 µg/cm³ of C, according to each pedoenvironment. In general, RPE has the potential to meet between 15 and 38 % of the forest ecosystem N demand (trees + litter), under the studied situations. Higher temperatures and rainfall volumes may contribute to a more exuberant rhizospheric contribution (in absolute values) in Brazil than in Australia, what also explain the low N limitation in the first country.

(2856 - 2291) Variation of nematode population of soil in tomato crop with introduction of service crop (*Sinapsis alba L.*).

Maria de los Ángeles Quinteros[1]; Hector Alfredo Sanchez[1]; Cristina Picon[2]; Elena Boggiatto[2]
INTA[1]; Fundación Miguel Lillo UNT[2]

Horticulture production in Tucumán is important economically and socially; the productive area is extended mainly along the foothill plain

of the province, associated to the streams and rivers that run down the mountains satisfying its irrigation necessities. The soil where this activity is done is generally alluvial, with a loam texture or enriched with silt and fine sand due to the influence of rivers and streams. The principal management does not consider crop rotation to maintain soil fertility. Although there is a crop alternation, it is generally of the same botanic genre, which makes some plagues endemic. The main cause of crop yield reduction is the presence of nematode phytophagous. The use of control measurements is needed to reduce the level of population. For this reason, the development of management strategies to reduce the density of the population to a level below the threshold of the crop damage is considered fundamental. The aim of this work is to evaluate the effects of mustard crop (*Sinapsis alba L.)* as a service crop to diminish the nematode phytophagous population in soil. Materials and methods: mustard was sown in a recently harvested tomato lot, highly infested with nematodes. Before sowing, a sample was taken to evaluate nematodes. New samples of the same soil were taken after harvesting the mustard. In this work, the information presented is related to the variation of soil nematode population with the incorporation of a service crop. Results: It was observed a reduction of a nematode pfytophagous in soil; it indicates the importance of the introduction of a service crop, such as mustard, to control nematode pfytophagous and to contribute to soil sanity.

(7809 - 796) Comparison of Physical Quality and Water Management of Substrates Mixtures and Soil Through the Least Limiting Water Range Index

Gabriel Garbanzo León[1]; Róger Fallas Corrales[1]
University of Costa Rica[1]

In oil palm, the physical soil quality and water management in the bags substrate is important for healthy root development. The oil palm nurseries requires loamy soil texture, balance nutrient status, good drainage and low bulk density. In the present study the physical quality of the soil and water management were evaluated in substrates mixtures calculated by using the Least Limiting Water Range index (LLWR) in oil palm nurseries and total biomass productivity. We made volumetric mixtures of 12, 25, 37, and 50% composted residues of oil palm fiber (C) with Eutric Inceptisol material. Compacta x Ghana oil palm hybrid plants were planted in 20 L bags. At 90, 210 and 320 days after sowing (dds) rings with soil were sampled, saturated with water and then equilibrated on pressure plates at potentials (ψ) of -0.005, -0.015, -0.033, -0.1, -0.5 y -1.5 MPa. Bulk density, volumetric water content, soil resistance and air-filled porosity (10%) were correlated with the LLWR Index. The water retention curve model decreased with the substrates mixtures (r^2= 0.3 – 0.4) in comparison to 100% soil bags (r^2= 0.6). Likewise, the soil resistance curve model increased to applied 12% fiber with 88% soil (r^2= 0.7) in comparison to 100% soil (r^2=0.6). Total biomass showed the highest accumulation in the 12% C than the 100% soil in the bags. It was concluded that application upper that 25% C with soil can affect the physical properties if the mixtures by decreasing the water content in oil palm nurseries bags. Also LLWR Index can help to quantify the quality and this could be an alternative to adjust irrigation in oil palm nursery.

(3245 - 2755) Fostering a Global Alliance for Monitoring, Mapping, Modeling, and Managing the Earth's Critical Zone

Henry Lin[1]; Han Zheng[2]; Yunqiang Wang[2]; Zhao Jin[2]; Yi Song[2]; Li Feng[2]; Da Luo[2]; Yunlong Yu[2]; Harry Vereecken[3]; Kris Van Looy[3]
Dept. of Ecosystem Science and Management, Penn State Univ.; State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences[1]; State Key Laboratory of Loess and Quaternary Geology, Institute of Earth Environment, Chinese Academy of Sciences[2]; Forschungszentrum Juelich GmbH; International Soil Modeling Consortium[3]

With growing interests in international scientific communities to establish various observatory networks to monitor the ever-changing environment, a synergistic effort to foster a global alliance for monitoring, mapping, modeling, and managing ("4M") of the Earth's Critical Zone (from the top of the vegetation down to the bottom of the aquifer) is needed. Large-scale monitoring networks are increasingly called for by funding agencies and scientific consortia to address "big" science questions. Long-term recording of the health of our land – through monitoring its "blood pressure," temperature, respiration, and other vital signs is critical. The emerging interests in Critical Zone science bring a promising hope of a unified framework for the holistic understanding of soil, water, rock, air, and biotic resources in the Earth's surface and near-surface environments. Long-term monitoring, along with precision spatial mapping, process-based modeling, and sustainable management of the landscape-soil-water-ecosystem relationships across scales and regions can serve many purposes of societal importance. Optimization of whole systems for multiple benefits rather than one benefit permit synergistic outcomes and cost-effectiveness. Since nature does not recognize disciplinary divides, and artificially-fragmented knowledge hinders integrated understanding of the complex Critical Zone, it is imperative that a systems approach be taken to achieve a comprehensive understanding and integrated management. Thus, while large-scale environmental observing networks are being developed in different parts of the world for various spheres of the Earth system (e.g., the atmosphere, the biosphere, the hydrosphere, and the lithosphere), an integrated one for observing, mapping, modeling, and managing the Earth's Critical Zone as a whole is still lacking. The complex interdependence of climate, hydrology, biology, lithology, topography, pedology, chronology, and anthropogenic forcing at the central juncture of the Critical Zone (i.e., soils) provides an excellent opportunity to study important interfaces, decisive moments, controlling mechanisms, and feedback loops in the Critical Zone across space and time. However, no one team or organization can do that alone, and a diversity of funding sources supporting a heterogeneous mixture of overlapping programs is probably the best formula for long-term stability of such a systems approach. Hence, a global alliance is suggested here.

(2830 - 1193) Optimizing and coupling the hillslope hydrological and biogeochemical simulations in stony soils

Qing Zhu[1]; Xiaoming Lai[1]; Zhiwen Zhou[1]; Kaihua Liao[1]
Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences[1]

Stony soils with rock fragment contents more than 30% are widely distributed in the mountainous areas. However,pedotransfer functions, which are the key parameters in soil hydroloy and biogeochemstry models, are not reliable in predicting the soil hydraulic parameters for these soils due to the impacts of rock fragments. In addition, traditional soil hydrology models lack of sound mechanisms in describing biogeochemical processes, while traditional biogeochemstry models are weak in simulating soil hydrological processes. This may result in the poor simulations of these models. In this study, we aimed to (i) improve the model simulations of Hydrus-3D and DNDC by considering the rock

fragment, and (ii) couple these two models to better simulate the spatial and temporal variation of nitrate leaching on a stony-soil hillslope in Taihu Lake basin, China. We obtained soil hydraulic parameters using different approaches including (1) Rosetta predicted, (2) Rosetta predicted and then corrected by rock fragment content, (3) extracted from observed soil-water retention curves fitted by dual-pore function, and (4) model defaults. These different sets of soil hydraulic properties were then input into Hydrus-3D and DNDC to simulate the soil hydrological and biogeochemical processes, and then the simulation results were statisticall validated by the observed data. The optimal strategies of simulations were then determined. After this, the sursurface flow simulated by Hydrus-3D and the soil nitrate concentrations simulated by DNDC were used to calculate the spatial and temporal variations of nitrate leaching on this stony-soil hillslope using the nitrate leaching equation extracted from the codes of DNDC. Finally, controlling factors and their contributions to the spatial and temporal variations of nitrate leaching were quantitatively determined.

(9525 - 1276) Phosphorus contents as indicator of the chemical quality of a yellow red latosol under direct planting with npk, organomineral and bioactivator

Lucas Alves Fernandes[1]; Wilber Pereira Machado[1]; Guilherme Camilo de Andrade[1]; Fabrício Messias Dias da Silva[1]; Roberta Ferreira Coutinho[1]; Gabriel Junqueira Pires[1]; Adriana Aparecida Ribon[1]; Camilla Barbosa de Oliveira Madruga[1]; Taíza Nogueira Barros[2]; Bruno Mikael dos Santos Mariano[1]
State University of Goiás[1]; Federal University of the Recôncavo of Bahia[2]

The management of fertilization is one of the most common practices of Brazilian agriculture. Most of the state of Goiás is covered by Latosols, which are soils of low natural fertility and require greater care regarding the levels of nutrients existing to maintain agricultural productivity. The Latosols, because they present higher levels of iron oxides present specific adsorption for the phosphorus (P). The objective of this work was to evaluate the effect of fertilization with NPK, organomineral and bioactivator on the P content of a Yellow Red Latosol under no - tillage, under soybean succession in the Palmeiras region of Goiás. The experiment was carried out at Bom Sucesso farm, Palmeiras de Goiás - GO, under the coordinates 16º 52 '48,63' 'S and 49º 59' 30,06 "O, at 669.2 m altitude, during agricultural crops 2014/15 and 2015/16 under Red Latosols, in a completely randomized design. A soil analysis was performed before the installation of the soil classification and classification experiment. The sample was collected in the 0 to 0.20 m layer. For sampling a drill was used on a bro drill bit, associated with the tractor battery. Several simple samples were collected, and after homogenization, the sample was transformed into a composite sample. According to the soil analysis, shown in Table 1, the soil was classified as YELLOW RED YELLOW Eutrophic clay (400 g kg-1 of clay and 420 g kg-1 of sand), according to the classification criteria of the Brazilian Classification System Solos (EMBRAPA, 2013). The treatments were organized as follows: T1 - 0.05 kg ha - 1 of Penergetic P and 0.05 kg ha - 1 of Penergetic P; T2 - 0.05 kg ha-1 of Penergetic K and 630 kg ha-1 of NPK; T3 - 630kg ha-1 of NPK; T4 - 0.05 kg ha-1 of Penergetic K, 630 kg ha-1 of NPK and 0.05 kg ha-1 of Penergetic P; T5 - 0.05 kg ha-1 of Penergetic K, 2100 kg ha-1 of organomineral and 0.05 kg ha-1 of Penergetic P; and T6 - 2100 kg ha-1 of organomineral. The treatments with NPK provided the highest levels of initial soil P. Followed by the treatments that associated the organomineral associated with Penergetic. The use of organomineral fertilizer and bioactivator can be used in association and / or substitution of mineral fertilizer.

(1993 - 528) Significant Accumulation of Reactive Nitrogen in the Deep Red Soil Critical Zone

Huayong Wu[1]; Xiaodong Song[1]; Xiaorui Zhao[1]; Xinhua Peng[1]; Hu Zhou[1]; Gan-Lin Zhang[1]
Institute of Soil Science, Chinese Academy of Sciences[1]

The commonly recognized low potential nitrification of highly weathered soils with low pH suggest that nitrate is difficult to accumulate in these acidic soils where ammonium-based nitrogen fertilizers or urea are the main N fertilizers applied in agriculture. Here we determined the amounts of NO_3^--N, NH_4^+-N and dissolved organic nitrogen (DON) across the regolith with depth up to 9 m under land uses of upland, woodland and paddy field in the Red Soil Critical Zone Observatory, in a typical subtropical region. The results displayed 92% (827 ± 97 kg N ha^{-1}) of NO_3^--N and 82% (521 ± 153 kg N ha^{-1}) of DON on average stored in the deep (from 1 m to bedrock surface) of the upland regolith. More than 92% (283 kg N ha^{-1}) of NO_3^--N and 78% (820 kg N ha^{-1}) of DON were stored in the deep of woodland regolith. No significant accumulation of reactive nitrogen was observed in the deep of paddy field regolith with different cultivation ages. The low macroporosity (> 25 μm) of the regolith, measured using micro-Computed Tomography, may greatly contribute to nitrate leaching to the deep of regolith and its sharp decrease most likely resulted in the occurrence of peak nitrate storage. Our findings put forward a challenge to the common understanding of low potential nitrification and little nitrate accumulation in subtropical and tropical acid soils and the huge reactive nitrogen storages in the deep Critical Zone raise concerns about groundwater contamination under heavy rainfall in humid regions.

(8637 - 932) Soil Classification System based on Pore Space Structure

Marta V. Ottoni[1]; Theophilo B. Ottoni Filho[2]; Maria Leonor R.C. Lopes-Assad[3]; Otto Corrêa Rotunno Filho[2]
Geological Survey of Brazil (CPRM)[1]; Federal University of Rio de Janeiro (UFRJ)[2]; Federal University of São Carlos (UFSCAR)[3]

A soil classification system was proposed based on the clustering of similar air availability curves [$A_a(s)$ curves, s is the suction] determined in the soil sample scale, where $A_a(s)$ is the complement of the water retention curve, θ(s), in relation to the saturated water content, Φ. This system is identified by the acronym SPSCS (*Soil Pore space-Structural Classification System*) and defines the structural Families as the soil classes that group similar $A_a(s)$ curves. In SPSCS, the $A_a(s)$ curve was modelled by the van Genuchten (VG) equation with a protocol for the determination of its parameters valid in the suction range from 30 cm to 18000 cm, for which the prediction of water retention data by the VG model is acknowledged to be more adequate. Two categorical levels are indicated in SPSCS: Orders and Suborders. SPSCS was based on the textural classification system and conceives a triangle analogous to the textural triangle, called structural triangle, where samples plotted in specific sub-areas have similar pore size distribution curves. These sub-areas define the soil Orders. The Suborder represents the soils with similar active pore space, a term proposed in this work to express the difference between Φ and the residual water content, θr. Nine Orders (from A to I) and four Suborders (from 1 to 4) are proposed, thus resulting in 36 possible structural Families. SPSCS was implemented with a broad and diverse soil database with approximately 3,000 soil samples from tropical and temperate environments. All the structural Orders and Families were represented, with exception of three Families, with a greater concentration of samples in Orders B, G

and H and Suborders 2 and 3. Because it is based on an analytical methodology, SPSCS may be a useful tool in the development of pedotransfer functions of hydraulical properties when information related to the soil structure is taken into account. Its use may also be relevant in studies to correlate soil pore structure and hydraulic functioning, pedological classes and soil physico-chemical properties, which may contribute to build up knowledge on hydraulical and pedological processes.

(1677 - 2426) Soil water repellency influenced by two tillage systems and wheel track in a Mollisol of central Chile

Ángela Faúndez[1]; Oscar Seguel[1]; Edmundo Acevedo[1]; Cristian Kremer[1]; Manuel Casanova[1]
Universidad de Chile[1]

Excessive water repellency is a problem to a greater or lesser extent in most soils, caused by the accumulation of organic compounds. The hydraulic behavior of the soil depends on the continuity of the porous system, which is negatively affected by conventional tillage (CT) during plowing. The no tillage (NT) maintains the soil structure, being a more stable system, however, it increases the superficial mechanical strength and accumulate salts and organic matter (OM), potentially forming physical, chemical and/or biological seals. The objective of this work was to evaluate the origin and influence of surface seals on the water repellency of a Mollisol under conventional and no tillage systems. The trial was conducted at the Antumapu Campus of the University of Chile, during the 2016-2017 season. The classical method of water repellency, which relates the sorptivity (S) in ethanol and water (R index = $S_{ethanol}/S_{water}$, where R>2 means water repellency) does not discriminate the agent of sealing or repellency. In the present study we proposed two new indices: HCl index for carbonates (R_{CO3} = S_{HCl}/S_{water}, with critical value of R_{CO3}³1.2) and H_2O_2 index for OM (R_{OM} = S_{H2O2}/S_{water}, with critical value of R_{OM}³1.08), where the ethanol, H_2O_2, HCl and water were measured outside (OT) and inside (IT) of the machinery wheel track, in order to determine possible agents of sealing. Also, we determined the OM and the $CaCO_3$ contents at the surface (0-2 mm). Both, tillage systems and positions, showed water repellency, being higher in CT (R = 4.17) than NT (R = 2.91). The concentration of $CaCO_3$ was the same in both systems, and the OM reached values close to 9% in the crust in NT, while in CT did not exceed 2.3%. In the case of R_{CO3}, only the CT shown values above the critical level, with R_{CO3}=1.43, possibly by clogging of the porous system. Finally, in R_{MO} both systems are affected, but NT had significantly higher values than CT, with R_{MO} = 3.4 in NT and R_{MO}= 2,0 in CT. In the case of the wheel track, CT in the three indices showed higher values at OT position, attributed to the mechanical breakdown of the crust by traffic. In conclusion, tillage systems showed hydrophobicity, but the CT system is affected mainly by the presence of $CaCO_3$, generating a chemical seal, while in NT the OM acts as a structuring agent.

(5249 - 1268) The resistance of soil to penetration as indicator of compaction in different classes of soil under the integration system for livestock and native wood

Gabriel Junqueira Pires[1]; Wilber Pereira Machado[1]; Guilherme Camilo de Andrade[1]; Fabrício Messias Dias da Silva[1]; Roberta Ferreira Coutinho[1]; Lucas Alves Fernandes[1]; Adriana Aparecida Ribon[1]; Camilla Barbosa de Oliveira Madruga[1]; Taíza Nogueira Barros[2]; Sidarta Oliveira[1]
State University of Goiás[1]; Federal University of the Recôncavo of Bahia[2]

Soil compaction is a limiting character for agriculture, usually caused by man's action. Among the properties indicative of compaction, soil resistance to penetration is highlighted, being considered a rapid and direct measure of the degree and / or state of compaction of the soil in cultivated areas. The objective of this work was to measure soil resistance to penetration in five soil profiles in an area on the Forest Animal Husbandry Integration System (HIS) and adjacent native forest in the region of Midwest of Goias. The Penetrometric samplings were obtained up to 60 cm depth with Stolf (1996) model impact penetrometer, following the STOLF methodology (1991), with a standard weight of 7 kg and a drop weight of 4 kg in the 5 soil profiles in open trenches up to 2 m deep and 2 m long in distinct locations of the Forest Livestock Integration area and in a legal Mata reserve area adjacent to the Livestock Forest Integration area in the city of Palmeiras de Goiás-GO. Together with soil penetration resistance, samples were collected to determine the gravimetric moisture of the soil and this was randomly collected, in a total of 6 points / ha in the experimental area, on the same days of soil resistance to penetration. For determination of soil moisture (FORMULA 1), the gravimetric method was used to determine the mass of the humid soil using a precision analytical balance. The soil resistance to penetration curve varied according to the classes of soils and managements submitted in the area. Soil resistance to penetration has been shown to be a sensitive indicator of the physical quality of soils under integration systems and native forest, with values considered critical for the growth of the root system of the crops for all soil classes, also showing that the implantation of systems of production in function of different soil classes through the pedological survey in cultivated areas should be encouraged due to the benefits related to productivity and to the improvement in the physical quality of the soil.

WG11 Land Degradation: Restoring degraded lands through soil carbon management

(8250 - 2267) Calcium and magnesium contents accumulated in different soil uses in the municipality of Pindaré Mirim, Maranhão, Brazil

Elimilton Pereira Brasil[1]; Victor Roberto Ribeiro Reis[1]; Luciano Cavalcante Muniz[1]; Thaís Santos Figueiredo[1]; Diana Signor Deon[2]; Joaquim Bezerra Costa[2]
UEMA[1]; EMBRAPA[2]

Due to the use of the soil and forests in the Amazon region we have sought to reduce deforestation. Thus, the systems of Crop-Livestock-Forestry integration - CLFi appear as technological alternatives for a more productive and sustainable livestock. The objective was to evaluate the calcium and magnesium contents accumulated in different land uses in the municipality of Pindaré Mirim, MA. The soil samples were collected in four different environments in the municipality of Pindaré Mirim / MA: Native forest with babassu (*Attalea speciosa*), Capoeira, degraded pasture (with *Brachiaria brizantha* cv. Marandu) and ILPF (with corn in a consortium with Marandu grass and eucalyptus). Samples were collected at seven depths: 0-10, 10-20, 20-30, 30-40, 40-60, 60-80 and 80-100 cm. Calcium and magnesium were extracted with 1 mol L-1 KCl solution. Calcium and magnesium were determined by atomic absorption spectrophotometry. The means were submitted to analysis of variance by the Kruskal-Wallis method, followed by the comparison of means by the Bonferroni test (Dunn), at 95% confidence level. In layers 20-30, 30-40 and 40-60 cm, the Ca2 + contents were higher in the degraded pasture and in the ILPF system. These two areas also presented high levels of Mg2 + at depths greater than 40 cm. Among the layers, the Mg2 + contents were similar for areas with degraded pasture, ILPF and native forest. Ca2 + values increased in depth in all uses. It is a fact that conserving or increasing soil quality can provide a number of economic and especially environmental benefits. However, the evaluation of soil quality is not a simple task, given the great complexity of the physical, chemical and biological processes that occur in the soil and the heterogeneity of the system.

(5706 - 1324) Carbon stock of an Oxisol under conventional management in chronosequence in the cerrado Northeastern

Leovânio Rodrigues Barbosa[1]; Fernando Julião de Medeiro Júnior[1]; Francisco Rafael da Silva[2]; Victor Vinicius Rodrigues[2]; Catharina T. Cortez[3]; Luiz Alfredo Pinheiro L. Nunes[2]
Universidade Federal da Paraíba[1]; Universidade Federal do Piauí[2]; Fundação Agente[3]
Carbon stock of an Oxisol under conventional management in chronosequence in the cerrado Northeastern Leovânio Rodrigues Barbosa[1]; Fernando Julião de Madeiro Júnior[1]; Francisco Rafael da Silva[2]; Victor Vinicius Rodrigues[2]; Catharina Teixeira Cortez[3]; Luís Alfredo Pinheiro Leal Nunes[4] (1) Doutorando em ciência do solo - UFPB, leovaniobarbosa@hotmail.com;(2) Eng. Agrônomo; (3) Biologa; Professor Dr - Universidade Federal do Piauí.

Conventional soil management in the Northeastern cerrado is still a practice adopted by many producers due to the need for soil correction. However, the negative effect from the adoption of this agricultural practice can be verified over time years after the installation and maintenance of this production system by reducing the carbon stock. The objective of the present work was to evaluate the carbon stock in an Oxisol under a conventional system in chronosequence in the Northeastern cerrado. The study was carried out at Chapada Grande Farm located in Regeneração municipality, in the northern region of the State of Piauí, in an area under Cerrado biome. Areas with one, three and six years of conventional soybean cultivation were selected. In each area, soil samples were collected in the 0.00 - 0.10 m layer and 0.10 - 0.20 m, to determine the soil carbon stock. The carbon stock in the superficial layer in absolute values was higher in the area under native vegetation, however there was no statistical difference between the treatments studied. On the other hand, under subsurface, the areas under native vegetation and soybean cultivation in the first year, obtained a lower carbon stock, differing statistically from the other areas with a longer time of adoption of conventional management (three and six years). The constant upwelling of the soil over time adds plant residues to the subsurface layer and provides higher C stock in this soil layer. Areas under conventional management in the Piauí cerrado with up to six years, have in the superficial layer, carbon stock statistically similar to that found in an area of native vegetation. Conventional management over time provides greater carbon stock in depth. Keywords: chemical attribute, chronoseguence, degradation

(9916 - 631) Dry matter yield and soil physical properties after growing cover crops in winter

Katiely Aline Anschau[1]; Edleusa Pereira Seidel[1]; Jean Sérgio Rosset[2]; Emerson Fey[1]; Marcos Cesar Motin[1]; João Henrique Silva Caetano[1]; Marcio André Fransczisko wski[1]
Unioeste[1]; Universidade do Est do Mato Grosso do Sul[2]

The objective of this work was to evaluate the dry matter yield of winter cover crops grown in monoculture and intercropping in no-tillage system, and its effects on soil physical properties. The experimental design was a randomized complete block design, with four replications. The treatments used were: black oat, black oat + forage turnip, forage turnip, black oat + forage pea, forage pea, and control (fallow). The winter cover plants were sowing mechanically under no-tillage system, used 45 kg ha^{-1} of forage pea (*Pisum sativum* L.), 15 kg ha^{-1} forage turnip (*Raphanus sativus*), and 80 kg ha^{-1} of black oat (*Avena strigosa* S). In the sowing of forage turnip, consorciated with black oats, 5 and 30 kg ha^{-1} of seeds were used, and forage pea with black oats, 25 kg and 30 kg ha^{-1} of seeds. After 100 days of sowing of the cover plants, the dry matter yield was evaluated, and the values observed were: oat 4.69 t ha^{-1}; forage turnip 6,24 t ha^{-1}; pea 6.01 t ha^{-1}; oat + forage turnip 7.81 t ha^{-1}; oat + forage 7.31 t ha^{-1}; and the control (fallow) 0.45 t ha^{-1}. It was found that the consortium of oats + forage pea, and oat + forage turnip provided an increase in dry matter yield to the soil of 35% and 41%; respectively, when compared with monoculture oat cultivation; and then, the cover plants were managed chemically, and after desiccation, undisturbed soil samples were collected at 0 - 0.10; 0.10 - 0.20 and 0.20 - 0.30 and 0.30 - 0.40 m layer for the determination of macroporosity, microporosity, total porosity, and soil bulk density. The highest volume of macropores was found in the 0 - 0.10 m layer in treatments with forage and forage turnip. Control was the one with the highest soil density for all the evaluated strata; for microporosity of the soil no changes were observed after the cultivation of the different cover plants. The soil resistance to penetration was evaluated using the digital penetrometer, and there was a difference between the control and the oat / forage pea consortium in the depth of 0.15 m. Key words: Green manures, soil physical quality, soil management.
Keywords: Green manures, soil physical quality, soil management

(6144 - 2545) Including winter service crops for forage production and soil organic carbon buildup in soybean rotations

Girard Rodrigo[1]; Eclesia Roxana Paola[2]; Ojeda Jonathan Jesús[1]; Piñeiro Gervasio[3]; Caviglia Octavio[4]

Facultad de Ciencias Agropecuarias, Universidad de Entre Ríos[1]; Instituto Nacional de Tecnología Agropecuaria, EEA Paraná. Oro Verde. Entre Ríos[2]; 3IFEVA-Facultad de Agronomía, Universidad de Buenos Aires; Consejo Nacional de Investigaciones Científicas y Técnicas[3]; Facultad de Ciencias Agropecuarias, Universidad de Entre Ríos; Instituto Nacional de Tecnología Agropecuaria, EEA Paraná; Consejo Nacional de Investigaciones Científicas y Técnicas[4]

The use of winter service crops (SC) for both forage production and soil organic carbon (SOC) buildup could be an interesting option for agricultural sequences dominated by soybean (*Glycine max [L.] Merr.*). We evaluate the effects of harvesting aboveground biomass of two winter SC in rotation with soybean, on SOC dynamics. Three crop sequences were evaluated: melilotus (*Melilotus albus Medik.*)/soybean (Mel/S), ryegrass (*Lolium multiflorum Lam.*)/soybean (Rye/S) and soybean as monoculture (S-S), under no-till systems. The field experiment was conducted for three years on a vertisol soil. Each year Melilotus and ryegrass were planted in april and cut at a low intensity (LI, the SC was cut leaving a remnant of 12 cm) and at a high intensity (HI, the SC was cut leaving a remnant of 6 cm), two or three times during their growing season and killed in October, to allow soybean planting on November. A reference treatment included SC without defoliation. We evaluated the aboveground and belowground biomass in all sequences each year and Soil organic matter (SOM) after the third year. SOM was fractionated into particulate organic matter (POM) and mineral associated organic matter (MAOM) and the carbon and ^{13}C content in each fraction were analyzed. ^{13}C was used to estimate the new SOC inputs from crops (Cn) and the SOC remaining from initial SOC previous to the installation of the experiment (Cr), in each SOM fraction. The Cn-POM in Ry/S was ~ 30% and ~ 60% higher than Mel/S and S-S, respectively. No differences were found in Cr contents. Defoliation treatments did not significantly alter total SOC, Cn or Cr contents. Belowground biomass production was associated with the POM contents (R^2=0.74) and Cn-POM (R^2=0.60 to 0.76) but not with the Cn-MAOM stocks. The inclusion of SC increased near 50% total C-SOM contents during the period evaluated. Our results showed that the inclusion of SC for forage productions during winter in rotation with soybean is an alternative to increase SOC contents.

(3771 - 3189) Organic matter humified as a phytostimulant of *Brachiaria decumbens*: effect on the metabolic profile of the microbial community rizosferica Field experiment

Lady Karina Aparicio Sánchez[1]; Nelson Valero Valero[2]

National University of Colombia (Bogotá, D.C.)[1]; University of La Guajira (Riohacha, La Guajira)[2]

Humic acids as phytostimulants influence metabolism and increase rhizodeposition, this leads to plants releasing compounds into the rhizosphere, which can induce changes in the structure of microbial communities and therefore improve the growth of plants. In post-mining land reclamation processes, the establishment of gramineous plants in the initial stage is a key factor, since their high potential to contribute with soil organic matter yield, as well as their influence on microbial populations, which in turn can promote plant growth. In this research, changes in the metabolic profile of the rhizosphere of *Brachiaria decumbens* were evaluated in response to the application of humic acids obtained from lignite coal and a lignite-based humic bioconditioner inoculated with coal biotransformer bacteria. The trial was conducted under field conditions in plots in the initial stage of rehabilitation after coal mining, in a semiarid zone located in the Colombian dry Caribbean. The metabolic profiles of the microbial community of the soil were determined through the BIOLOG® panel ECOPLATE method; the evaluated parameters were the average metabolic response, the metabolic diversity of the microbial community and the metabolic profiles. It was found that the metabolic response was increased with the application of humic materials and differences were found with respect to the control treatment; an increase in the levels of metabolic activity was also observed in response to treatment with humic acids, this is related to the increase of the microbial populations of the rhizosphere, induced by the hormonal effect enhanced by humic acids on plant growth. These results support the purpose of using residual lignite coal as a source of humic acids to improve the establishment of vegetation cover in the early stages of rehabilitation, through constructed soil in open-cast coal mines in the Colombian dry Caribbean.

(4586 - 2523) Particulate organic carbon in agrosystems in the brazilian semiarid

Mônica da Silva Santana[1]; Eunice Maia de Andrade[1]; Vanderlise Giongo[2]

Universidade Federal do Ceará[1]; Embrapa Semiárido[2]

Drylands cover about 40% of the planet, in which 44% are occupied with cultivated systems. Covering 45% of Brazilian Semiarid the grasslands are main land use this region. In order to increase biomass production and provide food for goats, sheep and bovines are implanted different agrosystems with differences species *Cenchurs ciliairis* L. (CC), *Opuntia ficus indica* Mill. (OF), *Gliricidia sepium* Jacq. (Walp.) (GS), *Leucaena leucocephala* Lam. De Wit. (LL). However, with removal of native vegetation (NV) there is a change in supply plant material and hence in soil organic matter (SOM), which is formed by substances in different stages of decomposition. Among the chemical components contained in SOM is carbon (C), the main structuring element of nature. In soils, the C can be in the form particulate organic carbon (POC), coming from the biotic residues being quite susceptible to change of land use, and mineral-associated carbon fraction formed by organomineral complexes that are not available to decomposition . POC is associated with the active compartment and can be lost more easily, depending on land use. In sense, to evaluate how the introduction of new species for animal feeding can modify the POC, soil samples were collected at following depths: 0-5, 5-10, 10-15, 15-20, 20-30, 30- 40 cm, with four replicates for uses with different ages: NV (always preserved), CC (30 yr), OF (21 yr), GS (17 yr) and LL (24 yr). The air dried soil was separated in a 53 µm sieve, where the particles larger than >53 µm corresponded to POC. The C levels were determined in the LECO elemental analyzer. In the 0-5 cm layer CC showed the highest POC content (3.42 g kg^{-1}), in 5-10 cm depth NV had the highest POC content (3.12 g kg^{-1}) while in the other layers (10-40 cm), the GS and LL uses had the highest POC values. The OF use exhibited lowest POC content. Thereby, we can verify that GS and LL can be cultivated in semiarid region without compromising the levels POC, while the OF can be used but in consortium with other species, such as CC, that increase organic materials on soil and consequently increase C concentration. NV presented POC levels varying between 0.85 and 3.12, while the other uses had values between 0.78 and 3.42, which indicates that agrosystems when properly managed, there may be increase POC levels. Thus, ensuring higher C concentration and sustainability in agrosystems in the Brazilian Semiarid.

(6951 - 3144) Phosphorus and potassium contents in the soil of an agroforestry system, deforested and fallow area, and under native vegetation

Julian Junio de J. Lacerda[1]; Luiz Eutimio R. Nogueira[1]; Ariane S. R. L Ascenso[1]; Sara Leticia P. da Silva[1]; Caio de M. Cabral[1]
UFPI[1]

Agroforestry systems (AS) are land use systems in which, as trees interspersed with agricultural and / or animal cultures, simultaneously or sequentially, in order to increase the total production of plants and animals in a sustainable manner per unit area. Agroforestry systems, by approaching natural ecosystems in structure and diversity, represent a great potential for restoration of degraded areas and ecosystems. The objective of this work is to evaluate the available P and K content of the soil in a regenerative agroforestry system, after one year of implantation in Bom Jesus, Piaui State. The experiment was carry out in a regenerative SAF implanted in October 2016, characterized by the cultivation of plant species in consortia. The SAF is located in the experimental area of the Federal University of Piauí, Campus Cinobelina Elvas, in Bom Jesus-PI. The experimental design was completely randomized with subdivided plots and four replications, totaling 48 experimental units. The 12 treatments consisted of three adjacent areas: the agroforestry system, a deforested and fallow (DF) area and another under native vegetation (NV); and four soil layers, at depths of 0-10, 10-20, 20-30 and 30-40 cm. Avaliable P (Mehlich-1) and K was mensuared in the soil samples. Data was subjected to variance analysis, applying F test at 0.05 level, and when F was significant, the means were compared by the Skott-Knott test at 5% probability. It was observed that both the uncovered soil and the AS presented similar available P content (DF= 4.08 mg dm^{-3}; AS= 3.36 mg dm^{-3}) and the soil under native vegetation, presented lower values (NV= 2.37 mg dm^{-3}). Regarding depths, the surface layer presented a higher value of available P than the others (0-10 cm- 7.16 mg dm^{-3} a; 10-20cm - 2.57 b; 20-30 cm- 1.75 b; 30-40 cm - 1.60 mg dm^{-3} b). K content in the soil under native vegetation presented the higher value (NV = 62.37 mg dm^{-3} a), while the others had similar levels (DF= 43.66 mg dm^{-3} b, AS 46.93 mg dm^{-3} b). The values of K found in the depths also were higher in the first layer (0-10 cm- 80,20 a; 10-20 cm - 51,16 b; 30-40 cm - 39,46 b; 20-30 cm - 33,12 mg dm^{-3} b). With the one-year implementation period of agroforestry system, it is not possible see the benefits in the content of P and K available to the soil, in relation a deforested and fallow area.

(5678 - 2673) Proctor test with undisturbed samples and its relation with the structural quality in a Mollisol

Evelyn Henríquez Aravena[1]; Oscar Seguel Seguel[1]; Ian Homer Bannister[1]; Hugo Peréz[1]
Universidad de Chile[1]

The Proctor test corresponds to a mechanical test used in engineering to evaluate the water content at which a material undergoes the highest densification in response to standard compaction energy, equivalent to a known mechanical load. The procedure considers the use of disturbed soils, so it is exclusively dependent on the particle size distribution; however, it could be used with undisturbed soils to characterize the effect of structure on aggregate stability under mechanical loads. Disturbed and undisturbed samples of a Mollisol were taken from a loam soil (clay content 27±6%) with different uses, considering from lower to higher structural quality: agricultural road, traditional tillage, vineyard, fruit trees with organic management and meadow. Bulk density, OM content, aggregate stability and Proctor test (standard, with undisturbed samples and with natural aggregates >4mm) were measured. Bulk density was not useful to discriminate the different soil uses, but the OM content follow the expected results, with values from 1.3 to 5.0% according to soil use. Compared to the same energy of compaction in the Proctor test, there is a logical order of uses, where the agricultural road showed the highest bulk density with the lowest water content, and as the structure increases (ie, the intensity of use decreases) the water content increases and the maximum bulk density decreases. The difference between the maximum bulk density of a high and low intensity of use increases when the Proctor test is performed with aggregates, validated by the microaggregate stability, reason why this test can be used to evaluate the structural quality of the soil.

(3893 - 2571) Short-term effects of loosening and incorporation of straw into the upper subsoil on soil physical properties and crop yield

Gizachew Tarekegn Getahun[1]; Thomas Kätterer[1]; Lars Juhl Munkholm[2]; Mohammed Masud Parvage[1]; Thomas Keller[3]; Katrin Rychel[1]; Holger Kirchmann[1]
Department of Soil and Environment, Swedish University of Agricultural Sciences, Sweden[1]; Aarhus University, Faculty of Agricultural Sciences, Department of Agroecology and Environment, Research Centre Foulum, Denmark[2]; Department of Soil and Environment, Swedish University of Agricultural Sciences, Sweden; Agroscope Reckenholz-Tänikon Research Station ART, Switzerland[3]

Subsoils that are compacted, nutrient-poor or low in soil organic matter (SOM) often limit crop growth and yield. Improvement of subsoil conditions by deep loosening is laborious and expensive and its positive effect may not last. This study investigated the effect of deep loosening and injection of slurry made from cereal straw (30 Mg dry mass ha^{-1}) at 25-34 cm depth on soil properties and crop performance in a Swedish field experiment that started in autumn 2015 and monitored soil and crop properties during 2016. Loosening + straw incorporation into subsoil resulted in higher soil organic carbon (SOC) content, water content and porosity and lower bulk density (BD) in spring 2016 compared with the control. Bulk density remained low throughout 2016 even after a number of field operations. In autumn 2016, penetrometer resistance (PR) and BD were both significantly lower and SOC, water content and porosity were still higher in the loosening + straw treatment compared with the control (29-34 cm). Furthermore, BD was lower in the loosening + straw treated subsoil than in the top soil layer of the control (0-10 cm). Observations indicated that continuous pores were occupied by roots to a greater extent in the loosening + straw treatment than in other treatments. Roots and soil fauna were found more frequently where straw was incorporated. Grain yield increased by 5.6% due to loosening + straw addition (P=0.03) and by 4% due to loosening only (P=0.07). These results indicate that loosening + straw input into subsoil had a positive short-term influence on soil physical properties, potential plant-available water and grain yield. Straw addition prolonged the effect of loosening.

(4296 - 1949) Soil organic carbon recovery and coffee grain yield following bauxite mining

Hiran F. Vilas Boas[1]; Luís Fernando Januário Almeida[1]; Rafael Silva Teixeira[1]; Ivan Francisco de Souza[1]; Ivo Ribeiro da Silva[1]
Universidade Federal de Viçosa[1]

Bauxite mining requires the removal of topsoil, which causes considerable impacts on both natural and managed ecosystems. This is typically the case of agricultural activities across Minas Gerais, southeastern Brazil, where bauxite mining often displaces pastures and coffee plantations. In this study, our objective was to assess the effects

of chemical and organic fertilizations combined with cover crops on the reestablishment of coffee plantations following bauxite mining. The experiment consisted on a split-plot design which main plot received four types of fertilization: no fertilization (NF), chemical fertilization (CF), poultry litter (PL), and chemical fertilization + poultry litter (CF+PL). In subplots, four cover crops were cultivated in between the rows of the coffee plantation, including: no cover crops (NCC), grass (*Brachiaria brizantha* (B)), legume (*Stylosanthes macrocephala* (S)) and grass + legume (*Brachiaria* + *Stylosanthes* (B+S)). We had 4 blocks as replicates. Organic and chemical fertilization (PL+CF) combined with cover crops (B+S) led to significant recovery of soil organic carbon (SOC), N (SON) and $KMnO_4$-oxidizable SOC. PL+CF and B+S, led to SOC increments of 14.5 g kg^{-1} soil (0–10 cm depth). Based on isotopic data, (^{13}C), both B and S contributed to recover SOC. Over three consecutive harvests, coffee grain yield as high as 1800–2000 kg ha^{-1} occurred under PL or PL+CF. There was no recovery of coffee grain yield when B was the cover crop, irrespective of fertilization. Overall, recovering SOC and SON contents determine the capacity of soil to sustain the reestablishment of coffee plantations following bauxite mining.

Keywords: bauxite mining; soil reclamation; cover crops; soil organic carbon; coffee productivity.

(9565 - 1249) β-Glucosidase and total organic carbon as indicators of the erosion stabilization process of gullies in "Mar de Morros" environment, Rio de Janeiro, Brazil

Cristiane Figueira da silva[1]; Luiz Alberto da Silva Rodrigues Pinto[1]; Marcos Gervasio Pereira[1]; Sabrina Aparecida Teodoro[2]; Marcelo Antoniol Fontes[3]

Universidade Federal Rural do Rio de Janeiro[1]; Universidade Federal de Lavras[2]; Embrapa Agrobiologia[3]

In the state of Rio de Janeiro, especially in the Pinheiral region, rugged relief, the vegetation cover (pasture), land use, and high rainfall have favored the occurrence of water erosion, which is one of the main forms of soil degradation, causing damages of economic, environmental and social order. This kind of erosion leads to the emergence of gullies, which are formed by run-off mass processes and high soil loss. The objective of the study was to use the enzyme *β*-Glucosidase activity and total organic carbon (TOC) as indicators of the erosion stabilization process in gullies at different period of formation, using as reference a forest fragment, and two pasture areas, in the municipality of Pinheiral, Rio de Janeiro, Brazil. The study was carried out in three gullies (stages: initial, mature and senile), two pasture areas (with and without natural regeneration) and a forest fragment. At the end of the rainy season, in the areas of forest and pasture, soil samples (depth 0-0.5 m) were collected in an area of approximately 400 m^2, while in the gullies the samples were collected in the inner part throughout its length. In each of the sample units 16 single samples of soil were collected in a total of four samples composed per unit. *β*-Glucosidase activity was analyzed according to Tabatabai (1994), using 1.0 g of soil and the substrate PNG (p-nitrophenyl-β-d-glucoside; 0.05 mol L^{-1}). Colorimetric determination was performed in a spectrophotometer at 410 nm. Results were expressed in µmol · g^{-1} · h^{-1} p-nitrophenyl. Total organic carbon in the soil was quantified according to Yeomans & Bremner (1988). The highest levels of *β*-Glucosidase and TOC in general were observed in forest and pasture areas (with and without natural regeneration), while the lowest values were verified in the gullies at initial and mature period of formation. The senile stage gully, which presents the vegetation cover almost everywhere, presented intermediate values when compared to the other sample units. In this way, it can be suggested that due to the gully colonization by the vegetation, the erosion processes decrease, the litter accumulation favoring the stimulation microorganisms activity and the soil carbon incorporation, which can be verified in the gully senile period. Thus, both *β*-glucosidase and TOC can be considered good indicators to erosive processes stabilization in gully areas.

(2445 - 2467) Could biochar and green manure be a substitute for synthetic nitrogen fertilization to guarantee rice grain yield and decrease greenhouse gas emissions?

Mellissa Ananias Soler da Silva[1]; Alberto Baêta dos Santos[1]; Beáta Emoke Madari[1]; Márcia Thais de Melo Carvalho[1]; Adam Price[2]; Priscilla Lacerda Mendonça[3]; Yoná Serpa Mascarenhas[3]

Embrapa Rice and Beans[1]; University of Aberdeen[2]; Federal University of Goiás[3]

Hunger, poverty, climate change, health, soil quality and clean water are all connected by the agriculture sector. In the world, there are about 815 million people who are undernourished, and 663 million do not have access to clean water. More than 33% of the soils are degraded, largely due to intensively mechanized agriculture, and excessive pesticides and mineral fertilizer use. Rice is a staple food for most of the world population, and improving the nitrogen use efficiency (NUE) and reducing greenhouse gas (GHG) emissions is fundamental for the sustainability of this crop. Within this context, the objective of this study was to find a feasible alternative to the use of nitrogen fertilizers for smallholders and commercial farming in tropical flooded rice systems. The cultivation of rice (BRS Catiana) was assessed in a flooded system on a Latossolo Amarelo (Ferralsol, FAO, 2014), throughout the 2016/2017 growing season. The field experiment was carried out in strips without (0 char +0 N [control], 0 char+ green manure (GM), 0 char + synthetic nitrogen (N)), and with application of biochar (char +0 N, char+ GM, char + N) made of rice husks (21 Mg ha^{-1}, composition: 8% total C, 0.08% N, 63.6 g kg^{-1} organic C, 1482 mg dm^{-3} K and 10.9 mg dm^{-3} P), incorporated into 10 cm soil depth using a harrow, about six months before sowing rice. Within each strip, N sources treatments were added: green manure (*Crotalaria juncea*), cultivated for 60 days and incorporated into the 10 cm soil depth using a harrow at 10 days before sowing rice; and synthetic N (urea, 115 kg ha^{-1} N) applied at sowing rice (15 kg ha^{-1} N), and twice during rice growth (24 days after sowing [DAS] and 60 DAS). Fluxes of N_2O and CH_4 were quantified using manual static chambers throughout the rice growing season. The highest fluxes of N_2O were observed in the treatment with green manure. The treatments with synthetic N, without or associated with biochar, and the treatment with green manure only, increased N2O emissions. Similarly, synthetic N and green manure associated with biochar promoted higher total CH_4 emissions than the treatments with biochar only and the treatments with synthetic N and green manure only. The total emissions of N2O and CH4 per unit of grain produced were higher in treatments with biochar. Grain yield by the use of green manure and N synthetic fertilizer had no statistical diferences, with or without biochar. However, rice grain yield was lower in treatments with biochar.

(8506 - 482) Cropping systems and conservation tillage impacts on soil

health and functionality in a rice ecosystem

Mohammad Mofizur Rahman Jahangir[1]; Rahana Pervin[1]; Mohammad Jahiruddin[1]

Bangladesh Agricultural University[1]

Soil health and functionality is a critical concern for sustainable intensification of agroecosystems for advancing food security and environmental safety. Response of soil health to crop and cropping systems has not been evaluated in subtropical rice ecosystem like Bangladesh. Impacts of cropping systems and conservation tillage on soil quality and crop yields were evaluated over three years in Old Brahmaputra Floodplain soils (Aquept Inceptisols). The experiment comprised two factors with three replications in a split-plot design. Factor A: minimum soil disturbance with 20% crop residue retention (MT) and conventional tillage (CT) in the main plots and factor B: three cropping systems with mustard –rice–green manure–rice, wheat–rice–rice, and lentil–rice–rice in the subplots. Soil aggregate formation and stability were higher in MT than in CT ($p<0.05$). Soil organic carbon (SOC) was influenced by tillage and cropping systems ($p<0.01$), being higher in MT than in CT, and lower in wheat than mustard and lentil based systems. Macro and micro aggregate protected SOC was higher in MT compared to CT and in lentil and mustard compared to wheat based system. Likewise, soil total nitrogen (TN) was higher in MT than in CT. With respect to the cropping systems, TN was higher in lentil and mustard than the wheat based system ($p<0.05$). Unlike SOC and TN, basal respiration (BR) rate was higher in CT than MT and in wheat and lentil than the mustard based system. Higher BR rate in CT and wheat/lentil based systems indicates that these soils are more stressed for microbial activities. Net N mineralization rate (mainly nitrate) was higher in MT than in CT and lower in wheat than mustard and lentil based systems. Soil moisture content was significantly higher in MT than CT, but not influenced by the cropping systems. Soil bulk density in these three years of conservation tillage was similar in all tillages and cropping systems. Soil earthworm population was consistently higher in MT compared to CT. Results suggest that MT can enhance soil aggregation and aggregate protected C and N content and soil microbial processes (e.g. nitrification). The system productivity can be ranked in the order of mustard-green manure-rice-rice > wheat-rice-rice > lentil-rice-rice. In addition, being with lower BR rate, MT with mustard-green manure-rice-rice system can lower the agricultural input cost (e.g. fuel) and enhance soil health and functionality without compromising crop yield.

(9230 - 1451) Effects of cover crops on soil organic matter fractions under no-tillage systems in the Cerrado

Arminda Moreira de Carvalho[1]; Luana Ramos Passos Ribeiro[2]; Cícero Célio de Figueiredo[2]; Thais Rodrigues de Sousa[2]; Douglas Lino Vieira[2]; Thais Rodrigues Coser[2]

Empresa Brasileira de Pesquisa Agropecuária[1]; Universidade de Brasília[2]

In Brazil, approximately 31 millions of hectares of land are managed under no-tillage system. In this scenario, the use of cover crops can improve soil's chemical, physical and biological qualities, and therefore, its productivity. The diversity of plant species associated with practices such as succession, rotation and consortium of crops, may provide more favorable conditions for the stock of carbon (C) and nitrogen (N) in the upper soil layers in a short-term period and also in deeper layer in a long-term period. Soil organic matter (SOM) is considered a key indicator of soil quality because it is important for the formation and maintenance of soil functions, especially in highly weathered soils, such as Oxisols. In this sense, it is important to understand the relationship between the chemical composition of cover crops and the accumulation of labile and stable fractions of SOM in the no-tillage system. The experiment was conducted at Embrapa Cerrados, Planaltina, DF, Brazil. The succession of cover crop/maize under no-tillage system was established in March, 2006 and the cover crops were: *Urochloa ruziziensis* (syn.: *Brachiaria ruziziensis* - Poaceae), *Canavalia brasiliensis* (Mart. ex Benth - Fabaceae), *Cajanus cajan* (L. Millsp - Fabaceae) and *Sorghum bicolor* (L. Moench - Poaceae). Soil samples were collected in March, 2014 at 0.0 to 0.10 m and 0.10-0.20 m soil layers. Cover crops were characterized in terms of hemicellulose, cellulose and lignin, following a serial method and of total-N by the Kjeldahl method. The cover crops organic carbon content was determined by oxidation. The physical and chemical fractionation of SOM, labile C content (LC) and microbial biomass carbon (MBC) were also performed. The results showed that the high levels of N in cover crops associated with increased production of dry matter, higher concentration of hemicellulose and lower lignin content resulted in higher SOM under the use of *Canavalia brasiliensis*, represented by higher C in the humic acid (HA), in the ratio humic/fulvic acid (HA/FA) and in the labile carbon (LC). The use of *Brachiaria ruziziensis* with lower lignin contents and lignin/N ratios increased soil organic C stocks and C in the mineral associated organic matter (MAOC). Therefore, *Canavalia brasiliensis* may be recommended as cover crop to increase SOM quality in terms of HA, HA/FA ratios and LC, whereas, *Brachiaria ruziziensis* may be used to increase soil organic C stocks, mainly in the MAOC fraction.

(8392 - 1795) Four-year impact of the adoption of different integrated crop-livestock systems on the chemical attributes of a lowland soil

Luiz Gustavo de Oliveira Denardin[1]; Amanda Posselt Martins[1]; Tales Tiecher[1]; Lucas Aquino Alves[1]; Dionata Filippi[1]; Filipe Selau Carlos[2]; Paulo César de Faccio Carvalho[1]; Ibanor Anghinoni[1]

Universidade Federal do Rio Grande do Sul[1]; Instituto Rio Grandense do Arroz[2]

Lowland soils represent 4 to 6% of the earth's surface, occupying an area of 7 to 9 million km^2. In Brazil, most of these soils are situated in the southern region, mainly under crops such as irrigated rice. These soils commonly have low fertility due to the traditional irrigated rice cultivation systems, which are based on intensive soil tillage and rice monocropping. On the other hand, conservationist soil systems, such as integration crop-livestock systems (ICLS), promote several benefits, such as nutrient cycling, leading to a rapid improvement in soil chemical fertility. Therefore, our study aimed to evaluate some soil chemical attributes by measuring soil organic matter (SOM) and available phosphorus (P) and potassium (K) contents, four years after the adoption of different paddy-farming systems in an Albaqualf soil from Southern Brazil. The treatments consisted of four ICLS under no-tillage (NT), with different arrangements containing different intensities and frequencies of the animal and of cash crops in the system, in comparison to the traditional system (TS) of irrigated rice cultivation with ploughing and heavy disking. The experiment was established in a long-term ICLS trial at the Corticeiras Farm, located in Cristal County, Rio Grande do Sul State, Brazil. It was verified that soil chemical attributes were affected by the adoption of NT, crop diversity and integrated grazing practices. After four years, the TS was the only one that presented a reduction in SOM, of 0.23%, with a content of 1.8% SOM. All other ICLS increased SOM in 0.13 to 1.21%. Similar behavior was verified in available P, with reduction of 0.7 mg P dm^{-3} in TS and increase of 5.7 to 24.7 mg P dm^{-3} in the other treatments. All treatments increased the available K over time, although in different proportions. While TS showed an increase of only 5.7%, the treatment with NT, crop rotation (rice and soybean) and insertion of the animal component showed a 64% increase in available K. Based on the results, it was concluded that adoption of conservation management practices in lowlands, such as NT, combined with crop rotation and ICLS, promote improvement in soil chemical attributes, as seen in SOM and available P and K contents. Thus, unlike the traditional

systems of irrigated rice cultivation, ICLS coupled with NT are capable of improve soil chemical attributes and reaching the sustainable intensification of the lowlands in Brazilian subtropics.

(7107 - 1238) The impact of nitrogen fertilizer management on nitrous oxide and ammonia emission in an irrigated rice crop system in the Brazilian Savannah

Beata Emoke Madari[1]; Glaucilene Duarte Carvalho[2]; Alberto Baêta dos Santos[1]; Mellissa Ananias Soler da Silva[1]; Márcia Thaís de Melo Carvalho[1]
Embrapa Arroz e Feijão[1]; Embrapa Arroz e Feijão / Univ. Fed. Goiás[2]

The lack of synchronism between nitrogen (N) fertilization and the stage of high demand by plants results in a low efficiency recovery of N in the cropping system, mainly due to losses of N. The objective of this study was to estimate the gaseous losses of N (N_2O and NH_3 emission) and characterize the dynamics of N-N_2O fluxes in an irrigated rice production system of the Brazilian Savannah. The experiment was conducted on a Gleissol, located at the *Meia Ponte* river basin, along two cropping seasons 2011/2012 (S1) and 2012/2013 (S2). The cultivar used was BRS Tropical. The experiment consisted of three treatments: (T0) control (without N); (T1) application of recommended dose of N (110 kg ha^{-1}); and (T2) application of N based on reference index using the Minolta SPAD-502 chlorophyll meter. Fluxes of N_2O and volatilization of NH_3 were quantified using manual static chambers. Soil variables related to gaseous losses were also monitored along seasons. The highest N-N_2O fluxes occurred soon after sowing at the period before flooding. These fluxes were related to soil moisture and nitrate availability. The emission factor for N_2O due to nitrogen fertilization was low (0.3%). The volatilization intensity (g NH_3 emitted per kg of grain produced) was lower for T2. The total loss of N was greater along the off-season period han along the cropping seasons.

(2219 - 2871) Agromining for the recovery of nickel from contaminated and anthropized soils

Marie-Odile SIMONNOT[1]; Baptiste LAUBIE[1]; Mathilde GUILPAIN[1]; Vivian HOUZELOT[1]; Claire HAZOTTE[1]; Guillaume ECHEVARRIA[1]; Jean Louis MOREL[1]
University of Lorraine[1]

Hyperaccumulator plants are able to extract and accumulate metals (or elements) at high rate from soils. The recovery of these metals and the production of compounds of industrial use would contribute to mitigate the costs of disposing the contaminated biomass from soil remediation projects. Moreover, recovering metals from secondary sources (e.g. polluted soils, serpentine soils, mine tailings, wastes) has become an essential challenge in a context of increasing demand of metals and rarefaction of mineral resources. Agromining is a chain of processes aiming at growing hyperaccumulator plants in order to reach high yields of metals and recover metals by pyro or hydrometallurgy. It has been mainly developed for nickel (Ni) since i) more than 400 Ni hyperaccumulators have been identified, ii) large areas covered by serpentine soils or mine tailings are available worldwide, and iii) processes have been designed and upscaled to obtain Ni metal or Ni-based compounds (salts, oxide, catalysts). The objective of this contribution is to present two types of hydrometallurgical processes to recover Ni from the biomass of a Ni hyperaccumulator, *Alyssum murale*, containing *ca* 1 wt% of Ni. It has been demonstrated that yields of 110 kg of Ni per ha can be reached by growing this plant, with appropriate agronomic practices. The first approach consists of burning dry plants to produce ashes and energy. Ashes contain 15-20 wt % of Ni, which is far higher than any Ni ore. They also contain potassium, calcium and magnesium as major cations. Ni can be recovered from ashes, after ash washing, acid leaching and several precipitation steps, in order to produce Ni salts or oxide. These processes have been designed at the lab scale and up-scaled to the pilot scale. Details will be presented on the operating conditions and Ni mass balance along the process. The re-use of the by-products has been also investigated, as well as the overall environmental impacts of the agromining chain. The second approach consists of extracting Ni directly from the dry plant, using water as a solvent. The challenge is to recover Ni from the leach liquor, which is a multicomponent solution containing dissolved organic matter to which Ni is strongly bound. An original method has been developed using a complexing resin, selective of Ni. The presentation will end up with a comparison of both approaches, to show the advantages and drawbacks of recovering Ni after combustion or directly from the dry plant.

(1424 - 1894) Characterization and classification of the soils used for urban agriculture in Seoul and its vicinity through soil profile description

Kye-Hoon Kim[1]; Jun-Seok Oh[1]; Dan-Bi Lee[1]
The University of Seoul[1]

Presently, about 50% of Korean population lives in Seoul and its vicinity which cover only 12% of Korea. Like any other countries, demand for urban agriculture is increasing in Korea for various reasons such as leisure activities, enhancing mental health, educational purposes, food safety, etc. Most of the soils used for urban agriculture in Seoul and its vicinity were known to be transported from other areas. This made the difference of soil characteristics between the natural soils and soils used for urban agriculture. Natural soils are developed slowly by the interaction of soil forming factors, whereas anthropogenic soils including soils used for urban agriculture can be changed rapidly within a short time due to the influence of human activities. For that reason it is very important to identify characteristics of the soils used for urban agriculture. Therefore, this study was carried out to investigate the soil characteristics of five urban agriculture areas of Seoul and its vicinity by soil profile description. Eight pits were prepared in these areas, followed by profile description and sampling of 75 soils. All the soils from 8 pits were not developed naturally from the site but transported from outside. Some soils had even foreign materials like municipal waste. The transported materials seemed to affect characteristics of the original soils. Results showed that the average soil pH was higher than that of upland soils, whereas the average EC (electrical conductivity) was lower than that of upland soils. The heavy metal contents of all the analyzed samples were lower than the concern level of the Soil Environment Preservation Act of Korea. Results of the classification of the soils in 8 pits based on WRB classification system showed that all the urban soils in this study belonged to anthrosols or technosols. They have very different soil characteristics from those of conventional upland soils. Therefore, the management plan for the soils used for urban agriculture should be prepared for maintaining sustainable soil health through systematic investigation.

(4335 - 614) Direct-push techniques applied to high-resolution lithostratigraphic characterization of a brownfield site in alluvial environment

Leandro Gomes de Freitas[1]; Marco Aurélio Zequim Pede[2]; Hung Kiang Chang[2]
IPT[1]; LEBAC/UNESP[2]

The application of high resolution characterization tools based on Direct Push drilling methods, for the lithostratigraphic assessment of contaminated sites, has made it possible to obtain more consistent conceptual models. To evaluate the application of these techniques in alluvial environments, a university campus, built on a redeveloped brownfield site on the Tiete river floodplain, in São Paulo city, Brazil, was chosen for the present study. At this site, sediments dredged from the river channel rectification were deposited on a 25 hectares settlement pond, creating a 4 m high terrace. This landfill covers the Quaternary fluvial sediments (~ 6 m thickness), which in turn overlies the neogenic sediments of the São Paulo Basin. Three field techniques were adopted: electrical conductivity sensor (EC) probing, Soil Color Optical Screening Tool (SCOST) probing, and whole core soil sampling with Direct Push Dual Tube system. Additionally, laboratory procedures were adopted for grain size and organic matter content analyses of the soil samples. The high-resolution profiles obtained with the EC and SCOST showed a good qualitative correlation with the lithological descriptions and with the grain size distribution profiles, improving the lithostratigraphic characterization of the site. Organic matter profile analysis showed presence of high organic content and high methanogenic potential layers, especially in the organic clay and silt layers of the Quaternary sediments. The Direct Push techniques demonstrated great potential for high resolution lithostratigraphic characterization of alluvial environments.

(6993 - 693) Estimating Bioaccessible Pb and As in Urban Soils: Application of Vis-NIR Diffuse Reflectance Spectroscopy

Anna Paltseva[1]; Claudio Colombo[2]; Maha Deeb[3]; Erika Di Iorio[2]; Valentina Torino[2]; Zhongqi Cheng[1]
CUNY Graduate Center, Brooklyn College[1]; University of Molise[2]; CUNY ASRC[3]

As lands contaminated with lead (Pb) and arsenic (As) are converted to residential and farming uses, the potential risk to human health is increased through direct or indirect exposure pathways arising from incidental ingestion and further transfer through the food chain. The popularity of urban gardening in recent years emphasizes the need for fast and reliable field techniques to evaluate the bioaccessibility of Pb and As, and to monitor the effectiveness of remediation. Diffuse Infrared Reflectance Spectroscopy in the visible-near infrared (Vis-NIR) has rarely been applied in environmental protection and urban soil management. The aims of the research are to develop a diagnostic screening method for Pb and As bioaccessibility in treated and untreated urban soils using Vis-NIR. VisNIR analyses were performed on 21 samples from a New Jersey (USA) urban farm. The use of VisNIR resulted in a good estimate of both phytoavailable Pb (extracted with ammonium acetate – modified Morgan method) and bioaccessible Pb (extracted with 0.4 M Glycine - EPA method 1340). Total and bioaccessible elements were predicted by improving the 'cross' correlation between surface soil metal concentrations and Vis-NIR reflectance measurements via partial least-squares regression (PLSR) modelling. The two principal components (PC1 and PC1) accounted for 94 % of the variation in the data. Both the PC1 and PC2 were mainly correlated with Vis wavelengths. The plot of the first two principal components (PC1 and PC2) allowed to identify five different clouds based on the soil treatment. These clouds primarily depend on similar adsorption in Vis range and are related to several chemical soil components. The total and bioaccessible concentrations of Pb and As were qualitatively estimated (RPD > 1.5). The two principal components likely indicate that bioaccessible Pb and As are linked to the form and distribution of the organic matter and the crystalline Fe oxides or Fe amorphous mineral. Therefore, the NIR spectroscopy provides a potential diagnostic screening method for bioaccessible Pb and As in urban soils.

Keywords: Lead, arsenic, Vis-NIR spectroscopy, urban soil, metal bioaccessibility

(2561 - 460) Phytoextraction of lead, cadmium, chrome and nickel in contaminated soil of the Santo Amaro de Purification municipality - BA

Romualdo de Almeida[1]; Robson Rui Cotrim Duete[2]; Weliton Antônio Bastos de Almeida[3]
Environmental Engineer, specialist in Audit and Environmental Expertise; Master in Regional Development and Environment - FAMAM; romuangel@hotmail.com;[1]; Agronomist D. Sc., Prof. Advisor and Assistant at FAMAM; rrcduete@oi.com.br;[2]; Agronomist D. Sc., Prof. Co-advisor and Assistant at FAMAM and UFRB; weliton@famam.com.br.[3]

Phytoremediation is a technique with increasing application in areas of polluted soil aiming at the decontamination of soil and water, using plants as decontamination agent. It is of lower cost, environmentally correct and operationally feasible. This research aimed to identify plant species with the extraction potential for lead, cadmium, chrome and nickel in soil contaminated with lead ore slag. For this, an experiment was carried out under semi-controlled conditions, at the Maria Milza Faculty Campus, located in the municipality of Governador Mangabeira-BA. The experimental design used was a completely randomized with four treatments and six repetitions. The species investigated were jack bean (Canavalia ensiformis), sunflower (Helianthus annuus), sweet basil (Ocimum basilicum), maize (Zea mayz). The plants were cultivated in recycled black pots with a capacity of 9 L, filled with 8 L, of the substrate (soil + slag) in a 50/50% (v/v) ratio. Soon after, five seeds of each of the species were sown (maize, sunflower, jack bean) as well as a seedling of basil. The cultivation took place under an improvised roof, protected in the upper and the lateral sides by a black sombrite screen with a mesh of 50% of interception of solar radiation. The pots were irrigated daily. After 60 days of cultivation, the plants were harvested and separated in the aerial part and the roots. The variables evaluated were: Dry phytomass of the aerial parts and the roots; concentration of metals in the aerial parts and the roots; their contents in the aerial part, roots and whole plant; bio-concentration and translocation factor. The statistical analyses of the data included the use of parametric techniques for some variables and the use of non-parametric methods for other variables. The species differed as regard to the phytomass production; as to the contents of heavy metals in their tissues, the roots of all the species showed higher concentrations of all the heavy metals compared to the aerial parts. The jack bean and the maize plants accumulated more Pb, Cd and Ni; while the basil and the jack bean plants held more Cr. All the species are considered phytoextractive, but none of them can be considered a hyper-accumulating plant. The jack bean and basil plants can be considered Cd excluders; the jack bean, sunflower and basil plants as Ni excluders.

(9969 - 302) Phytoremediation of soil contaminated with residues of civil of construction (RCC)

Herika Karine Silva Gonçalves[1]; Domingos Sávio Barbosa[1]
Universidade Federal de Mato Grosso[1]

Construction and demolition residues represent 2/3 of the municipal solid waste, 50% of that volume refers to masonry, concrete, mortar and ceramic. In most cases the soil is the destination of these residues and these may interfere directly in vegetable production. The objective of this study is to evaluate the interference of civil construction residues (RCC) in the soil, using as indicators the soybean (*Glycine max*) and *Crotalaria ochroleuca* (cv. Common). Soils were sampled with RCC containing residues of a class located in a construction site laid down for 24 months and as close-to-ground control without RCC. The phytotoxicity trials were developed in 500ml vessels, with random distribution in 12 repetitions for each treatment. 7 Soy seeds and 10 crotalaria observing for 15 days were sown. After this period, the average length of the air was larger in *Crotalaria* (165 mm) relative to soybeans (333 mm). For soybeans there was no significant difference ($p > 0.05$ ANOVA) of the soil with RCC in relation to the control. For the *Crotalaria* there was significant difference. The results suggest *Crotalaria* as a probable indicator of phytotoxicity and soy as a potential fitorremediation.

Keywords: phytotoxicity, soybean, *Crotalaria ochroleuca*

(1726 - 1417) Rehabilitation of iron ore mine lands in the Southeastern Amazon: Enhancement of soil proprieties, plant establishment, and revegetation assessment

Silvio Ramos[1]; Cecílio Frois Caldeira[1]; Markus Gastauer[1]; Joyce Reis Silva[1]; Pedro Walfir M. Souza Filho[1]; José Oswaldo Siqueira[1]
Instituto Tecnológico Vale[1]

The exploitation of mineral resources in Amazon has been intensified in the last decade. One particular situation is the Carajás Mineral Province (CMP), which is recognized as one of the most important mineral provinces in the world, encompassing large iron ore reserves that has been extracted through open pit benching. This operation cause substantial changes in land cover, which has to be reclaimed. This process involves several steps, such as topological reformulation, soil fertilization, and planting native or non-native plant species to revegetate and to protect the soil. The main challenge of mineland revegetation is the establishment of species that promptly accumulate adequate biomass in the different mineland substrates. These are usually inadequate for plants establishment, requiring intensive interference. In CMP, there are several areas in different stages of revegetation, varying from bare soil to areas with more than 15 years of rehabilitation. In order to assess the rehabilitation status of these areas, soil quality, occurrence of plant species, and ecosystem services have been conducted. The results have shown that in more advanced revegetation sites there is an increase in soil organic matter. In some areas, the assessment of soil attributes has indicated the recovery of soil proprieties which are close to those found in native reference sites. It was also observed that the overall number of plant species is higher than those of native sites, while species richness and phylogenetic diversity is higher in native sites. Plant field establishment and the nutrient requirement for growth of native species are another important challenge we face. Seed purity, biometry, moisture, and germination rates have significant variation among species. Some native species requires treatments for suitable germination, while other exhibit low germination because of embryo abnormalities. Several of these species have shown consistent growth increase after application of macronutrient and lime, but a low response to micronutrients application. Although preliminary, these results are quite useful for efficient revegetation and environmental rehabilitation of iron ore mineland in the southeastern Brazilian Amazon.

(1054 - 814) Remediation of mining affected soil by a two-step process: washing with ferric chloride and amending with lime and organic matter: field experiments

Xiaofang Guo[1]; Zebin Wei[2]; Yangmei Chen[2]; Qi-Tang Wu[2]
South China Agricultural University; Taiyuan University of Science and Technology[1]; South China Agricultural University[2]

The efficiency of Cd, Pb, Zn and Cu removal by only $FeCl_3$ washing or combining with mixture of chelators (MC) was assessed in a field experiment on multi-metal contaminated soil. Soil amendment with lime and organic matter were conducted to revitalize washed-soil. The concentrations of heavy metals in groundwater were evaluated the leashing risk of soil washing with $FeCl_3$ and MC. Results showed that the removal efficiencies of Cd, Zn, Pb, and Cu were 70%, 17%, 33%, and 40%, respectively, when the $FeCl_3$ (25 mmol kg^{-1} topsoil) were used for 60 d. In addition, the leached Pb from topsoil was fixated in subsoil. Compared to the only amending treatment, the yields of *Z. mays* were significantly decreased with soil washing and amending treatment, while the yields of *B. juncea* were significantly increased. This indicated that the shallow root plant (*B. juncea*) could grow better than *Z. mays* on the remediate soil. In particular, the concentrations of Cd, Zn, Pb, and Cu in the grains of *Z. mays* and the edible parts of *B. juncea* with soil washing and amending were below the Tolerance Limit of Contaminants for foods in China. Soil washing with $FeCl_3$ did not worsen groundwater contamination during the study period. The results demonstrate that *in situ* soil washing with $FeCl_3$ combined with subsequent amendments is technically feasible for remediation of agricultural soils contaminated by heavy metals in mining area.

Keywords: Heavy metals; Soil washing; $FeCl_3$; Mixture of chelators (MC); Amendment; Groundwater

(7015 - 1972) Soils functions affected by urban use in Santa Maria, Brazil.

Jéssica Rafaela da Costa[1]; Fabrício de Araújo Pedron[1]; Ricardo Simão Diniz Dalmolin[1]; Luis Antonio dos Santos[1]
Universidade Federal de Santa Maria, Av. Roraima nº 1000, Camobi, Santa Maria, 97105-900, Brazil[1]

The number of research about urban soils has increased around world. These soils are classified in the World Reference Base (WRB) as Technosols, whose has been associated with variations in physical, chemical and morphological features associated with the presence of human artefacts. Although vulnerable to various alterations, these soils are responsible for environmental services essential in urban areas (e.g. vegetation support, building support; urban agricultural support; flood control; regulation of water and air quality; and while a place for heritage conservation). In Brazil, there are few studies urban soils. Therefore, the aim of this work was to evaluate how urban soils affect environmental services at urban perimeter of the municipality of Santa Maria (Brazil). The area has 125.48 km^2 and 261 thousand residents, characterizing a population density of 145.98 inh km^2. Five representative soil profiles were studied. The physics parameters bulk density (BD) and hydraulic conductivity (K) in the superficial layer were determined. The results revealed that all soils can be classified as Technosol due mainly to the presence of the anthropic material. The mean value of BD was 1.5 g cm^{-3} (variation from 1.42 to 1.53 g cm^{-3}), and K from 0.3 to 67.76 cm h. The most variable morphological characteristics were horizon/layer thickness, clay content (presented abrupt changes), soil color, size and strength of soil structure, showing the heterogeneous behavior of urban soils. Inputs of exogenous

materials were verified in all profiles. Thus, due the heterogeneous behavior of these soils there is a decrease in the functions related to soil/atmosphere interaction, such as water infiltration and gas diffusion, while there is an increase in soil density to benefit the infrastructure support and place for waste disposal. As these soil characteristics change, the environment becomes more vulnerable to events with negative social and environmental impacts like erosion, flood, and declined vegetation support capacity.

(5022 - 3138) Source identification of heavy metals in farmland soil surrounding Huludao Zinc Plant in northeastern China

Guochen Li[1]; Yanhong Wang[1]
Institute of Applied Ecology, , Chinese Academy of Sciences[1]

The severe pollution of heavy metals of the farmlands soil surrounding Huludao Zinc Plant (HZP)has been a historical problem and gained long-term intense attention from both local residents and government. HZP was supposed to be the primary or even the only source for the heavy metals in the surrounding area. In order to illustrate the specific sources for all the 8 species of heavy metals in this area, PMF and UNMIX were both used to analyze the data of concentration of 13 species of elements (including the 8 heavy metals) in 43 soil samples. The results indicated: UNMIX has better correlation between the predicted value and determined value for each element species than PMF, while PMF has better identification of sources since UNMIX did not divide anthropogenic and natural sources. However, both the two models indicate that although industrial source represented by HZP is the primary source, not all the 8 heavy metals are from it. Agricultural activities had a clear impact on As, Pb contamination of the farmland. Suggestions for soil use and management were proposed based on the above results for source identification.

(5557 - 522) Study on Soil Quality Changes of In-Situ Leaching Rare Earth Tailings Before and After Reclamation in south, China

Qin Zhang[1]; Xiaomin Zhao[1]
Land Resources & Environment College/Key Laboratory of Poyang Lake Basin Agricultural Resources and Ecology of Jiangxi Province, Jiangxi Agricultural University[1]

Due to the special mining technology of ion-adsorption type rare earth mine, the ecological environment was seriously destroyed, especially leaching agent residual, soil acidification, soil fertility degradation and heavy metal pollution. In this paper, an in-situ leaching ion-adsorption type rare earth tailings from Ganzhou Longnan County is studied. The soil quality changes before and after reclamation were compared through NH_4^+ concentration, soil pH value, soil nutrient content and heavy metal content, and the effects and potential problems of the reclamation were discussed. The results show that after reclamation the concentration of NH_4^+ decreased from 89.00 mg kg^{-1} to 8.70 mg kg^{-1}, soil pH increased from 4.15 to 5.16, and the comprehensive index of soil fertility decreased from 0.44 to 0.31. The Nemerow integrated pollution index of non-rare earth heavy metal indicated that the pollution level of tailing was clean before and after reclamation, and the geoaccumulation index of rare earth heavy metal showed that the pollution levels of tailing before and after reclamation were unpolluted to moderately polluted and unpolluted, respectively. Hence, reclamation could significantly improve the problem of leaching agent residue and soil acidification, but did not improve the problem of soil fertility degradation. In addition, heavy metal pollution is not serious and the soil is cleaner after reclamation.

The progress of urban areas is rapid. Similarly the demands on urban functionality develop very fast. This trend accelerated by population growth and changes in way of life in cities. The smart city concept, one with urban components and systems completely controlled and managed by a myriad of diverse communication networks, will also include functioning soils. With this future perspective it is of interest to understand what is the current trend of soil research and how did it develop in the last 20 years. The nine specific SUITMA conferences in nine different countries representing all continents, besides Australia and Antarctic, and each 5 symposia on the World Congresses of Soil Science and EUROSOIL offer a good opportunity to check this. The poster will show the objectives of presentations of the founding symposium of WG US/SUITMA at the 16th WCSS in Montpelier and of the following nine SUITMA Conferences. The treatment of themes of the individual SUITMA Conference was always complemented by one-day and post-conference field tours to visit urban, industrial, traffic and mine soils which are a regular part of SUITMA conferences. They are included in the poster as well. The poster will show the continuum of urban soil formation and classification research over the 20 years. Similar constants include pollution, remediation and heritage objectives. Not so frequent but also constant were questions of urban soil hydrology. In the last eight years new upcoming themes were ecosystem services such as biodiversity, soil carbon, health aspects and food production with a number of additional aspects presented as well. In part they indicate new upcoming urban soil problems or regional urban demands and hazards. By the diverse locations of performance of SUITMA

Conferences over the world, completed by the IUSS Soil World Congresses, the EUROSOIL and EGU Congresses, a good overview of worldwide awareness of urban soils and their services is achieved. Thus the poster about themes of WG SUITMA in the last 20 years will provide an overview on which types of soil information are available and which should be deepened and wait to be developed.

WG14 Acid Sulfate soils: Acid sulfate soils: processes, assessment and management

(4695 - 1126) Determination of the potential acidity of a drained peat bog in the Catalan Pyrenees.

A. Catalán[1]; R.M. Poch[2]; E. Ascaso[2]; A. Baltiérrez[3]
Student of University of Lleida, Lleida, Spain[1]; Department of Environment and Soil Sciences, University of Lleida, Lleida, Spain[2]; Cartographic and Geological Institute of Catalonia (ICGC), Spain[3]

The Pyrenean range (NE Iberian Peninsula), has some favourable lithological (iron-rich parent materials) and climatic (udic moisture regimes) conditions for the formation of acid sulphate soils. In spite of that, they have never been reported until now, probably due to the lack of adequate geomorphic locations with strong reduction conditions. In this context, the construction of C-28 road near València d'Àneu and the realization of land movements totally modified the morphology of a 2 ha old peat bog, partly drained at present, on the right bank of the Bonaigua River, at an altitude of 1.500 meters. In this spot a soil monolith was extracted as part of the Pyrenean soil museum project of the ICGC. Analyses revealed a high electrical conductivity in the first organic horizons reaching levels of 9.23 dS/m at 25 °C, an actual or effective acidity around 3.7 pH units according to the method of soil:water suspension (1:2.5) and around 2.5 pH units according to the method of soil:water suspension (1:5). We hypothesize that the old peat bog contained sulphydic material that was oxidized during the drainage, which could have caused a decrease in pH in organic soils. The main goal of this study is to characterize these peat bog soils to know their potential acidity and the consequences that could generate in the current environment. The experimental design has been based on delimiting the study area, describing several profiles in the field and augering to determine the volume extent of the black organic horizons. Subsequently, the samples have been analysed in the laboratory to determine the main chemical characteristics of the soils. From these results, on the one hand, it is discussed what could have happened to obtain high electrical conductivities and, on the other, whether the pH values could be an indication of acid sulphate soils (ASS) and to evaluate the possible sulphydic or sulphuric materials, not reported until now in the Pyrenees. The results will be useful to locate other spots with acidification risk and eventually add it to the geological risk programme of the ICGC.

Keywords: Acid sulphate soils; acidity potential; peat bog; acidification risk

(8305 - 1851) Quantification of metals and acidity leached from coarse-grained acid sulfate soil materials in western Finland

Stefan Mattbäck[1]; Anton Boman[2]; Andreas Sandfält[3]; Peter Österholm[3]
Åbo Akademi University / Geological Survey of Finland[1]; Geological Survey of Finland[2]; Åbo Akademi University[3]

Since the national mapping of acid sulfate (a.s.) soils in Finland began 2009, coarse-grained ($d_{50\%}$ grain size ≥ 63µm) hypersulfidic material (i.e. soil material with sulfidic S ≥ 100 mg/kg and a pH < 4.0 upon oxidation; Sullivan et al., 2010; IUSS Working Group WRB, 2014) attracted research attention due to many unknowns related to their classification and characterization. We quantified the acidity potential and the metals leached from some of these materials by conducting leaching experiments using a modified version of European norm EN 12457-2:2002 (cf. Åström & Björklund, 1996; Mattbäck et al. *in prep*), after the samples had undergone a 16-week incubation procedure (cf. Creeper et al., 2012). During and after the incubation period, the samples were leached with deionized water, and the leachates were recovered. The hypotheses were that (1) the electrical conductivity (EC) could be used for the quick assessment of the amount of acidity and metals released from soil materials to the liquid phase upon oxidation, and (2) the coarse-grained a.s. soils release less acidity and metals than fine-grained a.s. soils. Thus, EC in the leachates were compared with corresponding pH, acidity and element concentrations of different types of a.s. soil materials. For determination of the acidification rate, and the amount of acidity in the oxidized soil, duplicate soil samples were analyzed for the titratable incubation acidity (TIA; Österholm & Nystrand, 2016) at specific time intervals (in parallel to the leaching experiments). The aqua regia leachable trace and major elements in the soil samples were analyzed with ICP-OES and reduced sulfur species were quantified using a distillation sulfur speciation method (Dalhem et al., 2016). In accordance with previous studies (Mattbäck et al., 2017), sulfur has been extensively leached from the oxidized portions of the coarse-grained a.s. soil profiles, which therefore lack sulfuric horizons (i.e. pH < 4.0). The EC of the leachates from coarse-grained a.s. soils was significantly lower than that of fine-grained a.s. soils; and as expected higher than for coarse-grained non-a.s. soils, which shows that the leaching of potentially harmful elements from coarse-grained a.s. soils is less than from fine-grained a.s. soils.

(3791 - 1341) Sulfur gas analysis as a potential identification method for acid sulfate soils

Moa Sunabacka[1]; Antti Pasila[2]; Asko Simojoki[1]
Department of Agricultural Sciences, Environmental Soil Science, University of Helsinki, FINLAND[1]; Seinäjoki University of Applied Sciences, FINLAND[2]

In recent years, research on the environmental impacts by acid sulfate soils have been in focus, but studies on sulfur gas emissions are still relatively few. The aim of this study was to assess the potential of sulfur gas analysis for the identification of acid sulfate soils, especially sulfidic materials. In autumn 2016, soil samples were taken from three agricultural fields in Ostrobothnia and Southern Ostrobothnia, Finland. The fields have been classified as acid sulfate soils by the Geological Survey of Finland (GTK). The occurrence of sulfides in the soil material was identified based on the pH drop during a 10-wk aerobic incubation. First, the sulfur gas emissions after a short incubation period were investigated by gas chromatography (GC) and with a portable ChemPro100i gas detector (Environics Oy) in the laboratory. In summer 2017, the use of gas detector was tested directly in the field. Further, an additional tool for soil sampling and heating the sample to enhance gas detector measurements was tested and several factors likely involved in the sulfur gas emission/release were evaluated. Contrary to the expectations, hydrogen sulfide (H_2S) could not be identified in any soil sample and the occurrence of sulfur dioxide (SO_2) was lower than expected. The unknown gas that was present in most samples and had the biggest peak areas in GC was tentatively identified as carbonyl sulfide (COS) based on indirect evidence. The identification is to be confirmed with a standard gas in near future. Based on the GC analysis, the emissions of sulfur gases from soil samples were the larger, the larger was the pH drop after the aerobic incubation. According to the first results, five of the sensors (signals) of the gas detector showed significantly lower ($p < 0.05$) resistance for sulfidic compared with non-sulfidic soil materials. In further tests, one of these five signals have shown greater potential for the purpose to identify/differentiate sulfidic

soil material. Despite the promising results showing the potential of sulfur gas analysis to become a tool to aid the mapping of acid sulfate soils, more tests are needed. According to current results, it seems the sensitivity of gas detector measurements should be increased, for instance, by increasing the amount of soil in the ground probe, before the method can be usefully applied in practice. The speciation and quantification of emitted S gases needs GC or other more advanced analytical techniques.

(4210 - 1350) Temperature sensitivity of microbial greenhouse gas production in a boreal organic acid sulphate soil with a black schist derived subsoil

Asko Simojoki[1]; Kazi Md. Jahangir Kabir[2]; Minna Mäkelä[1]

Department of Agricultural Sciences, Environmental Soil Science, University of Helsinki, Helsinki, Finland[1]; Department of Soil and Environmental Sciences, University of Barisal, Barisal, Bangladesh[2]

Environmental problems by acid sulphate (AS) soils are of concern worldwide in the coastal areas of Asia, Australia and Nordic countries as well as some inland areas with black-schist derived subsoils, including acidic and metal discharge to waterways and high greenhouse gas (GHG) production. This study presents results from a series of experiments conducted to reveal the mechanisms and factors regulating and limiting GHG production in boreal AS soils. Soil samples were taken from a former peat excavation area in Pärnänsuo (Joensuu, Finland) at a site where black-schist derived subsoil is covered by a 50-cm peat layer and where the groundwater level is typically high at c. 60 cm depth and the overlying soil is often wet. Despite conditions seemingly favourable to denitrification, our earlier results indicated only modest N_2O emissions with little or no correlation to environmental conditions in the field. Temperature sensitivity of GHG production was studied by incubating moist soil samples (60% WFPS) from four different horizons (H1 upper peat at 0-15 cm, lower peat H2 at 15-30 cm, Cg upper mineral soil at 50-60 cm and Cr deep mineral soil at 90-110 cm Cr) at 5 or 20 °C temperatures for 12 days. The production rates of CO_2 and N_2O were measured twice a week by sealing the incubation bottles for 24 h and analysing the headspace air by GC. After the experiment, mineral N was extracted and measured from the samples. In the peaty horizons, the rate of CO_2 production was > 10-fold of that in subsoil. N_2O production was highest in topsoil but decreased strongly with depth. The production of CO_2 and N_2O decreased as organic C and nitrate N decreased, respectively, with depth. Such a pattern reflects a microbial activity distribution typical for mineral soils, but it contrasts to previous research conducted on boreal coastal AS soils with high microbial activity in subsoil. The CO_2 production was temperature sensitive in topsoil (Q_{10} about 2) but less so in mineral subsoil (Q_{10} about 1.3). In contrast, N_2O production did not increase with temperature in any horizon, which suggests cold boreal climate is not limiting N_2O production in this soil. Even though the factors limiting GHG production as identified at later steps of the experiments are not reported here, the above results suggest contrasting mechanisms and factors being involved in GHG production in different types of AS soils, such as in black schist derived inland and sediment derived coastal AS soils.

WG16 Cultural Patterns of Soil Understanding B: Dialogues between traditional and scientific knowledge and perceptions of soils by different stakeholders

(5177 - 2740) Contrasting female and male farmers' perceptions on soil ecosystem services

Angélica da Silva Lopes[1]; Heitor Mancini Teixeira[1]; Irene Maria Cardoso[1]; Cristine Carole Muggler[1]
Universidade Federal de Viçosa[1]

Soils can provide many ecosystem services, also known as nature benefits, including climate regulation, nutrient cycling, food production and cultural heritage. However, the maintenance of these services has been threatened by the use of technologies that produce changes in the dynamics of ecosystems, loss of biodiversity and soil degradation. To reverse this situation and to conserve soils functions, practices that promote and maintain soils quality and are needed. Family farmers hold rich and valuable indigenous knowledge, based on their practices and reality. Indigenous knowledge can be combined with scientific knowledge in order to develop effective and useful soil management strategies aiming the provision of multiple ecosystem services. Among farmers, the perception of women about ecosystem services can be rather different from men´s ones. The objective of this research was to compare perceptions of female and male farmers about nature benefits related to soils. The methodology followed action research principles. Fuzzy Cognitive Maps (FCM) were constructed to quantify and make explicit the perceptions among the two groups (female and male farmers) of São Miguel do Anta, in Zona da Mata Mineira region, Brazil. Twenty FCM were built individually, ten with female and ten with male farmers. The ten FCM in each group were combined to create social maps, which allowed to compare and to integrate different perspectives of female and male farmers on the nature benef
its related to soil. The women`s social map showed that female farmers can play an important role for maintaining the family well-being. The concept of health, for instance, is a component of human well-being which relies on different benefits obtained from nature, and appears only in the women's map. The concept of erosion was pointed out only in the men's map and was associated with practices that increase water infiltration into the soil. However, the importance of soil for water infiltration and storage was present in the map of both groups. The understanding of farmer´s perceptions can raise awareness about soil conservation and ecosystems services related to it. To understand the differences of male and female perceptions can contribute to find strategies for soil conservation and to empower women.

(3664 - 2562) Green and black landscapes: participatory environmental stratification and local soil knowledge in a quilombola community

Lucas Teixeira Ferrari[1]; Raphael Bragança Alves Fernandes[2]; Irene Maria Cardoso[2]; Ivan Carlos Carreiro Almeida[1]; Carlos Ernesto Gonçalves Reynaud Schaefer[2]
IFNMG[1]; UFV[2]

Traditional farmers' communities accumulate practical knowledge with the passing of generations, which allows them to elaborate their own interpretation, stratification and classification systems of the environmental units in their territories, which can be articulated with the scientific knowledge about soils and environments through an integrated ethnopedological approach and thus contribute to a suitable territorial planning on local reality. The objective of this work was to understand the relationships between local and scientific knowledge about soil and its interfaces with environmental components, in *Quilombo* Santa Cruz, in Ouro Verde de Minas, Mucuri Valley-MG. In this sense, we retrieved the history of land use and occupation with semi-structured interviews, conducted a participatory environmental stratification through participatory mapping and walking guided by different enviromental transects, allied to soil profiles description and sample collection for chemical and granulometric analysis. Finally, we compared local and scientific soil classification. The *quilombola* community of Santa Cruz has a strong political protagonism that allows its survival and the reproduction of its culture, facing scenarios of land conflicts and environmental degradation. The famers stratify the landscape, in different levels, according to varied criteria. The position in the landscape is decisive in distinguishing the larger and more heterogeneous environmental compartments (*Highlands, Lowlands and Stone*) and as the environmental stratification is deepened, other criteria appear, such as face of exposure, pedoform and presence of rocky outcrops, to distinguish smaller and more homogeneous *ethnoenvironments* (*Top of Highlands, Stone Foot, Rocky Hill, Non-rocky Hill, Dry Lowlands* and *Swamp*), that condition different soil types. Structure, moisture, colour and texture were the local criteria used to distinguish the four main soil classes: *Red Land, Sandy Land, Dusty Land* and *Mud*. These soils were mapped and corresponded to the following classes in Brazilian Soil Classification System, respectively: Argissolo Vermelho-Amarelo, Neossolo Regolítico, Cambissolo Háplico and Gleissolo Háplico. The participatory enviromental stratification revealed the diversity of the landscape in Quilombo Santa Cruz, which shows pedological gradients that determine agroecosystems design.

(7992 - 437) Land use and soil management: The genuine decision-maker and challenges of public policies in Brazil

Juliana Silva de Souza[1]; Lúcia Helena Cunha dos Anjos[2]
PPGA-CS, Federal Rural University of Rio de Janeiro[1]; Soils Department, Federal Rural University of Rio de Janeiro[2]

Despite the existence of environmental protection and nature conservancy laws in Brazil, there is no national policy to deal with soil protection and conservation. However, there are several public provisions or regulations focused on the agricultural sector, including financial incentives that have a direct impact on land use and management, with specific programs to smallholders like the National Program to Strengthen Family Farming - PRONAF. Considering that a public policy is the sum of the activities of governments, acting directly or through delegation, and influencing the lives of citizens, it is necessary to include in the government agenda the soil resources protection connected with the public policies of the agricultural sector. The decision-making process consists in finding the best solution to a problem or opportunity. Decision-making is a common everyday process in our lives, however, some decisions are more complex than others, and to find the best choice it is necessary to have sufficient knowledge about the risk involved in each possible choice. This is also demanded by smallholders in their unit of production, for decisions on how to improve production and choices of land usage. The term decision-maker, in general, is associated to the responsibilities of governor, minister, mayor and other rulers. Decisions on the best soil management practices depend on higher level decision-makers to promote public policies that increase the security of smallholders and allow the adoption of soil protection and conservation provisions. However, at the farm level, the decision-maker in the soil management is the smallholder. To test this hypothesis, a case study in the rural settlement Zé Pureza, located in Rio de Janeiro State, is ongoing to discriminate the criteria used by smallholders to decide on soil management and land usage. The goal is to show that to change the adopted soil management toward sustainable practices it is necessary to rethink the public policies from the smallholder perspectives and perceptions. Therefore, the first step is to recognize them as a genuine decision-maker and to understand the factors and constraints defining their choices. Next step is to look for ways to insert mechanisms in some public policies already existent that could benefit, preferentially, the smallholders that implemented the

best soil management practices.
