The air [CO<sub>2</sub>] can reach 600  $\mu\text{L CO}_2 \text{ L}^{-1}$  in the middle or the end of this century, depending on scenario. The first plant response to elevated CO<sub>2</sub> (e[CO<sub>2</sub>]) is the increased leaf photosynthetic rate (*A*) occurring parallelly by mainly non-sensitive or decreased stomatal conductance (*g<sub>s</sub>*) and decreased transpiration (*E*). In Arabic coffee, *A* increases under e[CO<sub>2</sub>], especially during the dry growing season, while *g<sub>s</sub>* responses vary during years under free-air-CO<sub>2</sub>-enrichment (FACE). The aim of this study was to estimate *A*, *g<sub>s</sub>* and *E* over a coffee vertical profile after five years cultivation under FACE, including the responses to water availability.

Coffee was cultivated under two CO<sub>2</sub> conditions, actual (a[CO<sub>2</sub>],  $\sim 390 \mu\text{L CO}_2 \text{ L}^{-1}$ ) and e[CO<sub>2</sub>] ( $\sim 590 \mu\text{L CO}_2 \text{ L}^{-1}$ ). The irrigation started at the end of the 4<sup>th</sup> year of experiment. The measurements were conducted in rainy season, in February 2016 (grain expansion). Values of photosynthetic active radiation (PAR) varied from 1131 to 0  $\mu\text{mol photons m}^{-2} \text{ s}^{-1}$  to construct curves of *A*, *g<sub>s</sub>* and *E* dependence on PAR in four 50 cm-thick layers. Simultaneously, PAR was measured in the morning, midday and afternoon. Punctual values were estimated from nonrectangular hyperbola (*A*) and polynomial (*g<sub>s</sub>* and *E*) models.

PAR reached  $\sim 1400 \mu\text{mol m}^{-2} \text{ s}^{-1}$  at the highest plant layer at midday, while the transmitted PAR at soil level was about  $4 \mu\text{mol m}^{-2} \text{ s}^{-1}$ . The *A* diminished gradually from plant top to bottom, from 7.2 to  $-1 \mu\text{mol m}^{-2} \text{ s}^{-1}$ . The *A* was positively impacted by e[CO<sub>2</sub>] in the highest and low layers. The *g<sub>s</sub>* and *E* showed similar trends in daily variation and in responses to CO<sub>2</sub> and water availability treatments, showing lower values under e[CO<sub>2</sub>] than a[CO<sub>2</sub>] over the plant profile, with exception of the most shaded leaves. Results suggest better water economy under e[CO<sub>2</sub>] than a[CO<sub>2</sub>] under high light conditions.

**Figure 1.** The mean, standard error and ANOVA P-values (n=8-20) of: **left column**) leaf photosynthetic rate (A,  $\mu\text{mol CO}_2 \text{ m}^{-2} \text{ s}^{-1}$ ); **central column**) stomatal conductance (g<sub>s</sub>,  $\text{mol m}^{-2} \text{ s}^{-1}$ ); and **right column**) leaf transpiration (E,  $\text{mmol m}^{-2} \text{ s}^{-1}$ ) estimated in four layers of coffee plants (**layer 1** = 0 - 50 cm; **layer 2** = 50 - 100 cm; **layer 3** = 100-150 cm and **layer 4** > 150 cm) grown under elevated (e[CO<sub>2</sub>]) and actual (a[CO<sub>2</sub>]) air [CO<sub>2</sub>] under irrigation (IRR) and rainfed (NI) water regimes. Data derived from photosynthetic light response curves measured in grain formation based on microenvironmental light availability. ANOVA P-values corresponding to effects of CO<sub>2</sub> and H<sub>2</sub>O environments (env) by layer are indicated. Letters in bold indicate the P<0.1, accepted because of high light microenvironmental variability and consequently, high variability in responses.
